Treatment centers around oral potassium supplementation to maintain eukalemia.[160] Proton pump inhibitors have recently been shown to be beneficial by decreasing the chloride load to the gut.[1] Oral butyrate in treatment of congenital chloride diarrhea was reported.[23] The short-chain fatty acid butyrate stimulates intestinal water and ion absorption through a variety of mechanisms, including the activation of a parallel Cl^-/butyrate and Na^+/H^+ exchanger.

Congenital Sodium Diarrhea

Congenital sodium diarrhea, first described by Holmberg and Perheentupa,[60] is characterized by voluminous secretory diarrhea noted to start soon after birth, with supranormal fecal sodium content (in stark contrast to congenital chloride diarrhea, as described earlier). It is an exceedingly rare disease and only a few cases have been reported in the literature worldwide.[92] The age of onset is quite variable. The youngest patient described in the literature is a 31-week premature infant, suggesting that the disease manifests in utero.[60]

GENETICS

Congenital sodium diarrhea is transmitted in an autosomal recessive manner.[92] Parental consanguinity and common ancestral inheritance were noted by Muller and coworkers in a kindred of five children with congenital sodium diarrhea from Austria when traced back five generations.[92]

MOLECULAR PATHOPHYSIOLOGY

Congenital sodium diarrhea is related to a defect in the sodium-hydrogen exchanger in the jejunal brush border,[18] which is responsible for the absorption of Na^+ in exchange for H^+. Muller and colleagues studied five related infants with secretory diarrhea in Austria to understand the sodium-hydrogen transporter (NHE) defect in congenital sodium diarrhea. Using the techniques of multipoint linkage analysis and homozygosity mapping, they were able to rule out the known transporters, NHE1 to NHE5, as the culprits. NHE3-knockout mice were found to have a sodium secretory state that bore a close resemblance to congenital sodium diarrhea; however, the diarrhea was mild.[92] Further research to identify the specific transport defect is ongoing. Intractable secretory diarrhea in a Japanese boy with mitochondrial respiratory chain complex I deficiency was reported by Murayama and colleagues.[93]

CLINICAL FEATURES

Congenital sodium diarrhea appears very early in life with severe secretory urine-like diarrhea, which is rich in sodium and has a pH of greater than 7. Sodium losses in excess of 100 to 150 mmol/L have been described, leading to profound and rapid hyponatremia, dehydration, and metabolic acidosis.[92] Affected children may require in excess of 300 mL/kg per day of fluids and 50 mmol/kg per day of sodium to maintain electrolyte balance.[4] It is of paramount importance to closely monitor urine output in these children, even if it entails placement of an indwelling catheter. Profound volume loss via stools can lead to acute renal failure, and the caregiver can be easily misled by wet diapers, thinking them an indication of a good urine output with minimal stools.[18] Urine sodium concentrations are low normal.[92]

Affected babies can also present with abdominal distention and failure to pass meconium within 24 hours after birth, mimicking bowel obstruction or Hirschsprung disease,[4] which can lead to unnecessary surgical interventions. Thus a correct diagnosis is very important.

The results of biopsies of the small intestine are normal in patients with congenital sodium diarrhea.[160] However, Muller and colleagues did report cryptic hyperplasia with jejunal villous atrophy on light microscopy in three patients, which on transmission electron microscopy had vacuolation of the surface epithelium.[92]

LABORATORY INVESTIGATION

An infant who presents with severe watery diarrhea should have fecal electrolytes, stool osmolality, and pH checked. Stool osmolality of less than 50 mOsm, high fecal sodium losses, and alkaline stool pH are characteristic of congenital sodium diarrhea.[160] Serum hyponatremia, metabolic acidosis, and hypokalemia are noted, which is in contrast to patients with congenital chloride diarrhea (Table 47-6). However, because of the rarity of the condition, it is not often entertained in the differential diagnosis, and affected infants may be diagnosed very late in the course of the disorder.[4]

TABLE 47–6 Characteristics of Congenital Chloride Diarrhea and Congenital Sodium Diarrhea

	Congenital Chloride Diarrhea	Congenital Sodium Diarrhea
Inheritance	Autosomal recessive	Autosomal recessive
Incidence	Common in Finnish, Polish, Middle-Eastern populations	Very rare; only six known cases in literature
Serum pH	Metabolic alkalosis	Metabolic acidosis
Serum chloride	Low	Normal to high
Serum potassium	Low	High
Serum sodium	Low	Low or normal
Stool bicarbonate	Low	High
Stool pH	Acidic	Alkaline
Stool sodium	—	High

PRENATAL DIAGNOSIS

Polyhydramnios may be noted antenatally, which suggests the intrauterine manifestation of the disease.[4] Failure to pass meconium postnatally may be explained by the severe secretory diarrhea experienced by the baby in utero.[92]

TREATMENT

Aggressive fluid and electrolyte replacement, either orally or parenterally, is necessary for survival.

DISORDERED VILLOUS ARCHITECTURE

Microvillus Inclusion Disease

Microvillus inclusion disease (MVI), also known as *microvillus atrophy*, was initially described as a clinical entity more than 3 decades ago. It is an important cause of neonatal diarrhea, occurring in both a congenital form (which presents in the first few days after birth) and a late-onset form (which has a better prognosis).[110] It is a congenital defect of the intestinal epithelial brush border that leads to severe intractable diarrhea requiring long-term parenteral nutrition.[26] Early small bowel transplantation alone or small bowel-plus-liver transplantation offers the only hope for long-term survival.[124] A multicenter survey of 23 patients by Phillips and Schmitz revealed a poor prognosis for the condition, with a 75% death rate among affected infants younger than age 9 months.[110] Metabolic complications, sepsis, and liver failure were responsible for a majority of the deaths associated with microvillus inclusion disease.[126] It is transmitted in an autosomal recessive fashion, but it has not been able to be linked to a particular gene.[125] Different series report either male[79] or female[115] dominance. Several reports of microvillus inclusion disease in members of the same family and in children delivered to consanguineously married couples have suggested a genetic association. Pohl and colleagues[115] noted a higher incidence in the Navajo population in northern Arizona, with a 1:12,000 prevalence in surviving infants.[49] In contrast to other causes of neonatal diarrhea (e.g., congenital sodium diarrhea and congenital chloride diarrhea), a history of polyhydramnios during pregnancy is absent.[139]

CLINICAL FEATURES

Microvillus inclusion disease presents with severe secretory diarrhea in the first few days after birth. Intestinal failure secondary to diarrhea is definitive. Diarrhea is watery (urine-like or cholera-like)[111] with an electrolyte concentration that is very similar to that of fluid derived from small intestine.[160] Diarrhea is profuse, and the affected infant could pass up to 500 mL/kg of body weight per day.[110] This persists even when the patient is not fed. Mucus is noted to be abundant in the diarrheal fluid, but blood is absent. Stool cultures are negative for the common pathogens, and the pH is neutral.[111] Reducing substances, if tested, are notably absent unless the baby is fed orally.[110] Massive losses of water lead to dehydration, electrolyte imbalance, and acidosis, which are the major causes of mortality unless the baby is treated with total parenteral nutrition and intravenous fluids.

Phillips and colleagues reported patients with late-onset microvillus inclusion disease, which usually presents beyond the neonatal period and carries a better prognosis.[111] They noted some atypical features (e.g., megaloblastosis with low vitamin B_{12} levels, muscular atrophy, metabolic acidosis, seizures, and cholestatic jaundice) in a few patients. These patients may also present with a picture of intestinal pseudo-obstruction in the neonatal period, and with abdominal distention that may be a diagnostic challenge.[160]

Gathunga and associates reported the association of microvillus inclusion disease with coarctation of the aorta and bicuspid aortic valve, cardiac malformations within the spectrum of left ventricular outlet tract obstruction.[40]

HISTOLOGIC APPEARANCE

When biopsy specimens from these patients are analyzed under light microscopy, villus atrophy without crypt lengthening is noticed.[42] Ultrastructural analyses reveal (1) a partial to total atrophy of microvilli on mature enterocytes with apical accumulation of numerous secretory granules in immature enterocytes and (2) the highly characteristic inclusion bodies containing rudimentary or fully differentiated microvilli in mature enterocytes.[126] Light microscopy shows accumulation of PAS-positive granules at the apical pole of immature enterocytes, together with atrophic band indicating microvillus atrophy and, in parallel, an intracellular PAS or CD10-positive line (marking the microvillous inclusion bodies seen on electron microscopy).[46] Recently, CD10 staining has become a valuable tool in identifying patients with microvillus inclusion disease. CD10 is a leukemia antigen that is normally associated with brush border epithelium in normal small bowel.

PATHOPHYSIOLOGY

The pathogenesis of the disease is unknown.[155] It has been suggested that there is a failure of migration of vesicles from the normal-appearing Golgi apparatus[111] to the surface of the enterocytes,[5] and that it is this migration that is responsible for the transportation of the microvilli.[94]

TREATMENT

Affected infants require lifelong parenteral nutrition. Isolated small bowel transplantation[19,155] or small bowel-plus-liver transplantation[56] is the definitive cure.

Tufting Enteropathy

Tufting enteropathy, also known as *intestinal epithelial dysplasia*, was first described by Reifen and colleagues in 1994 in three children who presented with severe watery diarrhea and weight loss, and whose symptoms did not meet the diagnostic criteria for other well-defined clinical entities.[117] Tufting enteropathy presents in the first few weeks of life with severe life-threatening urine-like diarrhea, weight loss, and persistence despite formula changes.[160] This diarrhea persists despite bowel rest and parenteral nutrition. Affected infants are usually of Middle Eastern or North African descent, and a history of consanguinity is not unusual.[94] To date, no epidemiologic data are available; however, the prevalence can be estimated at around 1 in 50,000 to 1 in 100,000 live births in Western Europe.[42] Histologically, epithelial shedding is noted, which proceeds in an irregular fashion, and associated changes of cryptic hyperplasia and increased mitosis in the crypts are noted.[9,117] The so-called tufts[9] refer to the closely packed surface enterocytes that are seen toward the villus tip and may affect up to 70% of the villi.[160] Various degrees of villous atrophy with low or without mononuclear cell infiltration of the lamina propria are seen. Several associated specific features, including abnormal deposition of laminin and heparan sulfate proteoglycan in the basement membrane, increased expression of desmoglein and ultrastructural changes in the desmosomes, and abnormal distribution of $\alpha_2\beta_1$ integrin adhesion molecules were reported.[42] Sivagnanam and coworkers identified epithelial cell adhesion molecule (EpCAM) as the gene for congenital tufting enteropathy[143] in a family with two children affected with tufting enteropathy.

Affected children require lifelong parenteral nutrition, and intestinal transplantation offers the hope for long-term survival.[108] Some infants are reported to have associated choanal, rectal, or esophageal atresia. Nonspecific punctuated keratitis was reported in more than 60% of patients.[42]

Autoimmune Enteropathy

Autoimmune enteropathy is characterized by severe intractable watery diarrhea with persistent villus atrophy, requiring lifelong total parenteral nutrition.[160] Murch and colleagues[95] were among the first to coin the term *autoimmune enteropathy* for a syndrome that was characterized by severe watery diarrhea that occurred in immunocompetent individuals and that was associated with other autoimmune conditions. Key features of this diarrhea are that it persists even after stopping oral feeding and that it is usually noticed within the first few weeks of life.[124]

IPEX syndrome, the best-characterized form of autoimmune enteropathy,[12,124] is a rare disorder with very few known cases.[160] The acronym is intended to suggest that it is a disorder of *i*mmune dysfunction, *p*olyendocrinopathy, and *e*nteropathy, and that it is transmitted in an *X*-linked fashion[12] (males are affected). It is caused by a mutation in the DNA-binding protein FOXP3, also known as *scurfin*,[163] which is responsible for the development of regulatory T cells.[100] The gene has been mapped to chromosome X, very close to the locus of the Wiskott-Aldrich syndrome gene.[12]

CLINICAL FEATURES

The initial presenting features of patients with IPEX syndrome include diarrhea,[163] type I diabetes mellitus,[84] eczema or atopic dermatitis,[100] poor feeding,[84] anemia,[84] thrombocytopenia,[163] hypothyroidism,[84] lymphadenopathy,[163] respiratory distress,[163] and bruising.[84] The first signs of the disease are usually noticed in the immediate neonatal period.[163] Affected infants come to attention because of severe watery diarrhea, which persists despite bowel rest, and hyperglycemia, which becomes a challenge to manage despite aggressive insulin therapy.[163] Diabetes mellitus is caused by the inflammatory destruction of the islet cells, and as the disease progresses, other autoimmune diseases become apparent.[84]

Autoimmune enteropathy must be differentiated from other causes of primary or secondary immunodeficiencies that can present in a similar manner.[160] Wiskott-Aldrich syndrome is characterized by eczema, thrombocytopenia, diarrhea, and enteropathy with low CD8$^+$ counts,[160] which are normal in IPEX.

The treatment of autoimmune enteropathy focuses primarily on immunosuppression and bone marrow transplantation.[124] Yong and associates reported their success with the use of sirolimus in children with IPEX.[165] Children with autoimmune enteropathy are predominantly dependent on parenteral nutrition for their survival.[124]

Syndromic or Phenotypic Diarrhea

Syndromic diarrhea, also known as *phenotypic diarrhea* or *tricho-hepato-enteric syndrome*, is a congenital enteropathy presenting with early-onset severe intractable diarrhea in infants born small for gestational age and associated with nonspecific villous atrophy with low or no mononuclear cell infiltration of the lamina propria or specific histologic abnormalities involving the epithelium. The diarrhea is associated with facial dysmorphism, immune disorders, and in some patients, early onset of severe liver cirrhosis,[43] hypertelorism, and woolly, easily removable hair with trichorhexis nodosa. Jejunal biopsy specimens showed total or subtotal villous atrophy with crypt necrosis and inconstant T-cell activation in some cases. Colon biopsy specimens showed moderate nonspecific colitis. All the patients had defective antibody responses despite normal serum immunoglobulin levels, and defective antigen-specific skin tests despite positive proliferative responses in vitro.[41] Two cases have been reported by Stankler and coworkers as unexplained diarrhea and failure to thrive in two siblings with unusual facies and abnormal scalp hair shafts.[148] Some cases reported by Girault and colleagues.[41] in 1994 presented with an early-onset severe cholestatic disease that rapidly progressed to cirrhosis and death. A recent report (including two cases with severe liver disease) and the review of the published cases suggested that these patients had the same heterogeneous disease (inappropriately separated into different entities), suggesting that syndromic diarrhea and tricho-hepato-enteric syndrome are two sides of a now well recognized disease of unclear origin.[37]

Clinical findings comprise intrauterine growth restriction, severe protracted diarrhea of infancy, abnormal facies, abnormal hair with tricorrhexis nodosa,[81] immune deficiency,[41] long-term growth failure, and, commonly, mental retardation. Liver disease is associated in about half of the patients and is variable in severity.[43,156]

To date, no epidemiologic data are available. The estimated prevalence is approximately 1 in 300,000 to 1 in 400,000 live births in western Europe.[44] Ethnic origin does not appear to be associated with syndromic diarrhea. Infants are born small for gestational age and present with facial dysmorphism including prominent forehead and cheeks, broad nasal root, and hypertelorism. Hair is woolly, easily removed, and poorly pigmented.[43] Severe and persistent diarrhea starts within the first 6 months of life (1 month or earlier in most cases) and is accompanied by severe malabsorption leading to early and relentless protein energy malnutrition with failure to thrive. Liver disease affects about half of patients with extensive fibrosis or cirrhosis. There is currently no specific biochemical profile, although a functional T-cell immune deficiency with defective antibody production was reported.[156] Microscopic analysis of the hair shows twisted hair (pili torti), anisotrichosis, poilkilotrichosis, and trichorrhexis nodosa.[81] Histopathologic analysis of small intestine biopsy shows nonspecific villous atrophy with low or no mononuclear cell infiltration of the lamina propria, and no specific histologic abnormalities involving the epithelium. The etiology remains unknown. The frequent association of the disorder with parental consanguinity or affected siblings suggests a genetic origin with an autosomal recessive mode of transmission. Early management consists of total parenteral nutrition. Some infants have a milder phenotype with partial parenteral nutrition dependency, or require only enteral feeding. Prognosis of this syndrome is poor, but most patients survive, and about half of the patients may be weaned from parenteral nutrition at adolescence, although they experience failure to thrive and final short stature.[44,156]

OTHER CAUSES OF DIARRHEA

Infectious Enteropathy

Diarrhea can be caused by any number of viral and bacterial agents and can be prolonged.[74] Stool studies for bacterial cultures and viral antigen detection should be a part of the workup for infantile diarrhea (see also Chapter 39). Gastrointestinal infections are worldwide the most frequent cause of enteropathy by increasing mucosal permeability, local expression of costimulatory molecules allowing antigen penetration in the mucosa, and T-cell activation leading sometimes to disruption of oral tolerance.[129] Concomitant malnutrition impairs not only the immunologic response but also the recovery of damaged mucosa with secondary intestinal and pancreatic enzymatic reductions manifesting as lactose intolerance.

Allergic Enteropathy

Food protein-induced allergic colitis very commonly affects infants in the first few months of life.[105] Offending antigens are usually derived from commercially prepared infant formulas[80] or via breast milk in breast-fed infants.[103] Affected infants present with hematochezia, with or without diarrhea, with prompt resolution of symptoms after elimination of the antigen from the diet.[103] The usual age of presentation is around 66 days,[103] but Kumar and colleagues[80] reported three neonates in whom symptoms were noted at as early as 2 days of life, which suggests in utero sensitization. The most commonly implicated antigens are cow's milk protein and soy protein, which form the basis for the majority of the proprietary formulas.[80] Furthermore, infants diagnosed with cow's milk protein allergy have a 30% to 40% chance of being allergic to soy protein.[103] The dietary approach to allergic disease is currently evolving from passive allergen avoidance to active modulation of the immune system to establish or reestablish tolerance. The gastrointestinal flora provides maturational signals for the lymphoid tissue, improves balance of inflammatory cytokines, reduces bacterial invasiveness and dietary antigen load, and normalizes gut permeability. Major attention has recently focused on the immune effects of dietary lipids in terms of possible prevention of allergic sensitization by downregulating the inflammatory response and protecting the epithelial barrier and host-microbe interactions modifying the adherence of microbes to the mucosa.[129]

Motility Disorders and Small Intestinal Bacterial Overgrowth

Severe and extensive motility disorders such as total or subtotal intestinal aganglionosis (long-segment Hirschsprung disease) or chronic intestinal pseudo-obstruction syndrome may also cause permanent intestinal failure. Small intestinal bacterial overgrowth is a common problem in motility disorders and contributes to diarrhea and malabsorption. Children undergoing bowel surgery in the neonatal period and those having more than one procedure are at greater risk of developing small intestinal bacterial overgrowth postoperatively.

Small intestinal bacterial overgrowth is characterized by nutrient malabsorption associated with an excessive number of bacteria in the proximal small intestine. The pathology of this condition involves competition between bacteria and the human host for ingested nutrients. This competition leads to intraluminal bacterial catabolism of nutrients, often with production of toxic metabolites and injury to the enterocytes. The excess bacteria classically produce diarrhea and malabsorption by deconjugating bile acids, rendering them inadequate for micellar formation and fat digestion Therefore villous atrophy may not be present.[112] Small intestinal bacterial overgrowth is characterized by diarrhea, bloating, flatulence, nausea, abdominal pain, and weight loss.[30,149] Subjects with small intestinal bacterial overgrowth may have protein, carbohydrate, and fat malabsorption. Vitamin B_{12} deficiency produces megaloblastic anemia. Steatorrhea due to fat malabsorption is also a common finding. Small intestinal bacterial overgrowth leads to carbohydrate malabsorption by reducing brush border disaccharidase levels.[139] Lactose intolerance is common and contributes to the diarrhea that typifies small intestinal bacterial overgrowth. Bacterial fermentation of carbohydrates contributes to abdominal discomfort and bloating in small intestinal bacterial overgrowth. The carbohydrate malabsorption is the basis for various breath tests used to diagnose this problem. Protein malabsorption in small intestinal bacterial overgrowth is caused by a number of factors, such as decreased absorption of amino acids and peptides, leading to mucosal damage,[71] low level of enterokinase, which may impair the activation of pancreatic proteases,[127] and protein-losing enteropathy.[78] Small intestinal histologic findings are generally normal in patients with small intestinal bacterial overgrowth, but transient abnormalities of the small intestinal mucosa may be present in some patients.[118]

The most common underlying factors are dysmotility, small intestinal obstruction, and blind or afferent loops. Small intestinal bacterial overgrowth can be diagnosed by jejunal aspirate culture for bacterial counts and hydrogen breath testing using glucose or lactulose.[116] Treatment usually consists of the eradication of bacterial overgrowth with repeated course of antimicrobials, correction of associated nutritional deficiencies, and when possible, correction of the underlying predisposing conditions. Interestingly, loss of the ileocecal valve does not seem to be associated with an increased risk of bacterial overgrowth.[89]

Acrodermatitis Enteropathica

Acrodermatitis enteropathica is a rare autosomal recessive disorder resulting from zinc deficiency. Patients present with poor weight gain, diarrhea, and dermatitis, most noticeably in the perirectal and perioral areas (see also Chapter 52).[160] The SLC39A (solute carrier 39A)[7] gene family consists of 14 members, which are thought to control zinc uptake into the cytoplasm. Among these, zinc-iron transporter protein (ZIP4) is known to be particularly important for zinc homoeostasis. Mutations in this gene cause acrodermatitis enteropathica.[7]

Hormonally Mediated Secretory Diarrhea

In 1958, Verner and Morrison[157] described a syndrome of watery diarrhea and hypokalemia associated with pancreatic tumors in the adult population.[142,154] Vasoactive intestinal polypeptide (VIP) was subsequently isolated in 1975[145] and found to be responsible for causing chronic high-volume watery diarrhea with hypokalemia and acidosis syndrome.[74] Affected children usually present between the ages of 1 and 3 years[74] with severe watery diarrhea that persists despite gut rest.[96] Stool sodium and potassium concentrations are elevated, and fecal osmolar gap is less than 50.[96] The serum VIP concentration, which must be measured if the diagnosis is suspected, is elevated.[74] The most common VIP-secreting tumors (VIPomas) in children originate from neural crest and are usually ganglioneuromas or ganglioneuroblastomas.[96] These tumors are most often localized to the adrenal medulla or the sympathetic chain.[74]

Steroids have been reported to afford transient improvement, but the VIPomas must be aggressively located via either computed tomography or selective arteriography from different parts of the body, because removal of these tumors is curative.[145]

Short Bowel Syndrome

Short bowel syndrome (SBS) is characterized by a complex of symptoms, including malabsorption, diarrhea, and failure to thrive that occur in neonates who underwent small bowel resection. Congenital short bowel in a neonate born with only 50 cm of small bowel has been reported by Hasosah and associates.[54] Most neonates with SBS may have suffered bowel loss as a result of congenital anomalies, such as omphalocele, gastroschisis, or intestinal atresia, or they may have acquired intestinal ischemia from volvulus or necrotizing enterocolitis.[144] Malabsorption in neonates with SBS may ultimately resolve because of the ability of the remaining bowel to grow and to adapt functionally. The small intestine of neonates is 250 cm long and grows to 750 cm by adulthood. In addition, proximal small bowel can differentiate to assume absorptive functions. When the intestine adapts to SBS, the symptoms of malabsorption may improve. In the meantime, nutritional needs must be met parenterally. Factors associated with a reduced likelihood of recovery of bowel function include a remaining small bowel with a length of less than 40 cm, together with either colonic resection or absent ileocecal valve. The health of the remaining bowel and its ability to adapt are important but largely unpredictable factors. Cole and colleagues reported small intestinal bacterial overgrowth to be a negative factor in gut adaptation in patients with short gut.[25] Patients with SBS are predisposed to intestinal mucosal barrier breakdown, bowel dilation, and bacterial overgrowth, all of which may increase the risk of food allergies.

Treatment of neonates with SBS involves a combination of aggressive parenteral nutrition and prompt but cautious enteral feedings. It is important to deliver enteral nutrition, even though absorption is of limited nutritional consequence, to promote intestinal adaptation. Joly and associates report that in patients with SBS, continuous tube feeding (exclusively or in conjunction with oral feeding) following the postoperative period significantly increases the absorption of nutrients compared with oral feeding.[70] Glucagon-like peptide 2 (GLP-2) has generated recent attention as a potential agent in the management of patients with intestinal failure. Several studies have described the various gastrointestinal properties of GLP-2, such as enhanced epithelial and mucosal proliferation,[34,135] improved gastric motility,[164] and decreased gastric secretion.[164] The initial studies using GLP-2, or its protease-resistant analogue teduglutide, have demonstrated improvements in intestinal absorption and decreases in fecal volumes.[67,68] Anecdotally, growth hormone alone or in combination with glutamine has been used in the treatment of SBS; to date, there is insufficient evidence to support the use of growth hormone, glutamine, or a combination of the two as standard therapy in SBS patients.[21,22,136]

Morbidity from SBS is related primarily to nutritional deficiencies, cholestatic liver disease, central line-associated sepsis, and critical limitation of venous access. Pharmaceutical care of the patient with SBS is complex and always changing as intestinal function improves or complications develop. Pharmacologic therapy is directed at controlling gut motility, enhancing intestinal adaptation, minimizing small bowel overgrowth, and preventing nutrient deficiencies and hepatic complications. Rapid intestinal transit may be treated pharmaceutically. Gastric acid hypersecretion may occur in proportion to the degree of bowel resection and is treated with histamine blockers or proton pump inhibitors. Cholestyramine may be used to bind bile salts in patients with choleretic diarrhea. Cholestatic liver disease may be treated with phenobarbital and ursodeoxycholic acid to enhance bile flow. It is helpful to follow stool-reducing substances to document intestinal carbohydrate malabsorption, and to limit feeding advances in the face of malabsorption. Because most absorption of carbohydrate, fat, protein, and micronutrients occurs in the proximal small intestine, losses in this region are associated with micronutrient deficiencies. Careful monitoring of serum levels of fat-soluble vitamins, vitamin B_{12}, zinc, and copper is recommended when long-term total parenteral nutrition is required. The management of SBS includes also as a key component bowel conservation (especially small intestine) and the prompt reestablishment of bowel continuity.[6]

Surgical procedures, such as longitudinal intestinal lengthening and tapering (LILT) or serial transverse enteroplasty (STEP), can increase mucosal surface area and may enhance intestinal adaptation. Survival after longitudinal intestinal lengthening and tapering ranges from 30% to 100%.[14,63] Survivors that were successfully weaned off parenteral nutrition ranged from 28% to 100%.[14,63]

In the serial transverse enteroplasty procedure a stapler is applied across the dilated bowel in an alternating fashion, leaving a zigzag-shaped bowel. This approach accomplishes two results, to lengthen and to taper the dilated bowel without damaging the mesenteric blood supply or diminishing mucosal surface area. The serial transverse enteroplasty procedure is simple to perform. Because of the adaptation process, there can be redilation of the bowel after a longitudinal intestinal lengthening and tapering operation. Multiple serial transverse enteroplasty procedures are possible by repeating the operation after the process of adaptation and dilation has occurred.[91,113] Data show a substantial increase in intestinal length and improvement of enteral tolerance, nutrition parameters and ability to wean off parenteral nutrition.[24,102]

Many children with SBS require transplantation. The most common indications for transplantation include failure to wean off parenteral nutrition, parenteral nutrition-associated liver disease, recurrent central catheter sepsis, and loss of vascular access to provide parenteral nutrition.[10] Similar to the longitudinal intestinal lengthening and tapering and serial transverse enteroplasty procedures, intestinal transplantation should be viewed as an adjunct to intestinal rehabilitation. Historically, intestinal transplantation was complicated by significant morbidity and mortality. With recent advances in immunosuppression, specifically the use of tacrolimus, outcomes such as mortality, cost-effectiveness, and quality of life have improved over the last decade.[150] Currently, patients undergoing intestinal transplants experience 1-year graft survivals of 80% and survival of 80% per the Intestinal Transplant Registry. Three different types of transplants can be offered to patients depending on the nature and extent of their intestinal failure: isolated intestinal, liver-intestinal, and multivisceral (e.g., stomach, duodenum, pancreas, intestine, and liver). Recent data show that of pediatric intestinal transplantations, 50% are liver-intestinal, 37% are isolated, and 13% are multivisceral per the Intestinal Transplant Registry (www.intestinaltransplant.org). The decision regarding the type of transplantation should be based on each patient's specific disease and condition.

CONCLUSIONS

Malabsorption syndromes are characterized by the association of chronic diarrhea, abdominal distention, and failure to thrive. There are many causes of malabsorption and chronic diarrhea in the newborn ranging from insufficiency of key elements required in the digestion of carbohydrates, protein, and fat, to electrolyte transport defects, disorders of villous architecture, motility disorders, and congenital causes leading to bowel resection and short bowel syndrome. Any of these disorders can lead to intestinal insufficiency or intestinal failure. Bowel rehabilitation is a key element in the survival of these children, and often requires a multidisciplinary approach for the diagnosis and management of these neonates with the help of a team comprising neonatologist, pediatric gastroenterologist, pediatric surgeon, pediatric pathologist, and nutritionist.

PART 3

Selected Gastrointestinal Anomalies

Edward M. Barksdale, Jr., Walter J. Chwals, David K. Magnuson, and Robert L. Parry

THORACIC ANOMALIES

Esophageal Atresia and Tracheoesophageal Fistula

Combined anomalies of the esophagus and trachea are regular occurrences in most tertiary neonatal units caring for high-risk infants. The spectrum of recognized deformities comprises a variety of combinations involving esophageal atresia (EA) and tracheoesophageal fistula (TEF). These malformations are well-recognized entities, yet they continue to stimulate a great deal of interest for a variety of reasons, and almost all are lethal unless surgically corrected. Many have concurrent pulmonary complications and most are associated with other congenital anomalies that require careful coordination of interdisciplinary care. The majority can expect a satisfactory outcome if all these considerations are properly addressed. There are few conditions, if any, that require a greater degree of cooperation between neonatologist and surgeon.

The reported incidence of EA/TEF is roughly 1 to 2 per 5000 live births.[48,103] The incidence of EA/TEF is higher in white populations than in nonwhite. There is also a slight preponderance of males and a disproportionate rate of twinning among affected infants. Although the majority of cases are sporadic, there are numerous well-recognized genetic associations. Approximately 7% of affected infants have a chromosomal abnormality such as trisomy 13, 18, or 21. Additionally, EA/TEF has been reported in infants with the Pierre-Robin, DiGeorge, Fanconi, and polysplenia syndromes.

Although usually sporadic, most cases of EA/TEF are not isolated. Most affected infants, up to 70% in some series, have at least one other anomaly.[34] The likelihood of coexisting anomalies is considered to be greatest with pure EA and least with pure TEF. The most widely recognized relationship between EA/TEF and other congenital anomalies is within the constellation of defects referred to as the VACTERL association—abnormalities involving *v*ertebral, *a*norectal, *c*ardiac, *t*racheal, *e*sophageal, *r*enal/genitourinary, and *l*imb structures. There is a lesser association with CHARGE syndrome (*c*oloboma, *h*eart defects, *a*tresia choanae, retarded development, genital hypoplasia, *e*ar defects/deafness). Gastrointestinal anomalies (other than anorectal defects) associated with EA/TEF include duodenal atresia, annular pancreas, jejunoileal atresia, and intestinal malrotation. Neurologic defects, especially hydrocephalus, may be associated with EA/TEF, as may diaphragmatic hernia and abdominal wall defects. In order of approximate frequency, the affected organ systems most commonly associated with EA/TEF are cardiovascular (35% to 45%), gastrointestinal (25%), genitourinary (25%), skeletal (15%), and neurologic (10%).

The anatomy of EA/TEF includes five well-recognized variants. A number of anatomic classifications have been devised but have been largely discarded in favor of simple descriptive nomenclature. The most common variant is the combination of a proximal esophageal atresia and a distal tracheoesophageal fistula. The proximal atresia/distal fistula variant occurs in about 85% of affected patients. It manifests classically as a dilated, blind-ending proximal pouch that extends to the lower neck or upper mediastinum, and a distal esophageal segment that originates from the posterior membranous wall of the trachea, carina, or main stem bronchus and connects to the stomach in a normal fashion. The next two most common variants are isolated EA and isolated TEF, both of which occur in approximately 5% to 10% of patients. An isolated TEF is often referred to as an H-type fistula; the fistula itself is usually angled downward, with the esophageal end inferior to the tracheal end. The rarest variants include the proximal fistula/distal atresia, and the double fistula, both occurring in no more than 1% or 2% of patients.

Theories regarding the pathogenesis of EA/TEF are currently undergoing reappraisal. Normal development of the esophagus and trachea includes the formation of a primordial lung bud as a diverticulum of the ventral foregut during the 4th week of gestation. The appearance of this diverticulum is associated with a pair of lateral infoldings of the foregut—the laryngotracheal folds—which begin at the caudal end of the lung bud and fuse to form the tracheoesophageal septum. This process of lateral invagination and fusion was historically believed to proceed cranially, displacing the orifice of the lung bud in a cephalad direction and separating the developing trachea from the esophagus as the tracheal bifurcation moved caudally in a relative sense. Therefore, in the traditional model for the cause of tracheoesophageal malformations, the esophagus and trachea shared a common foregut precursor over a significant distance, becoming separated by the cephalad movement of the tracheoesophageal septum. Perturbations of this process would account for the observed variety of abnormal connections between these two adjacent structures. This theory of cephalad migration of a tracheoesophageal septum is now controversial. Evidence suggests that the position of the laryngeal orifice remains constant relative to the developing notochord, and that the tracheal bifurcation descends simply as a result of linear tracheal growth without any cephalad movement of a tracheoesophageal septum.[69]

Given this alternative scheme of tracheoesophageal development, a different etiologic theory is required to explain tracheoesophageal anomalies. One such theory has arisen from observations in the Adriamycin-treated rat model of VACTERL deformities. In this model, pregnant rats are exposed to Adriamycin during early gestation and give birth to offspring that express VACTERL phenotypes, including EA/TEF. Investigations have demonstrated that the distal "esophageal" segment in EA/TEF arises from a respiratory precursor, descends from the carina along with the two main stem bronchi, and elongates caudally to merge with the stomach. A respiratory origin for this third structure is supported by the finding of pseudostratified respiratory epithelium and respiratory-specific thyroid transcription factor-1 (TTF-1) in distal fistulas from Adriamycin-treated rat model sources, and of TTF-1 expression in distal fistula specimens from human sources.[14,15,94] This structure does not branch as the developing bronchi do, because of abnormal epithelial-mesenchymal interactions caused by deficiencies of mesenchymal fibroblast growth factor (FGF-1) and epithelial FGF receptors.[16] In support of this hypothesis, findings document a brief stage in the Adriamycin-treated rat model during which the stomach is anatomically disconnected from the rest of the developing foregut.[93]

If current proposals of a respiratory-derived distal fistula are accurate, the proximal atresia must therefore have a separate etiology. One proposed explanation is an abnormal concentration gradient of the early embryonic morphogen known as *sonic hedgehog* (Shh), which is elaborated by the developing notochord and is believed to participate in early foregut differentiation. Notochord abnormalities have been documented in the Adriamycin-treated rat model, and in specimens of human distal fistulas that been shown to be specifically deficient in Shh.[27,95] A unifying theory that links these newer models and provides a comprehensive explanation for tracheoesophageal maldevelopment is still lacking.

The clinical presentation of infants with EA/TEF depends on the specific anatomic variant encountered. Most cases of EA/TEF are not diagnosed prenatally, but current prenatal imaging techniques may raise a suspicion of EA/TEF in a significant number of infants. The combination of maternal polyhydramnios and a small or absent stomach has both sensitivity and a positive predictive value for EA/TEF of approximately 40% to 60% in most series.[39,91] The finding of a dilated upper pouch in the neck by high-resolution ultrasonography or magnetic resonance imaging can increase the diagnostic accuracy in this selected group of patients to nearly 100%.[49,85]

In most affected infants, the diagnosis is made in the immediate postnatal period. The infant cannot swallow secretions and appears to drool excessively. As the upper pouch fills, tracheal compression and antegrade aspiration may occur, leading to significant coughing, respiratory distress, and cyanosis. In patients with a distal fistula, the stomach may dilate with air, leading to the reflux of gastric secretions back into the lungs, resulting in significant and progressive respiratory distress due to reactive bronchoconstriction and chemical pneumonitis.

Attempted passage of a gastric tube is usually diagnostic. The tube fails to pass distally and extrudes back through the mouth. A simple chest radiograph usually establishes the diagnosis by demonstrating the radiopaque catheter curled in the upper pouch (Fig. 47-4). If the diagnosis is still in question,

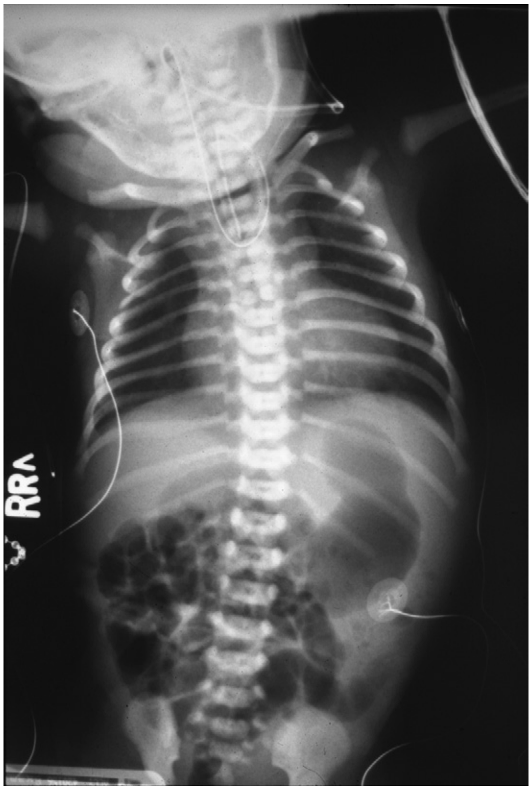

Figure 47–4. Typical chest radiograph of a patient with a tracheoesophageal fistula, with proximal atresia and a distal fistula.

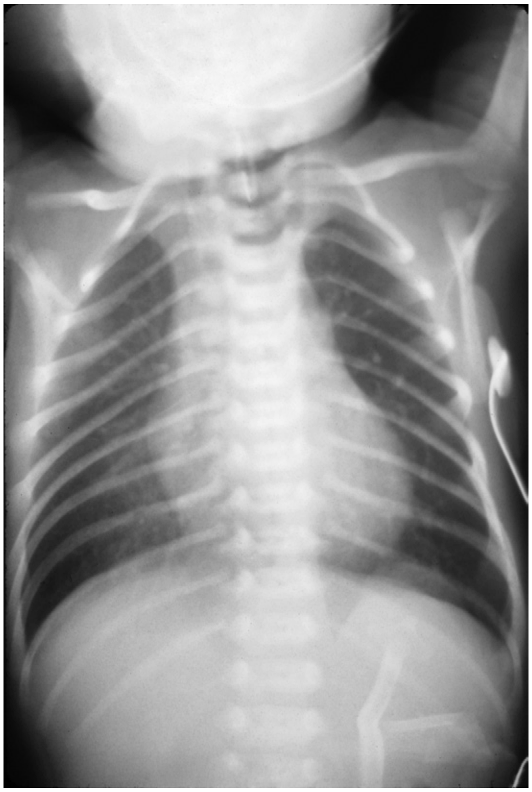

Figure 47–5. Chest radiograph of patient with pure esophageal atresia.

the upper pouch should not be studied with barium or water-soluble contrast agents, as aspiration of these can cause parenchymal lung injury. Air itself makes an excellent contrast agent, and the catheter can be pulled back under fluoroscopic guidance until the tip is positioned in the proximal esophagus, and then 5 to 10 mL of air is injected slowly. A radiolucent dilated pouch is then easily documented. If there is no luminal gas below the diaphragm, the anomaly can be further defined as a pure or distal atresia (Fig. 47-5). The clinical presentation of an H-type TEF is typically much more subtle and delayed. It usually includes a history of coughing during feedings and occasionally the development of pneumonia due to aspiration through the fistula. An H-type TEF may be very difficult to confirm radiographically. Contrast must be injected through a tube positioned in the thoracic esophagus, with the patient prone and in the Trendelenburg position, allowing the contrast to flow back up the angled fistula. Often, an H-type fistula is documented only on rigid bronchoscopy during evaluation for respiratory distress.

Once the diagnosis is established, efforts are made to prevent aspiration-induced lung injury, to provide respiratory support if necessary, and to define associated anomalies while preparing the patient for surgical correction. Gastric acid blockade is immediately instituted while the infant is maintained in a slightly head-up position to reduce reflux of gastric secretions into the airway. A small-caliber sump tube is kept in the upper pouch and suctioned intermittently. The use of preoperative broad-spectrum antibiotics during the first several days is advisable. Spontaneous ventilation is preferred to minimize the introduction of air into the stomach, as gastric decompression is possible only by percutaneous needle aspiration. This is particularly important in the presence of distal intestinal obstruction. The use of continuous positive airway pressure is contraindicated. If parenchymal lung disease mandates the use of positive-pressure ventilation, mean airway pressures are minimized to avoid shunting of tidal volume through the fistula. This may be difficult in patients with lung disease and poor compliance. Under these circumstances, the use of high-frequency oscillatory ventilation (HFOV) may allow adequate gas exchange to occur at lower peak airway pressures, preventing the loss of ventilation through the fistula. The failure or unavailability of HFOV in a patient requiring aggressive ventilatory support may be an indication for urgent surgical intervention to ligate the fistula, ligate the gastroesophageal junction, or occlude the fistula with a balloon catheter.

A thorough evaluation for other VACTERL-associated defects is mandatory. A preoperative radiograph provides much information regarding cardiopulmonary status, diaphragmatic integrity, and the presence of vertebral abnormalities. The only other studies necessary before surgical management of the EA/TEF are an echocardiogram in all patients and a renal ultrasound in patients with inadequate urine output. Echocardiography not only identifies significant intracardiac anomalies that may influence anesthetic management but also establishes the presence of aortic arch anomalies that may alter the surgical approach.

The nature and timing of surgical intervention depend on the specific anatomic variant being treated. Surgical strategies include immediate primary repair, delayed primary repair, staged repair, and esophageal replacement. Immediate primary repair is appropriate for the majority of infants with EA/TEF. Rigid bronchoscopy immediately before surgical repair is often a useful adjunct to confirm the diagnosis before thoracotomy and to obtain useful information: The location of the fistula can be determined, the presence of a second upper pouch fistula can be detected, and the structural status of the trachea can be assessed (Fig. 47-6). The repair is approached through a right extrapleural thoracotomy, or through the left side if preoperative echocardiography documents a right-sided aortic arch. An extrapleural approach is preferred to avoid a pleural empyema if an anastomotic leak subsequently develops. The fistula is divided and the tracheal side closed transversely to prevent narrowing of the trachea. A primary anastomosis between the proximal esophageal pouch and the distal esophageal segment is then performed. Single-layer end-to-end anastomotic technique is now universal as it results in less tension than two layers and does not substantially increase the likelihood of an anastomotic leak. A closed suction drain is placed and the thoracotomy closed.

In most patients, a gap of some degree exists between the proximal and distal esophagus, requiring mobilization of both ends, and still resulting in some degree of tension at the anastomosis. Anastomotic ischemia caused by overaggressive mobilization or excessive tension leads to fibrosis and stricture formation. The blood supply to the cervical esophagus originates proximally and extends distally through the submucosal plexus, allowing extensive mobilization of the upper pouch without causing ischemia at the distal tip. The blood supply to the normal thoracic esophagus derives from the intercostal vessels and is therefore more segmental. Whether or not this limits the ability to mobilize the distal fistula without causing ischemia is debated. If careful mobilization does not sufficiently reduce tension at the anastomosis, two options are available. The first option is to lengthen the upper pouch by performing a circular or spiral myotomy. Dividing only the muscle layers allows the redundant mucosa/submucosa to be stretched farther to gain significant additional length. Myotomies may result in the later development of pseudodiverticula and must be performed judiciously. A second option is to perform a staged lengthening of both the upper and lower pouches before performing the anastomosis. This technique, pioneered by Dr. John Foker of the University of Minnesota, is described in more detail later.

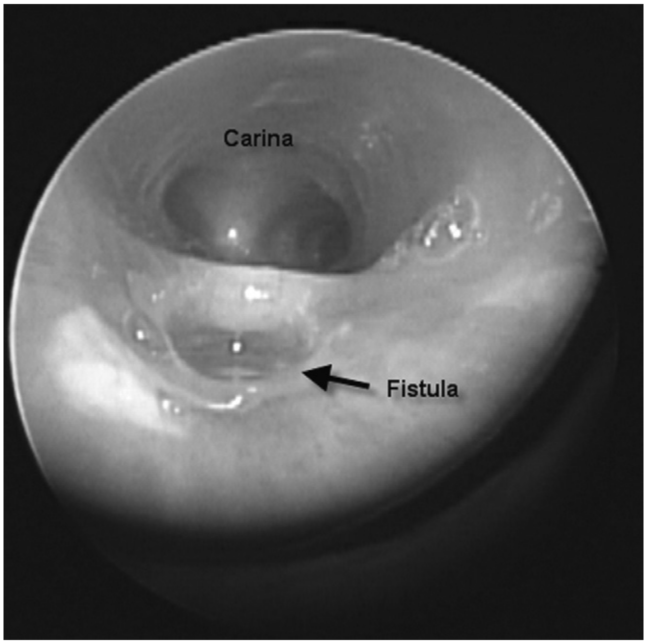

Figure 47–6. Bronchoscopic view of tracheoesophageal fistula.

The postoperative care of patients with primary esophageal repairs must be meticulous and conservative. Removal of the endotracheal tube should occur only after respiratory mechanics have been optimized, as failure of extubation may lead to aggressive bag-mask ventilation and reintubation—events that place the tracheal repair at risk for disruption. Extubation should occur only when the operating surgeon or other experienced clinician is available to perform reintubation. If a sump tube has been left proximal to the anastomosis, as some surgeons prefer, the tube should not be advanced or reinserted if it is pulled back inadvertently. Some surgeons leave a soft, silicone transanastomotic feeding tube to initiate early enteral feedings. In all cases, the head of the bed is elevated and gastric acidity neutralized to minimize reflux injury to the healing anastomosis. After 5 to 7 days, if the patient is clinically stable without signs of sepsis, a contrast esophagram is carefully performed with a water-soluble agent followed by barium. If no leak is demonstrated, oral feedings are initiated and the chest tube is removed. Small, asymptomatic leaks that are adequately controlled by the existing extrapleural chest tube may be managed nonoperatively and repeat studies performed until healing is documented. Large leaks and intrapleural leaks mandate exploration for repair or diversion.

In many clinical situations, the described primary approach is neither feasible nor appropriate. In the premature infant with very low birthweight, or in any infant with a significant cardiac defect, respiratory compromise, or sepsis, primary anastomosis should be postponed until the patient is a better surgical candidate. If the anticipated surgical delay is brief, careful upper pouch suctioning and parenteral nutrition may be used until the delayed primary repair can be carried out. If a lengthy or indeterminate delay is expected, a staged approach may be required. This strategy provides temporizing measures that allow later esophageal repair to be undertaken electively. Typically, a gastrostomy tube is placed for decompression and feeding, and the fistula is divided via an extrapleural approach to protect the lungs from further injury. Later, a transpleural approach may be taken to restore esophageal continuity.

The list of postoperative complications that occur in this complex group of patients is long and varied. Beyond the immediate postsurgical period, when anastomotic leak is the most feared problem, anastomotic strictures represent the most common complications of surgical treatment, occurring in up to 40% of patients in some series.[42] Strictures result from fibrosis during healing, which in turn results from ischemia, excessive tension, leakage, or acid-peptic injury. An anastomotic stricture should be suspected whenever dysphagia or respiratory symptoms occur in a patient who had previously tolerated oral feedings. A contrast esophagram reliably demonstrates the stricture and often demonstrates distention of the upper pouch with posterior compression of the trachea—the so-called upper pouch syndrome (Fig. 47-7). Strictures are best treated by tangential dilation under fluoroscopic guidance and control of acid reflux. Near-occlusive strictures require placement of an indwelling transanastomotic guide line that can be used to pull sequential dilators safely through the stricture on a frequent basis. If pharmacologic suppression of gastric acid secretion fails to prevent recurrent strictures, an antireflux procedure may be required. Finally, a stricture refractory to aggressive management may require segmental resection.

Recurrent fistulas occur in 5% to 10% of cases and usually present with respiratory distress during feeding or with recurrent aspiration pneumonia.[22] Diagnosis is made with a dilute barium esophagram in the prone position. Most recurrent fistulas result from small, contained anastomotic leaks that cause chronic inflammatory changes and gradually erode back through the tracheal repair. Surgical options range from primary closure to segmental esophageal resection, and they must include interposition of healthy, well-vascularized soft tissue such as a pleural or strap muscle rotation flap. Some repairs can be approached from a cervical incision, which limits the complications associated with secondary leaks.

Functional disturbances of the esophagus are nearly universal after repair of EA/TEF. Occasionally, dysphagia is associated with severe esophageal dysmotility in the absence of a stricture. Solid-phase esophagography demonstrates that solid foods have great difficulty traversing the anastomosis and lower esophagus because of a lack of peristaltic force. In these situations, dietary modification and adjustment of feeding behavior may be all that can be offered. Gastroesophageal reflux (GER) disease is present to some degree in most of these patients and may be clinically significant in up to 50% of patients with tracheoesophageal malformations.[104] Deficient autonomic and enteric innervation, intrinsic developmental abnormalities of the lower esophageal muscle, shortening of the intra-abdominal esophagus, and distortion of the angle of His may all contribute to lower esophageal sphincter (LES) dysfunction in varying degrees. LES incompetence is exacerbated by esophageal dysmotility, reducing clearance of gastric acid from the esophagus. The major consequence of uncontrolled reflux is anastomotic stricture. Some degree of tracheomalacia is also expected in all patients with EA/TEF. Most patients exhibit the typical raspy cough caused by vibration of the weak and flattened tracheal wall, and they outgrow these minor symptoms with age.

In patients with isolated EA, a long gap is anticipated, and primary repair, immediate or delayed, is not feasible. Historically, long-gap EA had been an absolute indication for esophageal substitution without attempts at staged primary repair. Over the past two decades, however, the proportion of patients with pure atresia who eventually undergo successful esophageal repair has increased dramatically, obviating esophageal substitution in a large number of children.[10,24] There is no universal agreement regarding the maximal gap that will permit esophageal repair.[74,96] However, a fluoroscopically measured gap of greater than four vertebral bodies with the segments in neutral position, or greater than two vertebral bodies (Fig. 47-8) with the segments stretched toward each other, portends a low likelihood of successful primary anastomosis. Elongating the upper and lower

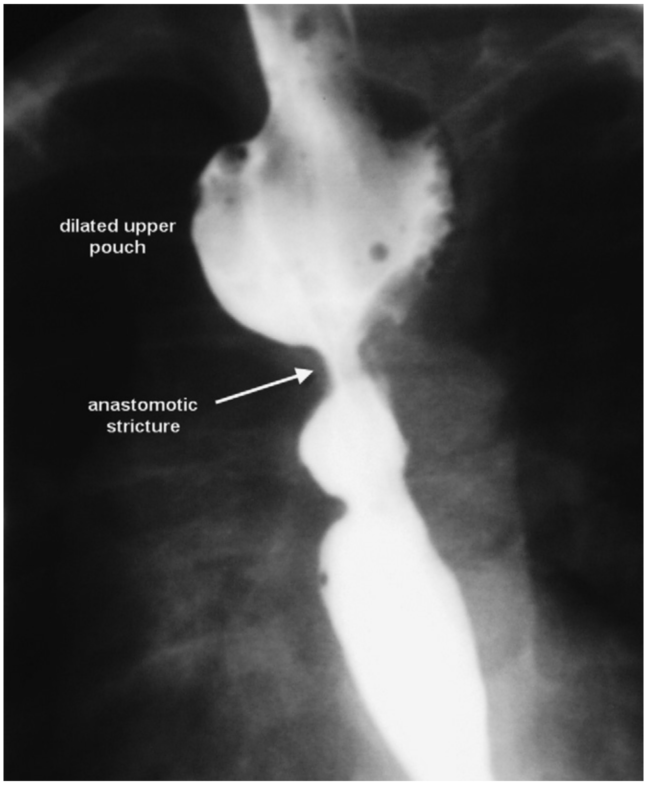

Figure 47–7. Barium esophagram demonstrating anastomotic stricture and upper pouch dilation.

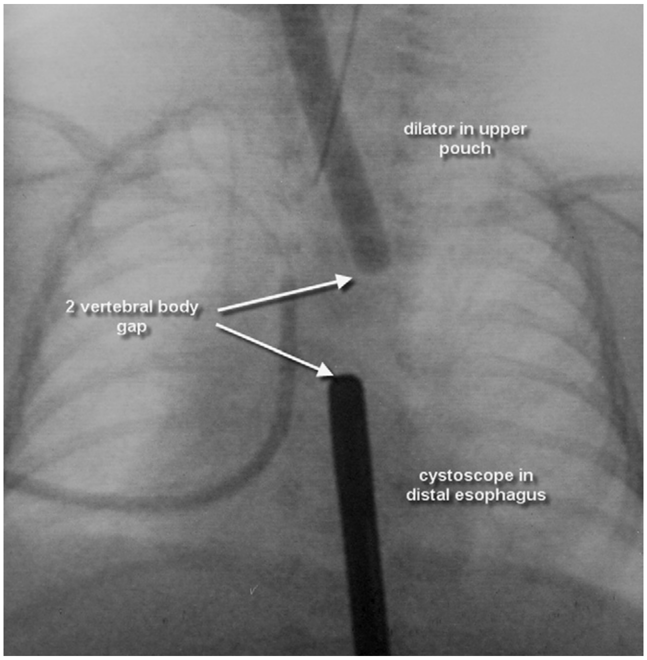

Figure 47–8. Measuring gap length in pure esophageal atresia.

pouches over a 1- to 3-week period, followed by primary anastomosis, has been very successful at keeping the native esophagus and avoiding esophageal replacement. Foker has performed no interpositions since 1983 while treating more than 70 patients with long-gap esophageal atresia.[24] Figures 47-9 and 47-10 show preoperative and postoperative contrast images of a patient with a long-gap atresia of nearly seven vertebral bodies treated by elongation and primary repair. Reflux requiring fundoplication is common in these patients as are dilations to relieve strictures. However, when compared with the multiple, significant complications associated with esophageal replacement using either small or large bowel, the Foker procedure requires strong consideration in all patients with long-gap esophageal atresia. Esophageal replacement is reserved for those cases of long-gap atresia unsuitable for immediate or delayed primary repair, and when attempted primary repair has failed irretrievably due to leakage or stricture.

Long-term outcomes for all variants of EA/TEF have improved steadily over the last three to four decades. Waterston and colleagues were the first to stratify patients on the basis of risk factors shown to affect prognosis, and to recommend treatment strategy based on this stratification.[111] In this analysis, prognosis was dependent on birthweight, associated anomalies, and the presence of pneumonia. Many stratification schemes subsequently evolved, and Spitz and associates refined this prognostic model to include only birthweight and presence of significant congenital heart disease (Table 47-7).[97] In the current era, most infants born with tracheoesophageal anomalies ultimately experience a positive outcome owing equally to refinements in surgical technique and to neonatal support over the past several decades.

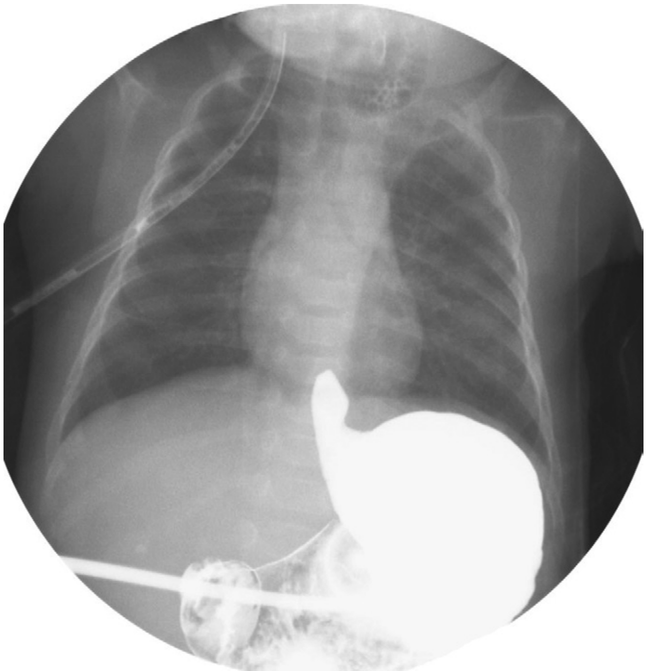

Figure 47–9. Long-gap esophageal atresia. Note proximal air-filled upper pouch and small distal esophagus. Gap is approximately seven vertebral bodies in length.

TABLE 47–7 Determinants of Survival in Cases of Tracheoesophageal Malformation

Group	Characteristics	Survival
I	Birthweight >1500 g without CHD	97%
II	Birthweight <1500 g or CHD	59%
III	Birthweight <1500 g and CHD	22%

CHD, major congenital heart disease.

ESOPHAGEAL DUPLICATIONS

Esophageal duplication cysts are uncommon causes of esophageal obstruction during infancy. These structures result either from abnormalities in the vacuolization process that reestablishes the esophageal lumen after obliterative epithelial proliferation during early embryonic development, or from the “budding” and separation of a portion of the developing foregut. These structures are usually cystic, but they may be tubular and may be located within the muscular wall of the esophagus or exist separately in the posterior mediastinum. They contain an epithelial lining derived from any foregut structure: squamous, columnar, or pseudostratified ciliated respiratory epithelium. They may also contain gastric epithelium and pancreatic or adrenal rests.

Infants with esophageal duplication cysts are usually asymptomatic, and the diagnosis is made when chest radiography unexpectedly demonstrates a mediastinal mass. Some

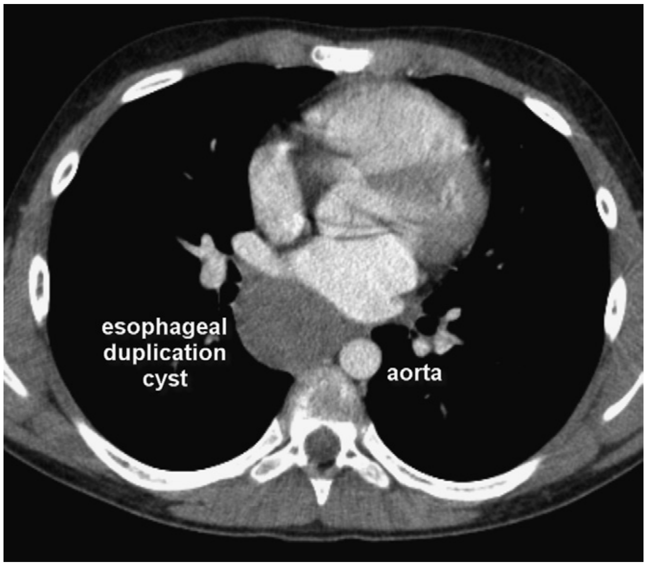

Figure 47–11. Esophageal duplication cyst demonstrated by computed tomography.

infants, however, experience feeding difficulties or respiratory compromise if the cystic structure compresses the adjacent esophagus or trachea. Cysts containing gastric mucosa may present with complications of acid-induced injury: upper gastrointestinal hemorrhage, ulceration, perforation, or erosion into the bronchial tree.

Although the diagnosis may be suggested by a plain chest radiograph or by contrast esophagram, computed tomography is definitive and helpful in planning the operative approach (Fig. 47-11). Magnetic resonance imaging provides additional information about the status of the spinal cord, which may be abnormal, and should be obtained in all patients with a vertebral abnormality or a cystic structure in close proximity to the spine. Esophagoscopy is unnecessary and potentially harmful.

Surgical treatment involves resection of the cyst and repair of any esophageal defect. This may require a thoracotomy, but many lesions lend themselves to thoracoscopic resection. Cysts complicated by infection with abscess formation or by internal hemorrhage may expand rapidly and may require urgent drainage before resection. Duplications that are deemed unresectable because of their extensive nature, which may include extension into the abdomen, should be treated by stripping the mucosa from the duplication and leaving the muscular remnant to heal to the existing esophageal wall. Excellent results can be expected in most patients.

CONGENITAL DIAPHRAGMATIC HERNIA

See also Chapters 11 and 44.

Congenital diaphragmatic hernia (CDH) is a condition in which the defective development of one or more diaphragmatic precursors results in an abnormal communication between the thorax and abdomen, leading to herniation of abdominal contents into the chest. This complex malformation is discussed more thoroughly in Chapter 44, as the principal causes of morbidity and mortality actually relate to secondary pulmonary hypoplasia, pulmonary hypertension, and cardiac maldevelopment. However, a number of gastrointestinal issues related to CDH merit separate discussion.

Most instances of CDH involve a posterolateral defect, the foramen of Bochdalek, resulting from a failure of the embryonic pleuroperitoneal canal to close. The majority of these, approximately 85%, occur on the left side, although the number of right-sided hernias is probably under-reported, as the liver may block smaller defects and render them asymptomatic. Bilateral hernias are rare and usually fatal. Less commonly, defective development of the central septum transversum leads to an anteromedial defect, the foramen of Morgagni. Morgagni hernias are usually diagnosed before the onset of symptoms when imaging studies are obtained for unrelated reasons. The overall incidence of all types of CDH is approximately 2 to 5 per 10,000 live births.[20] The true incidence may be higher, as a number of affected fetuses experience in utero demise as a result of associated defects, and a number expire in the immediate postnatal period before transfer to a tertiary neonatal center can be arranged, and thus may not be included in statistical surveys.

Current treatment of CDH includes preoperative stabilization, delayed repair, frequent use of prosthetic material to reconstruct the diaphragm, and a variety of management strategies to deal with varying degrees of pulmonary hypoplasia and hypertension. These include permissive hypercapnia, early use of HFOV, inhaled nitric oxide, and extracorporeal membrane oxygenation (ECMO). Advancements in the perioperative physiologic stabilization of these patients have led to an increase in survival rates from less than 50% to approximately 80%.[20] Accurate assessment of the impact of these modalities on survival has proved challenging, however, because of difficulties in applying these technologies in a prospective randomized fashion, and it is unlikely that precise outcome statistics will ever be ascertained.

The most common gastrointestinal complication of CDH is the development of GER, which occurs in approximately 15% to 60%, depending on study criteria and sample pool characteristics.[78,106] GER can be particularly damaging when it results in aspiration pneumonitis in a child with preexisting pulmonary hypoplasia. Esophageal dysmotility and ectasia are also increased in CDH, potentially exacerbating the peptic complications of GER such as esophageal stricture. Careful surveillance for GER and aggressive medical therapy are therefore mandatory in all survivors of CDH. Surgical treatment of GER may be compromised by dysphagia because of the effects of increased resistance on a dyskinetic esophagus. Therefore, in some circumstances, an incomplete fundoplication may be preferable to a fully competent fundoplication. The proportion of infants with CDH who require fundoplication has been as high as one third in some series.[42]

Although intestinal malrotation is nearly universal in infants with posterolateral CDH, midgut volvulus is uncommon in this population. Retrospective data suggest an incidence of midgut volvulus in survivors of CDH of 3% to 9%.[54,79] This relatively low incidence may result from the extensive intra-abdominal adhesions that form after CDH repair, especially if significant postoperative bleeding occurs as a result of anticoagulation for ECMO. There are no universally accepted recommendations regarding the advisability of performing a Ladd procedure and appendectomy for malrotation at the time of CDH repair. Certainly, the extensive dissection required for a Ladd procedure is contraindicated if the operation is undertaken after the patient has received anticoagulant therapy for ECMO, and appendectomy is ill-advised when placing a prosthetic patch for diaphragm repair because of the potential infectious complications. It may be wise to repair the CDH only, allowing adhesion formation to stabilize the intestinal tract against volvulus.

GASTROESOPHAGEAL REFLUX

Any discussion of GER in neonates must begin with the disclaimer that GER is a normal condition in this age group. Therefore, distinguishing pathologic from physiologic GER is often an exercise in semantics. The proper diagnosis and treatment of GER in neonates requires an understanding of the normal development of physiologic antireflux mechanisms and the natural history and complications of untreated GER. Only then can the somewhat fluid definition of GER be applied meaningfully to individual newborn patients.

Under normal circumstances, gastric contents are prevented from retrograde flow back into the esophagus by the actions of the lower esophageal sphincter. In spite of its accepted name, the LES does not actually consist of a simple circumferential muscle but instead represents the cumulative effects of several discrete physiologic and anatomic components. These include (1) the intra-abdominal esophagus, (2) the angle of His, (3) the gastroesophageal (GE) junction, and (4) the diaphragmatic crura. The intra-abdominal esophageal segment functions in the simple fashion of a Starling resistor—an external positive pressure produces a compressive force against the compliant esophageal wall as it emerges from the negative pressure environment of the thorax. The *angle of His* refers to the oblique angle at which the esophagus connects to the stomach. This obliquity transmits intraluminal pressure in the gastric fundus to the GE junction in an orientation that increases resistance through the GE junction. The circumferential muscle layer of the esophagus at the GE junction also functions somewhat independently, demonstrating anatomic thickening and manometrically detectable muscular tone. The diaphragmatic crura exert a caudad and rightward displacement on the intra-abdominal esophagus during inspiration, resulting in a pinch-cock effect when intrathoracic pressure is most negative. These individual components compose a functional antireflux sphincter that can be quantified in terms of pressure and length.

The LES may be approximately defined in any patient as a high pressure zone by esophageal manometry. The LES resting pressure is approximately 2 to 3 mm Hg at birth and increases linearly to adult levels of 10 to 15 mm Hg by the end of the 2nd month of life on average, and by 6 months of age at the latest.[9] The maturation of the LES by several months of life is seen in both full-term and premature neonates. Significant GER during the first months of life may, therefore, be physiologic and usually resolve without adverse clinical consequences.

The diagnosis of GER in neonates may be made on clinical grounds or bedside assessment via esophageal pH monitoring or the technique of multiple intraluminal impedance. The former is a measure of esophageal acidity, while the latter can quantify retrograde peristaltic waves in the esophagus via specially designed esophageal catheters.[87] When the diagnosis is unclear, a contrast esophagram may be helpful. Esophagography has a low sensitivity in neonates, but it is quite accurate when it does demonstrate reflux. Contrast esophagography is indicated in all neonates with pathologic reflux, to exclude anatomic reasons for excessive vomiting such as malrotation and intrinsic duodenal anomalies. Radionuclide scans are purported to achieve higher sensitivity and specificity than esophagography, but their utility is compromised by a significant false positive rate. They are more useful for assessing delayed gastric emptying, which may contribute significantly to GER and may require specific medical or surgical treatment.

Significant GER in high-risk neonates and infants who do not demonstrate improvement by 6 months of age may be considered an indication for medical therapy. Head-up positioning may be effective, as is the thickening of formula feedings with small amounts of cereal. Prokinetic agents to accelerate gastric emptying may have a beneficial effect. Because these agents increase mean intragastric pressure, they may also exacerbate GER in some patients and must be assessed for efficacy on an individual basis. The hallmark of medical therapy is neutralization of gastric acidity, which does not reduce GER events but does protect the esophagus from peptic injury secondary to prolonged exposure to gastric acid. This may be accomplished with either antacids or antisecretory agents, such as histamine blocking agents and proton pump inhibitors, although increased risk of infection is a potential side effect.[70]

Surgical treatment for GER is reserved for high-risk infants who have complications of GER and for those who are refractory to medical therapy. Complications of GER include failure to thrive, aspiration pneumonia, reactive airway disease, and esophagitis with bleeding, stricture, ulceration, or Barrett metaplasia. Antireflux surgery may also be performed electively in the older child who prefers surgery to a lifetime of medication. Finally, surgical intervention is often necessary in certain select groups—infants with coexisting tracheoesophageal malformations, congenital diaphragmatic hernia, hiatal hernia, and severe neurodegenerative conditions.

There are many surgical options for the treatment of GER, a reflection of the fact that no antireflux surgery is completely effective or without a significant incidence of complications. The Nissen fundoplication, which includes a complete, circumferential wrap of the gastric fundus, has emerged as the most effective option in most clinical settings. In this procedure, a high pressure zone is created just above the GE junction by the fundic wrap, which has been mobilized by dividing its normal attachments to the spleen and diaphragm. Crucial elements of this procedure include creation of a loose wrap 1 to 2 cm in length, provision of an adequate length of intra-abdominal esophagus, and secure closure and reinforcement of the diaphragmatic crural fibers behind the esophagus to prevent postoperative hiatal hernia. This procedure can be performed with similar results using either traditional open or minimally invasive techniques.

There is little controversy that Nissen fundoplication provides excellent control of GER in children, as assessed by symptom relief or quantitative pH measurement. The rate of complications, however, is more difficult to ascertain. Most postoperative complications are associated with symptoms of recurrent reflux or excessive resistance. The most common serious complication of fundoplication is hiatal herniation of the wrap, the incidence of which ranges between 3% and 10% in unselected studies to between 10% and 20% in neurologically impaired children.[57,88] Hiatal hernias occur when increased intra-abdominal pressure is transmitted to the wrap, which pushes up through the crural repair. Patients with hypertonia, spasticity, seizure disorders, constipation, and reactive airway disease may all be at risk for this complication. The wrap may also be pulled up into the chest by negative intrathoracic pressure, a congenitally short esophagus, and an intrinsically weak crural mechanism. These conditions exist in neonates with congenital hiatal hernia, esophageal atresia, and diaphragmatic hernia. The rate of wrap dehiscence is negligible in virtually every contemporary series. When recurrent GER occurs after antireflux surgery, hiatal hernia of the wrap is the most likely underlying problem.

The other main complication of fundoplication is dysphagia and gas-bloat syndrome, in which the patient is unable to relieve gastric distention by vomiting or belching. These occur when an over-tight wrap generates excessive resistance to flow in either direction. This complication should be minimal when a loose, "floppy" wrap is constructed. The goal of surgery is not to prevent all reflux but to reduce reflux to near-physiologic levels.

A major contributing factor to wrap herniation, wrap failure, and gas-bloat syndrome after fundoplication is delayed gastric emptying, which results in a distended stomach under increased pressure. Delayed gastric emptying results from dysfunction of the autonomic and enteric nervous systems, and it occurs frequently in patients with profound neurologic compromise and those with diffuse metabolic disorders. Diagnosis can be best made by radionuclide imaging, and treatment includes pyloroplasty at the time of fundoplication.[3]

In certain patients, a circumferential, fully competent fundoplication can be predicted to cause dysphagia and gas-bloat syndrome. Patients shown to have severe esophageal dysmotility may achieve a better clinical result with a partial fundoplication. The Toupet fundoplication, which includes a posterior partial wrap, and the Thal fundoplication, which includes an anterior imbrication of the fundus over the GE junction, are both less effective than the Nissen fundoplication at reducing reflux but produce less resistance and dysphagia. Careful preoperative patient selection should determine the most appropriate surgical option on an individualized basis.

ABDOMINAL ANOMALIES

Abdominal Wall Defects

The most common abdominal wall defects seen in neonates are omphalocele and gastroschisis, occurring in approximately 4 per 10,000 live births. These conditions result from different developmental miscues and manifest as distinct clinical entities. In the case of omphalocele, a central abdominal wall defect of variable size is covered by a domelike mesenchymal membrane composed of amnion. The umbilical cord connects to the central portion of this membrane (Fig. 47-12). The underlying abdominal organs are protected from exposure to amniotic fluid. In gastroschisis, the defect is usually smaller and located to the right of the umbilical attachment. There is no protective membranous covering. The abdominal contents, therefore, are eviscerated and suspended in amniotic fluid during gestation (Fig. 47-13).

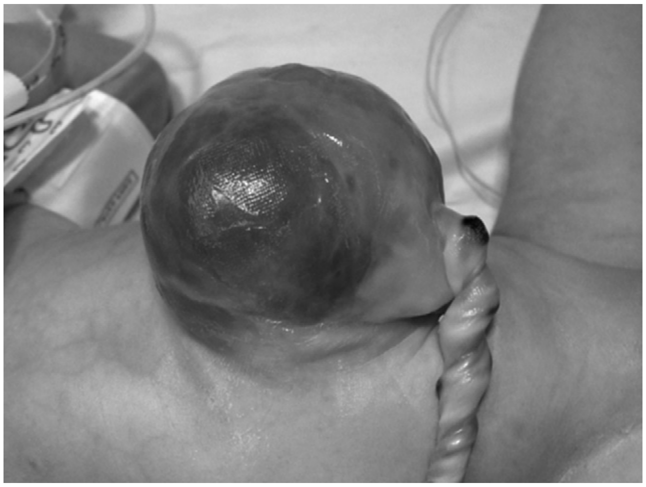

Figure 47–12. Typical medium-size omphalocele.

Omphalocele results from a failure in the folding mechanism that converts the flat trilaminar germ disc into a complex "tubular" structure starting at about 5 weeks' gestation. The lateral body folds and craniocaudal folds converge at the umbilical ring, which contracts, closing the ventral abdominal wall. In patients with omphalocele, this ring fails to contract and leaves a round defect of variable size and a corresponding sac composed of amnion. The liver and small intestine usually occupy a portion of the sac, along with a variable amount of other abdominal contents. The underlying failure of umbilical ring closure may be related to aberrant development and migration of abdominal wall muscular components, or to failure of the developing midgut to return to the abdominal cavity after a period of herniation into the umbilical stalk. Rarely, the defect is cephalad to the umbilicus, producing a complex deformity referred to as the

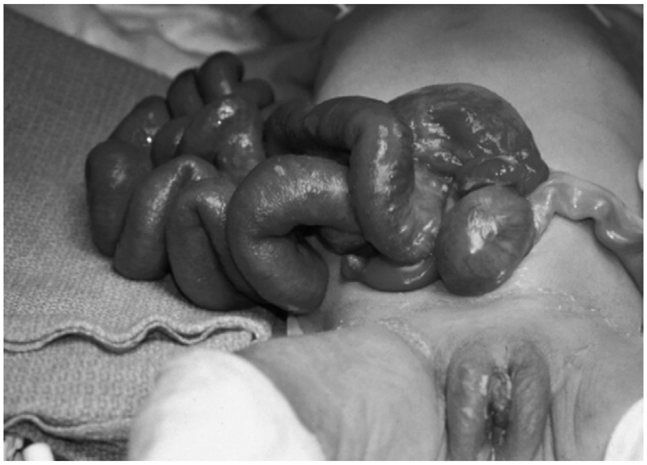

Figure 47–13. Typical gastroschisis defect with mild "peel."

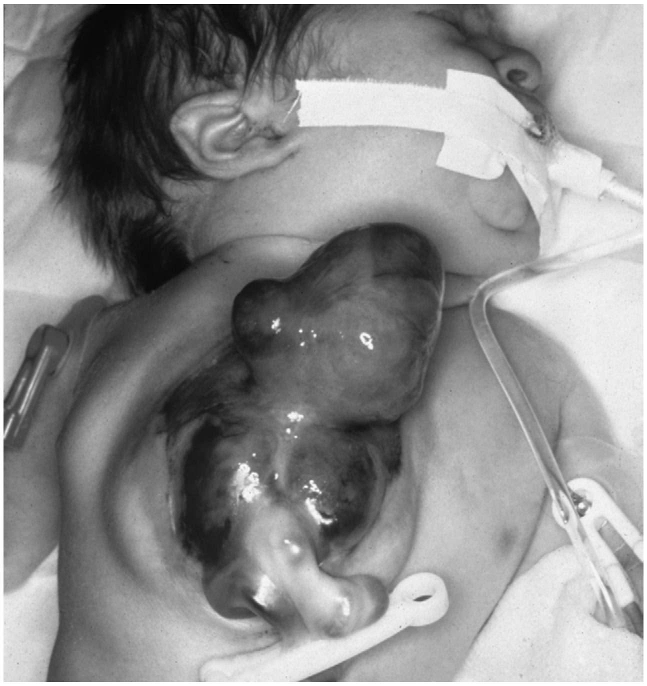

Figure 47–14. Pentalogy of Cantrell.

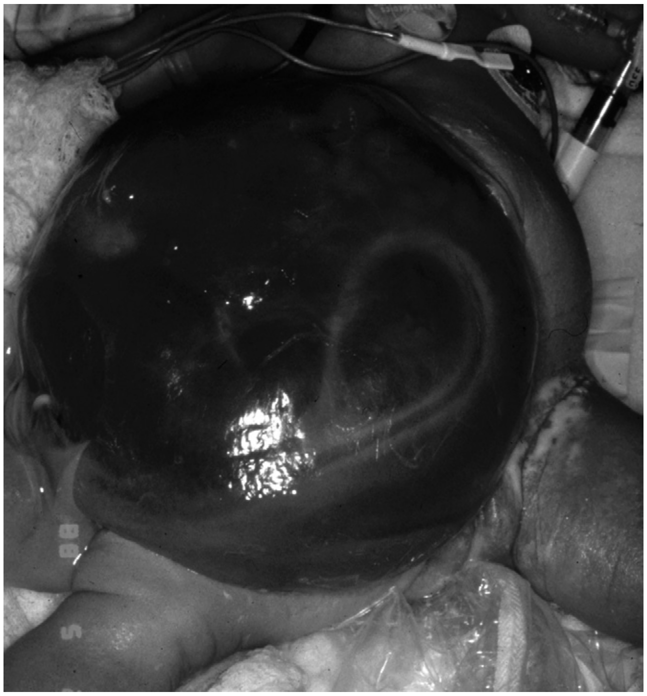

Figure 47–15. Giant omphalocele with predominate liver component.

pentalogy of Cantrell: sternal, diaphragmatic, and pericardial defects, upper abdominal omphalocele, and ectopia cordis (Fig. 47-14). When centered below the umbilicus, bladder or cloacal exstrophy may occur. The cause of gastroschisis is equally unclear, but it may involve a rupture of the umbilical stalk during the period of midgut herniation. Competing theories involving thromboembolic infarction of the developing abdominal wall or a failure of mesenchymal migration are less convincing.

The factors influencing morbidity and survival in these two distinct conditions are very different. Omphalocele, with a stable incidence of about 2 to 2.5 per 10,000 live births, is associated with other structural or genetic defects in 50% to 75% of affected infants.[13] These associated anomalies, which may involve the cardiovascular, gastrointestinal, genitourinary, or central nervous systems, account for most of the morbidity in these patients. Because the abdominal contents are protected throughout gestation, little morbidity accrues from injury to the intestinal tract. The discrepancy between the volume of eviscerated abdominal organs and the size of the abdominal cavity—the "loss of domain"—accounts for the other major source of morbidity in these patients. In a giant omphalocele, eventual closure of the abdominal wall by any means may be challenging, leading to a variety of problems related to structural integrity of the torso, chronic ventral hernias, and posture and gait development (Fig. 47-15). Additionally, infants with giant omphaloceles may have a high incidence of pulmonary hypoplasia, resulting in respiratory compromise and pulmonary hypertension.[5]

The syndromes most often associated with omphalocele include the VACTERL association, Beckwith-Wiedemann syndrome (macrosomia, macroglossia, visceromegaly, hemihypertrophy, hypoglycemia, renal pathology), EEC syndrome (ectodermal dysplasia, ectrodactyly, cleft palate), and OEIS complex (omphalocele, exstrophy, imperforate anus, spinal defects). An oft-reported association of omphalocele with cryptorchidism is unsubstantiated. Chromosomal abnormalities, including trisomies 13, 18, and 21, occur in 25% to 50% of affected patients. The presence of a small sac, the absence of liver in the sac, and the presence of other malformations strongly predict an abnormal karyotype.[18,26]

Gastroschisis, in contrast, is sporadic in the vast majority of cases. The incidence of gastroschisis is approximately 1.5 per 10,000 live births and increasing. Risk factors for gastroschisis include young maternal age, lower socioeconomic status, and exposure to external agents such as vasoconstricting decongestants, nonsteroidal anti-inflammatory agents, cocaine, and possibly pesticides/herbicides.[29,102] The 5% to 20% incidence of associated defects is lower than for omphalocele, and it represents mostly intestinal atresias directly associated with ischemic or mechanical injury to the eviscerated bowel during gestation. Abnormalities not directly related to the abdominal wall defect are uncommon.

Morbidity in infants with gastroschisis, as opposed to those with omphalocele, is almost entirely related to intestinal dysfunction caused by in utero injury to the eviscerated bowel. The spectrum of injury displayed by the eviscerated bowel in gastroschisis ranges from mild to catastrophic. Morphologically, the bowel appears edematous, matted, and foreshortened. Often, the mass appears to be contained within an inflammatory rind—the "peel" of gastroschisis (Fig. 47-16). Histologically, the intestine is characterized by villous atrophy and blunting, submucosal fibrosis, muscular hypertrophy and hyperplasia, and serosal inflammation.[51,98] The cause of injury is unclear, but it is probably related to a combination of two separate insults. Exposure to amniotic fluid appears to be a major contributing

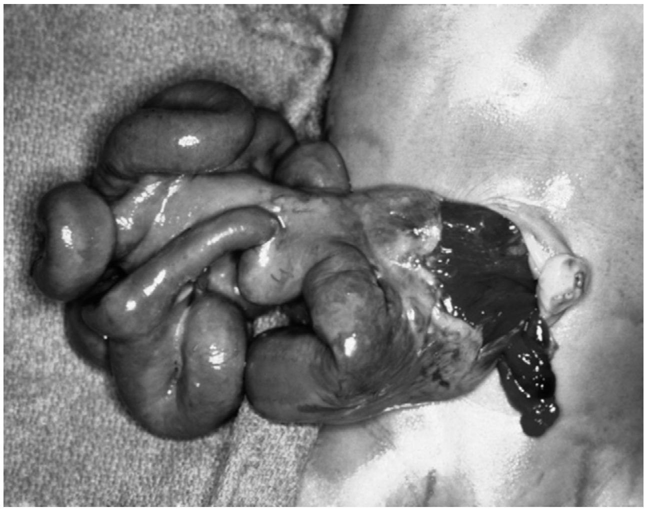

Figure 47–16. Gastroschisis with moderately severe peel.

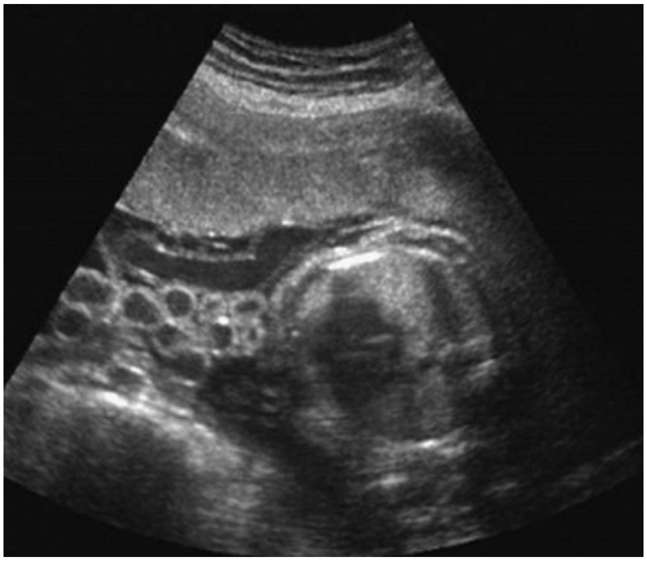

Figure 47–17. Ultrasound of fetus with gastroschisis.

factor, as amniotic fluid exchange can prevent peel formation.[2] The second cause of injury may be the partial closure of the defect around the base of the eviscerated intestinal mass. This causes progressive constriction around the intestinal mesentery, resulting in the obstruction of luminal, lymphatic, and venous outflow.

The functional consequences of these structural changes include impaired absorption, reduced brush border enzyme synthesis, and a prolonged motility disorder related to rigidity of the bowel wall and possible derangements in the production of enteric neurotransmitters such as nitric oxide.[6] These changes concur with the clinical observation that infants with a dense peel suffer prolonged gastrointestinal dysfunction that requires precise nutritional management. This nutritional failure and the complications arising from prolonged enteral and parenteral nutritional therapy constitute a significant proportion of the adverse clinical outcomes in these patients.

The prenatal diagnosis of abdominal wall defects by fetal ultrasonography is well established (Fig. 47-17). Any uncertainty in distinguishing omphalocele from gastroschisis may be eliminated by measuring amniotic fluid α-fetoprotein levels, which should be elevated in gastroschisis only. A prenatal diagnosis of omphalocele should prompt a thorough sonographic survey of the entire fetus to evaluate for associated anomalies. Chromosomal analysis may also be helpful in determining postnatal management and prognosis.

The obstetric decisions related to timing and route of delivery continue to engender considerable debate. In the case of omphalocele, if the membrane is intact, the pregnancy should be carried to term if possible, as early delivery has no theoretical benefit for the fetus. Cesarean delivery has historically been recommended to prevent rupture of the omphalocele membrane, which would necessitate emergent surgical intervention without the benefit of preoperative evaluation and stabilization. Studies, however, have suggested that the route of delivery has no effect on morbidity or prognosis in abdominal wall defects in general.[4,37,84] Recommendations regarding the route of delivery for a fetus with a giant omphalocele or associated anomalies should be individualized.

In gastroschisis, the belief that prolonged exposure of the eviscerated intestine to amniotic fluid and progressive mechanical constriction causes intestinal injury has led to the proposal that early delivery and repair might improve intestinal function and reduce morbidity. Early delivery after lung maturation has been enthusiastically endorsed by some, but definitive evidence that this strategy confers any statistically verifiable benefit is lacking. A more selective approach in which early delivery is undertaken when sonographic surveillance suggests progressive bowel injury, as defined by bowel dilation and wall thickening, has yielded numerous conflicting reports.[38,62] Until the efficacy of selective early delivery for gastroschisis has been studied in a prospective, randomized fashion, support for this intuitively appealing strategy will remain anecdotal. Serial amniotic fluid exchange in gastroschisis with oligohydramnios has been reported to reduce bowel injury, but this has not been subjected to a large scale randomized study.[19] Regardless of the timing of delivery, almost all infants with gastroschisis may be delivered vaginally without increased injury to the bowel.

The surgical goal of establishing complete fascial and skin closure without causing further injury to the underlying bowel is common to patients with both omphalocele and those with gastroschisis. The surgical strategies applied to these two conditions are, however, quite different. In patients with gastroschisis, emergent closure or coverage of the defect is of the highest priority to limit intestinal injury and reduce morbidity. The eviscerated intestine should be completely covered in the delivery room to prevent water and heat loss through evaporation, conduction, and convection. Temporary coverage can be provided by wrapping the torso with transparent plastic film or by placing the baby in a transparent surgical "bowel bag" and cinching the drawstring closed gently under the axillae. This arrangement effectively limits heat and water loss, and it allows the intestine to be visualized at all times so that inadvertent volvulus and ischemia can be detected and reversed. A lateral decubitus position is often better tolerated than supine. A gastric decompression tube is placed immediately to prevent intestinal dilation.

Many infants with gastroschisis are born prematurely, and aggressive respiratory care including supplemental oxygen, endotracheal intubation, and intratracheal surfactant may be necessary. Intravenous access is established for fluid resuscitation and administration of broad-spectrum antibiotics. As soon as the baby is physiologically stable, transport to the operating room for surgical management is advisable. Unnecessary delay only compounds the problems of further bowel swelling and possible ischemia.

Gastroschisis can be managed by either primary or staged closure, depending on the size discrepancy and the infant's physiologic status. Although 60% to 70% of gastroschisis cases can be closed primarily, the decision to do so is individualized in each circumstance. As the intestine is returned to the abdominal cavity and the abdominal fascia approximated, increased abdominal pressure may prevent safe, complete closure. In infants with preexisting pulmonary compromise, the restriction of diaphragmatic excursion may decrease extrinsic compliance and cause ventilatory pressures to rise to unacceptable levels. Increased abdominal pressures may also impair mesenteric, hepatic, and renal perfusion. Intraoperative monitoring of abdominal pressure by connecting a bladder catheter to a pressure transducer can provide useful information.

When respiratory problems or abdominal pressures prevent safe primary closure, placement of a temporary prosthetic "silo" allows for more gradual reduction of the eviscerated intestine into the abdominal cavity and delayed primary closure at a later time (Fig. 47-18). Previous retrospective studies had documented improved survival with primary closure, prompting an era marked by an aggressive approach to immediate closure. Appreciation of the fact that this survival advantage simply represented a selection bias, along with recognition of the deleterious effects of high intra-abdominal pressures, has led to a more liberal use of temporary silo coverage. Usually, the fascial opening is extended to produce a broad-based defect, and a cylinder of reinforced silicone or other nonporous material is sutured to the fascial rim. Many surgeons have abandoned the use of traditional handmade silos in favor of prefabricated silos that consist of an elongated prosthetic bag with an elastic, springlike base. These silos can be installed without sutures and may be placed in the delivery room, obviating an emergent trip to the operating room.

When a silo has been constructed, the intestinal contents are squeezed back into the abdominal cavity in daily increments. Abdominal wall cellulitis related to the open wound and presence of the prosthetic material limits the use of a silo to a period of approximately 2 weeks. When reduction of the silo contents is complete, the patient is returned to the operating room for final closure (Fig. 47-19). Broad-spectrum antibiotics are given until the silo is removed. Placement of a silo does not preclude postoperative extubation, and spontaneous ventilation during staged closure is preferable to positive-pressure ventilation. Infants should be maintained on a ventilator to allow for neuromuscular paralysis in only the most severe cases of abdominovisceral disproportion requiring aggressive closure. When postoperative mechanical ventilation is required, increased levels of positive end-expiratory pressure are necessary to maintain functional residual capacity and optimize compliance.

During staged closure, parenteral nutrition is administered through a peripherally inserted central venous catheter, or one placed at the time of silo placement. Complete bowel rest and gastric decompression are maintained during reduction of the silo. After abdominal wall closure, whether primary or delayed, enteral feedings should be initiated only after clinical resolution of the ileus is apparent—cessation of bilious gastric aspirates, presence of bowel sounds, and passage of meconium. Advancement of enteral feedings should be conservative, as infants with gastroschisis, especially those with a dense peel requiring silo closure, are extremely sensitive to changes in nutritional substrate load. Delayed enteral feedings and prolonged parenteral infusions are a principal

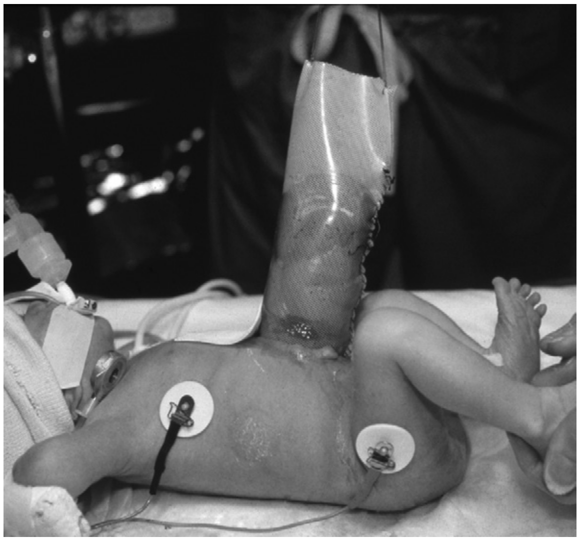

Figure 47–18. Silastic "silo" for delayed primary closure of abdominal wall defects.

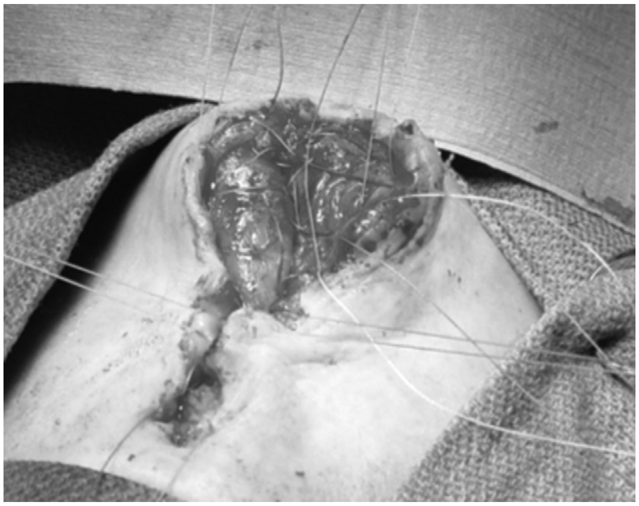

Figure 47–19. Final reduction and closure of abdominal wall defect after silo reduction.

source of morbidity in this group. Development of cholestatic jaundice is common, and hepatic dysfunction and fibrosis may occur in a small number of refractory patients. Early administration of partial enteral mini-feedings, meticulous avoidance of infection, and reduction of copper and manganese have all been advocated to reduce the incidence of cholestatic liver disease.[59]

The coexistence of intestinal atresias with gastroschisis deserves special mention. Intestinal atresias occur in 5% to 25% of patients with gastroschisis, and they are one of several independent variables that have a negative impact on prognosis in gastroschisis. They are commonly felt to be related to vascular compromise caused by in utero constriction on the intestinal mesentery, although this relationship has been cited by some as supportive evidence for a thromboembolic etiology for both conditions.[112] When atresias are recognized at the time of surgery, options include primary anastomosis if no peel exists and a straightforward abdominal closure is anticipated, or simple internalization of the uncorrected atresia if a peel exists or staged closure is necessary.[89] This is then followed by later reexploration and repair after the peel resolves in several weeks. Construction of an enterostomy in the presence of a silo is associated with an increased incidence of abdominal wall infectious complications.[30] In a patient who fails to exhibit intestinal patency within 2 weeks of abdominal wall closure, a water-soluble lower gastrointestinal contrast study should be obtained to exclude the presence of an unrecognized atresia.

The surgical options for abdominal wall closure for omphalocele are similar to those for gastroschisis. The main difference relates to the preoperative management of these patients. A careful assessment of physiologic status and a thorough search for syndromic and chromosomal anomalies is imperative to guide anesthetic management and to identify prognostic factors. The presence of a protective membrane allows a careful and unhurried preoperative evaluation. Small rents in the membrane may be sutured at bedside to maintain this elective posture. In some cases, neither primary nor staged closure is appropriate. These include cases associated with lethal anomalies, patients with profound cardiac compromise, those with severe pulmonary hypoplasia or pulmonary hypertension, and those with giant omphaloceles with no hope for autogenous tissue closure. In these circumstances, nonoperative management may be used. The membrane is preserved and treated by topical application of an antimicrobial agent such as silver sulfadiazine, allowing slow epithelialization of the amnion. This results in durable coverage and a chronic ventral hernia. If the patient survives the short-term medical challenges, removal of the amnion and placement of a prosthetic patch with overlying skin closure allows for gradual stepwise reduction of the patch and eventual abdominal wall closure later in childhood.

As defined previously, the factors affecting prognosis for gastroschisis and omphalocele are quite distinct. Prematurity, degree of peel formation, and associated atresias account for most of the morbidity in gastroschisis, which has an overall survival rate of 90% to 95%.[33,66] Most of the deaths attributed to gastroschisis are related to perioperative complications, such as sepsis, necrotizing enterocolitis, and abdominal visceral ischemia, or to late hepatic failure caused by parenteral nutrition-related cholestatic disease. Surprisingly, midgut volvulus related to obligatory intestinal malrotation in these patients is virtually nonexistent, possibly because of the development of peritoneal adhesions that limit mobility of the intestine. The reported survival rate for infants with omphalocele ranges from 30% to 80%.[65,113] When mortality caused by associated malformations is excluded, the survival rates approach those for gastroschisis. Long-term tolerance of enteral feedings, as well as physical growth and development, are usually normal after 1 or 2 years, even in severe cases. With thoughtful management and attention to the prevention of parenteral nutrition-related hepatic complications, most infants born with abdominal wall defects should survive with an acceptable quality of life.

GASTRIC VOLVULUS

Congenital deficiencies of mesenteric fixation of the stomach to the surrounding structures predispose to gastric volvulus and can take two distinct forms. Absence or laxity of the gastrohepatic and gastrosplenic ligaments allows the stomach to rotate around its longitudinal axis, producing an organoaxial volvulus. Similar abnormalities of the gastrophrenic ligament and duodenal attachments allow rotation around the stomach's transverse axis, referred to as a *mesentericoaxial volvulus*. Organoaxial volvulus is the more common of the two types in infants and children. A strong association has been found between gastric volvulus and malrotation, asplenia, and congenital abnormalities of the diaphragm.[58] Gastric volvulus may also be associated with conditions that result in gastric distention, such as aerophagia and hypertrophic pyloric stenosis. Because these entities all result in absence or stretching of stabilizing attachments, a causative role is assumed.

Although gastric volvulus can occur as either an acute or a chronic problem, the acute form is more common in children. The classic presentation of sudden epigastric pain, retching without emesis, and inability to advance a nasogastric tube into the stomach is rarely encountered in the actual clinical setting. Children may experience emesis, which can be bilious or nonbilious, and may not have abdominal distention. Intermittent gastric volvulus may be considered in the workup of infants presenting with apparent life-threatening events.[68] Any combination of symptoms suggesting a partial or complete proximal mechanical obstruction may be present. Profound physiologic decompensation, hemodynamic instability, or unrelenting metabolic acidosis suggests strangulation, ischemic necrosis, and possibly perforation.

Radiologic assessment can reveal several characteristic findings. On plain abdominal radiographs, massive gastric dilation can usually be seen, often with a distinct incisura pointing toward the right upper quadrant. The spleen and small intestine may be displaced inferiorly. If a contrast study has been attempted, the contrast column may be confined to the esophagus, with a long, gradual tapering at the bottom. Occasionally, a paraesophageal hiatal hernia is detected. Classic findings on barium upper gastrointestinal study include transverse lie of the stomach and inversion of the greater curvature and pylorus (Fig. 47-20). Operative treatment of acute gastric volvulus includes gastric decompression by nasogastric suction or needle aspiration and reduction of the volvulus. Perforations are closed primarily or, depending on

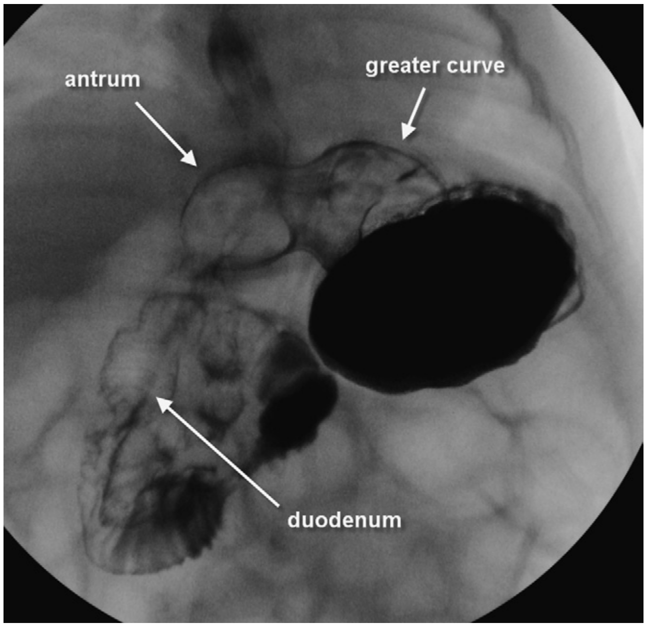

Figure 47–20. Upper gastrointestinal contrast study demonstrating gastric volvulus with rotation of the greater curve and antrum of the stomach above the duodenal bulb.

their location, around a Malecot tube; more extensive necrosis requires resection. Coexisting anomalies, such as malrotation and diaphragmatic defects, should be corrected. Recurrent volvulus is prevented by performing an anterior gastropexy. Historically, a Stamm-type gastrostomy has been used to increase stability of the gastropexy by creating a fibrotic scar that traverses all layers of the abdominal and gastric walls, although there are no data that suggest this is mandatory. Both laparoscopic and open approaches are effective. Recurrence is rare.

MICROGASTRIA

Congenital microgastria is a rare anomaly in which the stomach is characterized by very small volume, a tubular shape, and abnormal fixation. Gastric volume does not undergo complete compensatory growth and remains relatively small as the child ages.[8] Associated abnormalities include megaesophagus, GER, intrinsic duodenal obstruction, malrotation, biliary anomalies, situs inversus, asplenia, and skeletal defects.

Microgastria presents with vomiting and failure to thrive in the infant, often associated with persistent diarrhea. Vomiting may be due to gastric insufficiency, GER, or duodenal obstruction. Diarrhea is presumed to be due to rapid gastric transit and dumping. The diagnosis is established by contrast upper gastrointestinal tract study, which reveals a small stomach with a transverse lie and frequently a large, patulous esophagus (Fig. 47-21). Particular attention should be given to the anatomy of the duodenum and the ligament of Treitz.

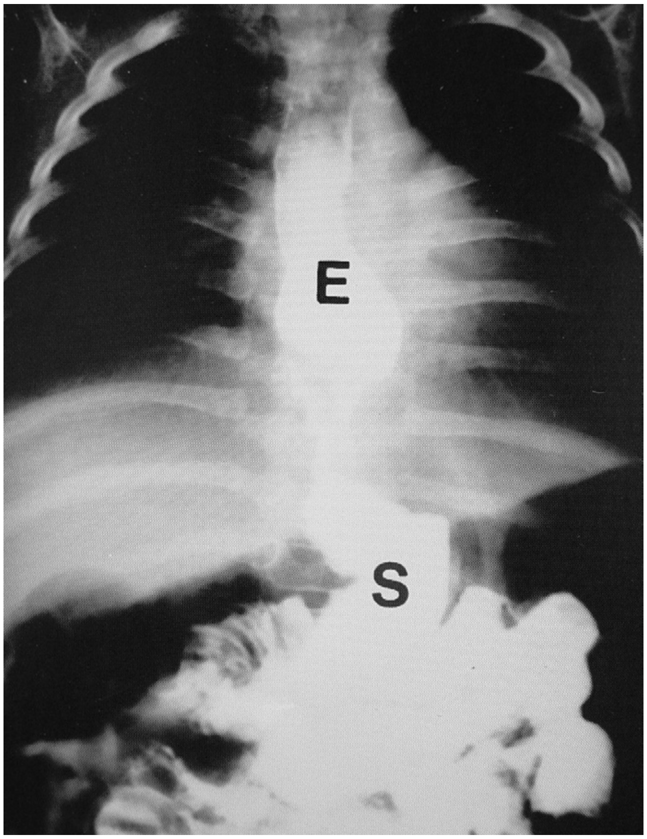

Figure 47–21. Upper gastrointestinal contrast study of patient with microgastria (S) and megaesophagus (E).

The initial management of microgastria includes continuous drip enteral feeding and supplemental parenteral nutrition. When continuous feedings can be maintained for several weeks, the stomach may undergo some enlargement, allowing for a gradual transition to bolus and ad libitum feedings. Antireflux precautions, including small frequent meals, may be required indefinitely. Although case reports of successful management by gastrojejunostomy exist, the favored surgical approach involves gastric augmentation with a Roux-en-Y jejunal reservoir.[108]

GASTRIC PERFORATION

The causes of gastric perforation in neonates can be categorized as traumatic, ischemic, or spontaneous.

In addition, the use of postnatal steroids for bronchopulmonary dysplasia (possibly in combination with cyclooxygenase inhibitors for ductal closure) has been implicated (see Chapter 44). Traumatic perforations are generally caused by puncture of the stomach during placement of a gastric tube, or by gastric distention from bag-mask ventilation or positive-pressure ventilation in an infant with a tracheoesophageal fistula. Usually, these appear as short lacerations or discrete puncture wounds. Ischemic perforations occur in the setting of severe physiologic stress, such as extreme prematurity, perinatal asphyxia, or necrotizing enterocolitis. The pathophysiology of these lesions is presumed to be associated with a reduction in submucosal blood flow resulting in impaired mucosal defense and/or focal infarction of the gastric wall. It is possible that some of these lesions represent perforated stress ulcers. Rarely, a healthy neonate presents with a spontaneous gastric perforation of unknown cause. The most common location is high on the greater curvature near the gastroesophageal junction.

The most constant diagnostic feature of gastric perforation in the neonate is massive pneumoperitoneum, unless the perforation is posterior and contained within the lesser sac. Surgical management is individualized to either simple débridement and closure, or closure around a temporary gastrostomy tube. Extensive gastric resections have not been necessary. Outcomes depend on the cause of the perforation and any associated disease, such as respiratory failure and complex congenital malformations. Reported mortality rates of 50% to 60% have changed little over the last two decades.[40,71]

LACTOBEZOARS

Lactobezoars are compact aggregations of undigested milk constituents that develop within the gastric lumen in infants. Little is known about their underlying cause, although a single etiology is unlikely. Historically, they were believed to result from commercial formulas of high caloric density, particularly those rich in casein protein, which precipitated in the stomachs of premature neonates. Lactobezoars, however, have been reported in term neonates and older infants on diets of human milk and homogenized cow milk.[86,105]

The majority of infants with lactobezoars present with abdominal distention, nonbilious emesis, and diarrhea. A palpable mass may be detectable on physical examination. Plain radiographs often display a frothy appearance in the gastric lumen. An upper gastrointestinal tract contrast series is diagnostic. Ultrasonography, which can detect a hyperechoic intraluminal gastric mass, may also be used to establish the diagnosis.[63] Treatment is nonsurgical in the great majority of patients who do not present with perforation. Simple withholding of enteral feedings and administration of parenteral nutrition usually results in spontaneous resolution of the bezoar; gastric lavage may hasten this process.[21] After follow-up imaging studies document resolution, enteral feedings can be reinstituted using the same formula. Recurrence has not been reported.

PYLORIC ATRESIA

Congenital partial or complete gastric outlet obstructions are rare causes of feeding intolerance in infants. The obstruction may involve either the antrum or the pylorus and may take the form of a segmental defect (gap), which is sometimes bridged by a fibrous cord, or a membrane (web), which can have one or more apertures through which gastric contents pass. Histologically, such membranes consist of mucosa and submucosa without a muscularis. Prepyloric membranes become redundant after exposure to antegrade propulsive pressures, creating a “windsock” web that can prolapse through the pyloric channel. Pyloric webs account for two thirds of these obstructions, pyloric atresia accounts for about a quarter, and most of the remainder are antral webs and atresias. Another, rare cause for the obstruction is the presence of ectopic pancreatic tissue within the submucosa of the pyloric channel that bulges into the lumen and causes a partial obstruction.

The etiology of antral and pyloric atresia is not understood. An in utero vascular accident, such as results in jejunoileal atresias, is unlikely because of the stomach’s redundant blood supply. As the stomach (unlike the duodenum) does not undergo a solid embryonic phase, failure of recanalization cannot account for these anomalies. Instead, some form of foregut segmentation mechanism is proposed but unproved. A genetic cause has been identified for some cases of pyloric atresia that occur in association with epidermolysis bullosa lethalis (Herlitz and Carmi syndromes), which is inherited in an autosomal recessive manner. A hemidesmosome defect has been identified in the gastric mucosal epithelium in this syndrome, and genetic studies have documented a variety of mutations in the genes coding for cell-surface beta 4 integrins.[64] This condition is marked by extreme mucocutaneous fragility and is usually lethal in the first year of life.

Complete membranes or atresias appear in the first few days of life as acute gastric outlet obstruction with nonbilious vomiting. There is often a history of maternal polyhydramnios. Gastric distention leading to respiratory compromise can occur, and frank gastric perforation has been reported as early as 12 hours of life. Incomplete gastric outlet obstruction due to perforated membranes or heterotopic pancreatic tissue can present early in the neonatal period or later in childhood. Radiologic evaluation reveals a large gastric air bubble, with little or no gas in the distal intestine (Fig. 47-22). Because neonatal gastric hypotonia can reproduce these radiographic

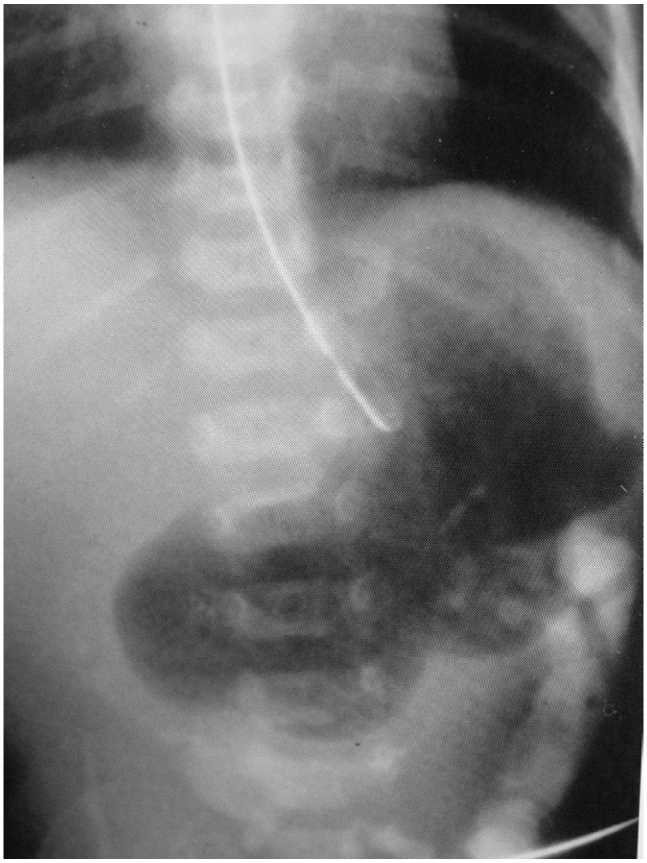

Figure 47–22. Plain radiograph of gastric bubble in patient with pyloric atresia.

findings, upper gastrointestinal tract contrast studies are mandatory. These studies either show nonfilling of the duodenum or delineate the membrane when viewed laterally. Ectopic pancreatic tissue can cause an eccentric protrusion into the pyloric channel.

Preoperative resuscitation and gastric decompression are necessary in infants with complete gastric outlet obstruction. A chloride-responsive contraction alkalosis is often seen and requires specific measures to restore fluid volume and correct chloride and potassium deficits. Prolonged vomiting in the neonate can also lead to profound hypoglycemia, which must be anticipated and corrected. In general, webs can be excised and closed transversely to avoid stenosis. Complete atresias with anatomic disconnection can usually be corrected by primary anastomosis, such as gastroduodenostomy. Gastrojejunostomy is poorly tolerated in the neonate and should be avoided whenever possible. Recognition of windsock deformities and distal atresias by passage of a balloon catheter proximally and distally can be helpful in defining the exact anatomy and in detecting additional distal obstructions. Ectopic pancreatic tissue in the pylorus requires excision of the mass and reconstruction of the pylorus.

HYPERTROPHIC PYLORIC STENOSIS

Hypertrophic pyloric stenosis (HPS) is an acquired condition in which the circumferential muscle layer of the pyloric sphincter becomes thickened, resulting in narrowing and elongation of the pyloric channel. This produces a high-grade gastric outlet obstruction with compensatory dilation, hypertrophy, and hyperperistalsis of the stomach. The incidence of HPS ranges between 0.1% and 1% in the general population and appears to be rising. A longitudinal study using ultrasound in 1400 randomly selected term neonates documented that all nine infants (0.65%) in whom HPS later developed had normal pyloric dimensions at birth.[83] There is a significant male predominance of about 4:1, although the long-held belief that HPS primarily afflicts first-born males is unproven. The incidence in whites exceeds that in blacks by severalfold; the incidence in Asian infants is low. The transmission of HPS appears to involve multifactorial threshold inheritance or the effects of multiple interacting loci. Transmission from mothers is more common than from fathers: HPS develops in 19% of boys and 7% of girls whose mothers had HPS as infants, and in 5% of boys and 2.5% of girls whose fathers were previously affected.[61]

The cause of HPS remains unknown. One hypothesis is that dyscoordination between gastric peristalsis and pyloric relaxation results in simultaneous gastric and pyloric contraction and work hypertrophy of the pyloric muscle.[41] This initiates a cycle of escalating pyloric resistance and gastric hyperperistalsis. Although functional disturbances in gastric emptying in the first weeks of life have not been proven to occur in neonates in whom HPS later develops, a report of in utero gastric dilation in a neonate who later developed HPS suggests a possible role for prenatal gastric emptying dysfunction. An association between maternal and infant exposure to erythromycin and the development of HPS has been identified, and a causal link has been postulated.[28,56,76,90] Erythromycin stimulates phase III migrating myoelectric complex activity and may expose the immature pylorus to markedly elevated gastric pressures.

The pathophysiology underlying pyloric dysfunction in HPS is undetermined. Observations of decreased ganglion cell density and elevated levels of prostaglandins E_2 and F_2 have not been causally linked to the development of HPS. Gastric outlet obstruction due to pylorospasm has been reported in neonates receiving prostaglandin infusions, but pyloric dysfunction in these infants does not lead to muscular hypertrophy.[60]

Perhaps a more promising hypothesis for the pathophysiology of HPS is a primary abnormality of the enteric nervous system (ENS). Axonal degeneration in both the myenteric plexus and the intramuscular nerves has been observed in patients with HPS. Studies have documented decreased and disordered innervation of the circumferential muscle layer in specimens of pyloric muscle taken at the time of pyloromyotomy.[45,50] Furthermore, the muscle layer in HPS appears to be nearly devoid of neurotrophins—peptides that govern differentiation and survival of ENS neurons.[32] Circumstantial evidence exists to suggest that such neural immaturity is transient, consistent with the observation that HPS does not recur after reconstitution of the pyloric sphincter after pyloromyotomy.[46] Immunohistochemical staining for neuropeptides has revealed a marked reduction in a variety of neuropeptides, such as gastrin-releasing peptide, vasoactive intestinal peptide, somatostatin, and substance P, in patients with HPS.[1] Nitric oxide synthase, which can be identified in significant concentrations in the circular and longitudinal pyloric muscle layers and the myenteric plexus in normal controls, has been shown to be selectively absent in the circular muscle layer in patients with HPS.[107] This has also been documented for nitric oxide synthase mRNA.[47] A deficiency of nitric oxide, a ubiquitous paracrine and neurocrine mediator of smooth muscle relaxation, might be a final common pathway in the dysregulation of pyloric function in HPS.

The typical patient is a term male infant between 3 and 6 weeks of age who has progressive, nonbilious, projectile vomiting. Many infants with HPS are significantly dehydrated at the time of presentation, and chemistry analyses may reflect a hypochloremic, hypokalemic, contraction metabolic alkalosis with paradoxical aciduria. Significant hypoglycemia can also be present and may precipitate seizures. Unconjugated hyperbilirubinemia is common and correlates with a decrease in hepatic glucuronyltransferase activity. This jaundice is transient and resolves as soon as the gastric outlet obstruction is corrected, making it attractive to speculate that the hepatic defect is secondary to abnormal enteroendocrine feedback between the stomach and the hepatocyte.

The hallmark of the diagnosis is the finding of a small, mobile, ovoid mass in the epigastrium. The process of detecting this mass, the “olive,” on examination may be quite difficult. A positive examination is very accurate, with a selectivity value of more than 97%.[28] If the pylorus is unequivocally felt, the diagnosis is established, and no further diagnostic maneuvers are necessary.

If the pylorus is not detected and the clinical presentation is sufficiently suggestive to warrant further evaluation, radiologic evaluation can be definitive. Real-time ultrasonography has supplanted barium upper gastrointestinal tract study as the procedure of choice. The hypertrophied pylorus appears to have a characteristic appearance on B-mode ultrasound, and measurement of pyloric dimensions accurately establishes the diagnosis of HPS. Parameters measured include overall diameter, single wall thickness, and pyloric channel length, with the latter two being the most commonly used (Fig. 47-23). Measurements found to have greater than 90% positive predictive value include overall diameter of 17 mm or more, muscular wall thickness of 4 mm or greater, and channel length of 17 mm or greater. In infants 30 days of age or younger, it has been suggested that diagnostic criteria for wall thickness be reduced to 3 mm. When parameters are equivocal, an upper gastrointestinal tract study can be diagnostic by demonstrating an elongated and narrowed pyloric channel, with the characteristic shoulders of the hypertrophied pylorus bulging into the gastric lumen. Although an accurate diagnosis based on physical examination should be possible in most cases, and should be attempted in all, it is evident that an increasing reliance on ultrasonography will continue to erode the skills of examiners. A review comparing diagnostic accuracy between two eras in a single pediatric institution found that the sensitivity of physical examination declined by half during a period of increasing reliance on ultrasound.[55]

Preoperative preparation is critical once the diagnosis is made. HPS is not a surgical emergency, so careful correction of fluid and electrolyte losses should be accomplished before operative intervention. The infant who presents early in the course of the disease with no clinical dehydration, normal serum electrolytes and glucose, and a normal urine output can be operated on at the earliest convenience. Many patients, however, present with dehydration, hypoglycemia, or a contraction alkalosis of sufficient severity to require preoperative resuscitation for 24 to 48 hours. Once volume status and urine output have improved, serum chloride, potassium, and bicarbonate have normalized, and paradoxical aciduria has resolved, surgery can be conducted safely.

The treatment of HPS is pyloromyotomy. Historically, the operation is performed through a transverse right upper quadrant incision. Over the past decade, the minimally invasive approach has gained widespread popularity (Fig. 47-24). The time to full feedings and discharge may be slightly shorter when the operation is done laparoscopically, and cosmesis is better.[25] Both approaches to pyloromyotomy are acceptable, and the choice of one or the other depends on individual factors and operator preference. In both approaches, the most common operative complication is inadvertent extension of the pyloromyotomy incision through the duodenal or gastric mucosa, resulting in a perforation. The reported rates of perforation range from 3% to 30%, although rates above 10% are unusual. If recognized at the time of surgery, the defect may be repaired primarily and the ramifications limited to a short delay in the resumption of feedings. A feeding regimen is begun 4 to 8 hours after operation with a small volume of sugar water, advancing volume and osmolarity every 2 to 3 hours until the infant is taking formula or breast milk ad libitum. It is common for occasional emesis to occur after pyloromyotomy; this should not delay the progression of the feeding schedule in most cases. In general, most infants so managed can be discharged within 24 to 48 hours of surgery.

Persistent postoperative vomiting beyond 48 hours is uncommon. In this circumstance, the possibilities of an incomplete myotomy or unrecognized perforation should be considered. Radiologic studies are of little value in evaluating the completeness of the myotomy because the fluoroscopic and sonographic appearances of the hypertrophied pylorus before and after myotomy are similar. A contrast study should be obtained to exclude a mucosal leak, which may produce a fluid collection that compresses the gastric outlet. In the absence of a leak or complete obstruction, an interval of at least 2 weeks is allowed to pass before the presumptive diagnosis of incomplete myotomy prompts reexploration.

Most children treated for HPS can expect excellent short- and long-term outcomes. With appropriate resuscitation, expert anesthesia, and a standard surgical approach, mortality

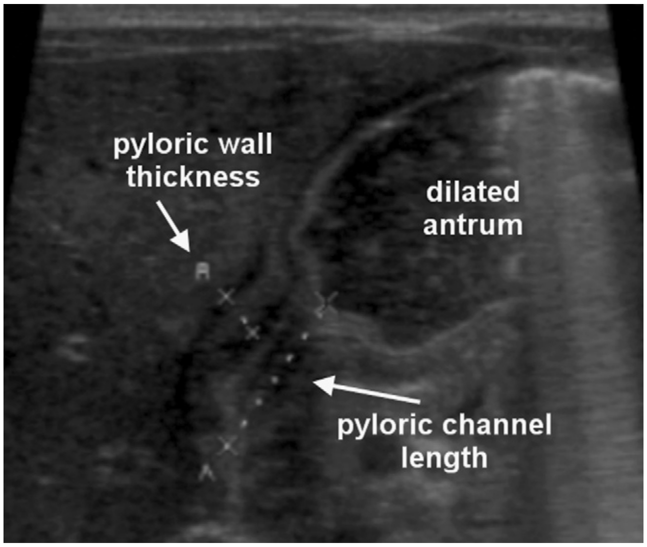

Figure 47–23. Abdominal ultrasound of patient with hypertrophic pyloric stenosis.

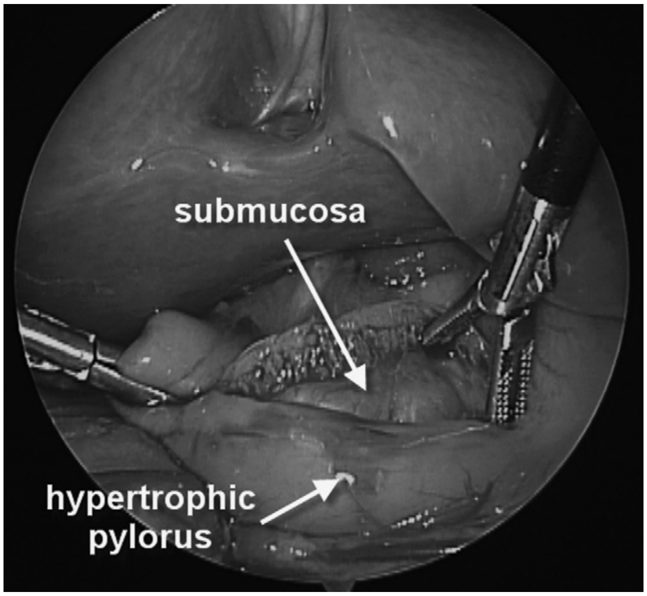

Figure 47–24. Laparoscopic pyloromyotomy.

has been virtually eliminated. Wound infection and dehiscence, significant problems in previous eras, are relatively uncommon today. Postoperative ultrasound studies have documented a return to normal muscle thickness within 4 weeks, associated with healing of the pyloric muscle and return of function. A study addressing gastric emptying and abdominal symptoms after pyloromyotomy found no differences between treatment and control groups several decades after surgery.[53]

DUODENAL ATRESIA AND STENOSIS

Congenital duodenal obstruction may be complete or partial, intrinsic or extrinsic. Intrinsic atresias or stenoses have an incidence of about 1 in 7000 live births and account for about half of all small intestinal atresias. Extrinsic obstruction has many causes, including malrotation with Ladd bands, preduodenal portal vein, gastroduodenal duplications, cysts or pseudocysts of the pancreas and biliary tree, and annular pancreas. Annular pancreas is commonly associated with an intrinsic cause of duodenal obstruction.

Intrinsic duodenal obstructions and annular pancreas result from events that occur during early development of the foregut. Duodenal atresia and stenosis are believed to result from a failure of recanalization of the embryonic duodenum, which becomes solid as a result of early epithelial proliferation. Annular pancreas occurs when the ventral pancreatic bud fails to rotate behind the duodenum, leaving a nondistensible ring of pancreatic tissue fully encircling the second portion of the duodenum.[100] Annular pancreas frequently coexists with intrinsic duodenal anomalies and anomalies of the pancreaticobiliary ductal system, suggesting closely linked mechanisms of pancreatic, duodenal, and biliary development during this stage.

Atresias of the duodenum have several basic morphologies. Type I atresias constitute luminal webs or membranes, some of which contain a central defect or fenestration of variable size, and result in a marked size discrepancy with mural continuity (Fig. 47-25). Type II atresias have dilated proximal and diminutive distal segments connected by a fibrous cord. Type III atresias are characterized by a complete discontinuity between the segments. The relationship between the point of obstruction and the ampulla of Vater is important. Most series document a predominance of postampullary obstructions, although some have described a preampullary predominance. Obstructions caused by type I membranes are frequently associated with anomalies of the common bile duct in which the common bile duct may terminate within the membrane itself.

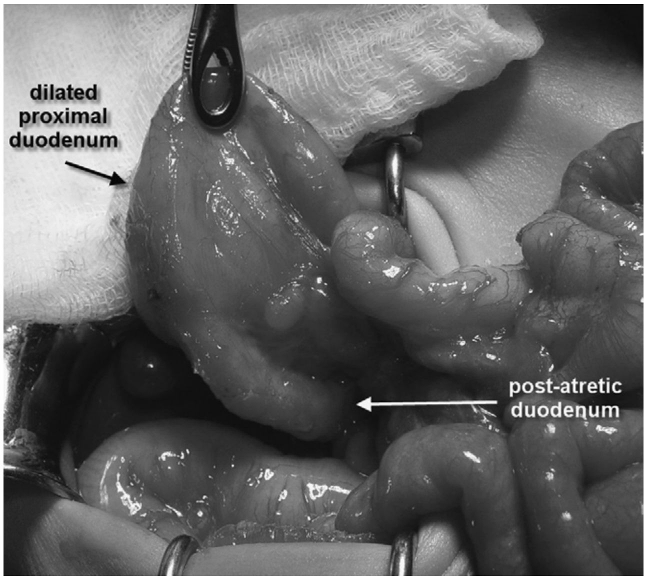

Figure 47–25. Type I duodenal atresia with continuity of muscular wall.

Congenital duodenal obstructions are often associated with other congenital anomalies, which account for most of the morbidity and mortality in these patients. Various reports put the incidence of associated conditions between 50% and 80%. Congenital heart disease and trisomy 21 are the most common associated conditions, each occurring in about 30% of cases.[31] Not infrequently, all three conditions coexist in the same patient.[23] Among patients with trisomy 21 who underwent prenatal ultrasonography, about 4% were found to have prenatal evidence of duodenal atresia.[67] Other associated anomalies include intestinal malrotation (20%), esophageal atresia, or imperforate anus (10% to 20%), thoracoabdominal heterotaxia, and gallbladder agenesis. The outcome for patients with duodenal atresia depends more on the severity of these associated anomalies and the ease with which they can be corrected than on the surgical management of the obstruction itself.

Many patients with duodenal atresia have the diagnosis suggested by prenatal ultrasonography. A maternal history of polyhydramnios is common in congenital duodenal obstruction, approaching 75% in one series.[92] Prenatal sonographic evaluation of the fetus at 22 to 23 weeks of gestation can reliably detect two dilated fluid-filled structures consistent with a double bubble. The unavailability of a sonographic diagnosis until relatively late in gestation frequently results in an ethical dilemma for prospective parents, who may consider elective termination based on the association of duodenal atresia with trisomy 21. Reliable data regarding the rate of false-positive examinations for duodenal obstruction in the fetus are unavailable.

The clinical presentation of the infant with congenital duodenal obstruction depends on the presence or absence of a membranous aperture, its size, and the location of the obstruction relative to the ampulla. The classic presentation of a complete postampullary obstruction includes bilious vomiting within 24 hours of birth in an otherwise stable infant with a nondistended abdomen. Plain radiographs of the abdomen typically show the classic double-bubble sign—two distinct gas collections or air-fluid levels in the upper abdomen resulting from the markedly dilated stomach and proximal duodenal bulb (Fig. 47-26). If the infant's stomach has been decompressed by vomiting or previous nasogastric aspiration, 30 to 60 mL of air may be injected carefully through the nasogastric tube and the double-bubble sign reproduced. Air makes an excellent contrast agent, obviating a barium or water-soluble contrast study in routine cases. The distal intestinal tract may be gasless or may contain a small amount of intraluminal air due to a membranous aperture or perforation, or an anomalous bile duct with openings on both sides of the obstructing diaphragm.[73]

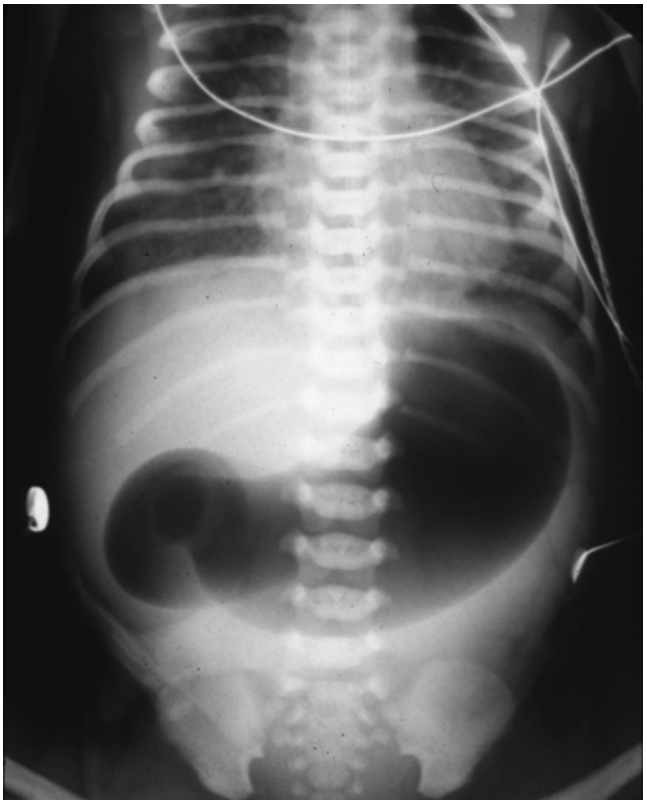

Figure 47–26. Plain abdominal radiograph in patient with duodenal atresia.

The importance of differentiating intrinsic duodenal obstruction from intestinal malrotation with a midgut volvulus in the infant who presents with bilious vomiting cannot be overstated. A clue may be derived from the appearance of the duodenum on the plain radiograph. In the classic double-bubble sign, the duodenum appears distended and round because of chronic intrauterine obstruction. When a distended stomach is associated with a normal-caliber duodenum, the diagnosis of malrotation with duodenal obstruction secondary to Ladd bands or volvulus must be entertained. In an unstable patient, echocardiography and contrast studies may be required to distinguish hemodynamic compromise caused by volvulus from that caused by cardiac disease. Even when the diagnosis of duodenal atresia is established in the stable patient, cardiac anatomy and function should be evaluated before surgical correction.

Preoperative preparation includes nasogastric decompression, fluid and electrolyte replacement, and a thorough evaluation for associated anomalies. If malrotation is ruled out, surgical correction of duodenal atresia can be temporarily postponed, and more urgent conditions evaluated and treated. Prophylactic perioperative antibiotics are begun preoperatively.

The surgical management of an intrinsic duodenal web is usually limited to excision of a portion of the web and an enteroplasty to widen the duodenal lumen at that point. As the membrane occasionally contains the terminal common bile duct, great caution must be taken in excising or incising the membrane to avoid biliary injury and stricture formation. The most widely accepted surgical management of both true atresia and annular pancreas involves constructing an anastomosis between the dilated proximal duodenum and the diminutive distal duodenum. The diamond duodenoduodenostomy has yielded consistently good results and remains the procedure of choice.[43] The diamond anastomosis is fashioned in such a way as to approximate the ends of one incision to the midpoints of the other incision. The tension resulting from this orientation tends to hold the anastomosis open in a self-stenting manner.

A feeding gastrostomy should not be necessary for postoperative management of an uncomplicated duodenal repair. Gastroduodenal function usually returns within 5 to 7 days, at which time enteral feeding can be initiated with small boluses and the volume progressively advanced as tolerated. One of the most problematic issues following repair of duodenal atresia is delayed transit, usually associated with a persistently dilated and dyskinetic proximal duodenum. Even with the preferred diamond anastomosis, a persistent megaduodenum with symptomatic partial obstruction and stasis can occur. This complication may be managed either by tapering duodenoplasty or by lateral seromuscular resection.[44] A significant number of infants with corrected duodenal atresia also experience GER, which may be exacerbated by an impairment in gastric emptying. Survival rates of 95% are reported in those who are deemed satisfactory surgical candidates. As mentioned earlier, morbidity and mortality are usually related to associated anomalies.

GASTROINTESTINAL DUPLICATIONS

The stomach and duodenum are the least common regions of the gastrointestinal tract in which duplications occur. For most congenital lesions of the stomach and duodenum included in this category, the term *duplication* may be a misnomer. The actual embryologic cause of these lesions is unknown, but the designation of *enterogenous cyst* or *congenital diverticulum* may be more accurate. Nevertheless, it is important to recognize that gastric and duodenal duplications are occasionally associated with other gastrointestinal duplications or with vertebral anomalies. Communications with or attachments to an abnormal vertebral column suggest they may be caused by aberrant splitting of the primitive notochord during early embryonic development.

Classically, four pathologic criteria are considered necessary to establish the diagnosis of gastric duplication: (1) contiguity with the stomach, (2) an outer smooth muscle layer, (3) a shared blood supply with the stomach, and (4) a gastric epithelial lining (which may also contain pancreatic tissue). Most gastric duplications are cystic, do not communicate with the gastric lumen, and are located along the greater curvature of the stomach. When a luminal communication is present, it may result from peptic ulceration of the common wall between the two structures. Tubular duplications are less common, frequently communicate with the gastric lumen, and are also most commonly found on the greater curvature (Fig. 47-27). Extragastric cystic structures lined by gastric epithelium and exhibiting a muscular wall, however, are usually referred to as gastric duplications regardless of their proximity to the stomach.

In the neonatal period, duplications often present with symptoms and signs of proximal gastrointestinal obstruction.

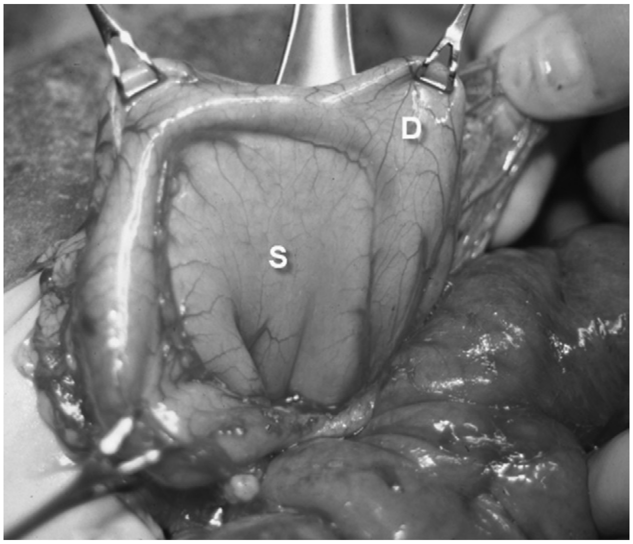

Figure 47–27. Gastric duplication of greater curvature. D, duplication; S, stomach.

Vomiting is common and can be bilious or nonbilious, depending on the location of the extrinsic compression relative to the ampulla of Vater. Case reports of gastric duplications, both adjacent to the stomach and in the retroperitoneum, have described connections to the pancreatic ductal system and have resulted in chronic pancreatitis and pseudocyst formation. Connections to the biliary system and to extrapulmonary sequestrations have also been reported. Duodenal duplications most commonly occur in the first or second portion, usually on the posterior surface, and may be lined with gastric mucosa. These may also cause pancreatitis by compression of the pancreatic duct within the duodenal wall. Gastroduodenal hemorrhage or perforation secondary to peptic ulceration is the usual emergency indication for surgery. Gastrointestinal hemorrhage secondary to ulcer penetration from a noncommunicating duplication cyst into an adherent loop of intestine or colon has been reported.

Gastroduodenal duplications are being detected by antenatal ultrasound with increasing frequency and should be considered along with choledochal cysts and omental cysts in the differential diagnosis of a fetal right upper quadrant cystic mass. Postnatally, an upper gastrointestinal tract contrast study may demonstrate an extrinsic compression of the stomach or duodenum, but ultrasound and computed tomography can definitively reveal the mass itself. Technetium-99m scans may identify duplications distant from the stomach if they contain ectopic gastric mucosa but are not specific for duplications per se.

Resection of the entire duplication, either by enucleation or by limited gastric resection, is the treatment of choice. Successful laparoscopic resection has been reported and may be advisable for smaller, uncomplicated lesions. Extensive duplications, however, require removal of the entire mucosal cyst lining to avoid potential malignant degeneration. Adenocarcinoma arising from the gastric epithelium has been described in later life. Partial excision of the duplication with stripping of the residual mucosa is acceptable for lesions around the pylorus and duodenum for which en bloc resection of the contiguous gastroduodenal wall would necessitate sacrificing important structures (e.g., the common bile duct). Internal drainage into the adjacent duodenum or a Roux-en-Y jejunal limb is reserved for the rare circumstance in which resection or mucosal stripping is not feasible. Partial resection of a contiguous aberrant pancreatic lobe or internal drainage of an associated pseudocyst may also be required. Marsupialization should be avoided.

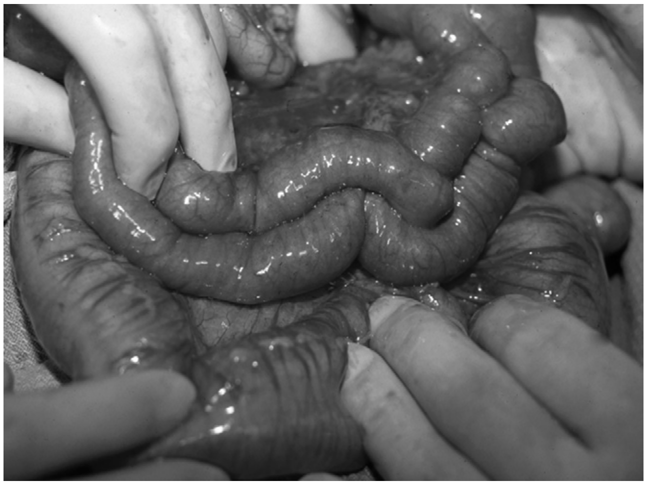

Figure 47–28. Long tubular duplication on mesenteric side of small intestine.

Duplications of the small or large intestine are more common than those of the stomach and duodenum. They are usually cystic but may be tubular and extend for a variable distance (Fig. 47-28). Cystic duplications may cause obstruction or volvulus, and they may present with a palpable mass. Either type may present with hemorrhage. Simple cystic duplications of the small or large intestine are most easily managed by resection and primary anastomosis. Long tubular duplications may be managed by mucosal stripping to prevent future peptic complications and to remove potentially dysplastic epithelium. Long colonic duplications may result in anal duplication. If the second anus is within the muscular sphincter, division of the septum to establish a common lumen may be sufficient. Cystic rectal duplications must be distinguished from sacrococcygeal teratomas and meningoceles before trans-sacral or posterior sagittal resection is undertaken.

MALROTATION AND MIDGUT VOLVULUS

As described in the development section, the bowel undergoes two independent 270-degree counterclockwise rotations during the 6th to 12th weeks of gestation. One involves the duodenojejunal junction around the axis of the superior mesenteric artery, and the other involves the ileocolic junction around the same axis. Although this is difficult to grasp spatially, the concept is simple. When the bowel rotates appropriately during development, it fixes itself in the abdomen in such a way that it absolutely cannot twist and obstruct itself or, as occurs in volvulus, compromise its own blood supply. This is remarkable, considering the length of bowel involved. However, if the bowel does not rotate and fix itself in the abdomen properly, the stage is set for later obstruction or volvulus. Yet malrotation, more comprehensively described as an anomaly of intestinal fixation and rotation, is not a problem in itself. It is estimated that nearly 1 in 100 people have some form of improper rotation or fixation, yet 1% of the population do not have the related clinical symptoms. Rather, 1 in 6000 live births leads to a clinical discovery.[12,110] So, anomalies of intestinal fixation and rotation are only potential time bombs, some much worse than others, that may, or may never, go off.

Because so many variations of malrotation can exist, there are many possible clinical presentations. Any case of unexplained abdominal pain or emesis should have malrotation somewhere in the differential diagnosis. However, the main symptom complexes can be grouped together as those related to acute volvulus, to duodenal obstruction, to evidence of intermittent or chronic abdominal pain, or as an incidental finding in an otherwise asymptomatic patient. More than half of patients present in the first month of life, with half of the rest in the first year. However, 25% can still present at any other time in life.[99] Bilious emesis in any child younger than 1 year of age should be assumed to be due to malrotation until proven otherwise.

The preoperative evaluation of the malrotation or midgut volvulus is the radiologic determination of the position of the ligament of Treitz, and secondarily, its distance and relation to the ileocecal junction.[109] The initial film is typically a plain radiograph. Although alone it is not sufficient for a diagnosis, obvious obstruction of the stomach with little or no distal air in an acutely ill newborn or infant can be enough to warrant taking the child immediately to the operating room. Midgut volvulus is one of the few pediatric emergencies in which operating takes precedence over resuscitation. More typically, plain radiographs are nonspecific and further urgent evaluation is warranted.

The upper gastrointestinal series is the gold standard for making the diagnosis of malrotation. The procedure must be performed in the radiology suite by a trained radiologist using fluoroscopy. In cases of volvulus, the site of obstruction is in the second or third portion of the duodenum and has the appearance of a bird's beak. If the duodenum is partially obstructed, a spiral or corkscrew configuration may be seen (Fig. 47-29). In diagnosing malrotation alone, the position of the duodenojejunal junction must be documented. Normally, it is to the left of midline, rising to approximately the level of the pylorus and fixed well posteriorly. In a patient with malrotation, it is anterior, low, and often midline or to the right of midline (Fig. 47-30). The diagnosis requires judgment and, therefore, an experienced and confident radiologist.

Barium enema was historically the procedure of choice, but it has several limitations. Most importantly, the cecum can be in the proper position in the patient with duodenojejunal malrotation, and the latter can therefore be missed. As the risk for midgut volvulus is related to duodenojejunal malrotation and not jejunoileal, the barium enema cannot be depended on. A contrast enema can, however, help determine the potential width of the mesenteric base, and therefore the risk of volvulus, in a child when the location of the duodenojejunal junction on upper gastrointestinal investigation is unclear.

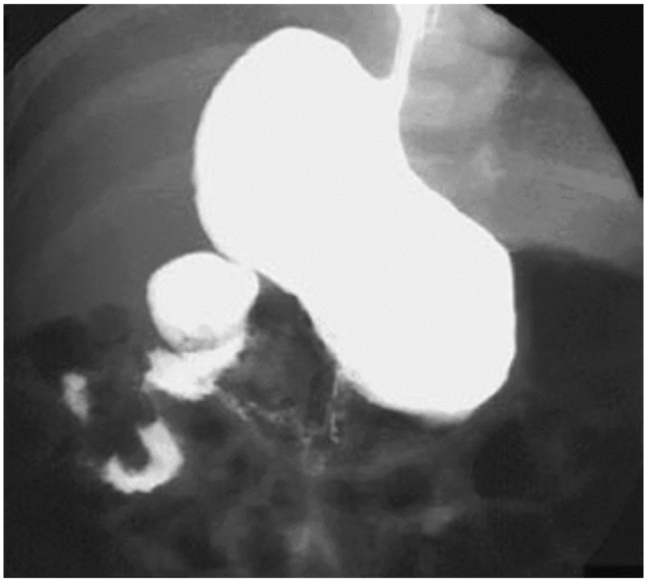

Figure 47–29. Upper gastrointestinal contrast study in patient with malrotation and midgut volvulus.

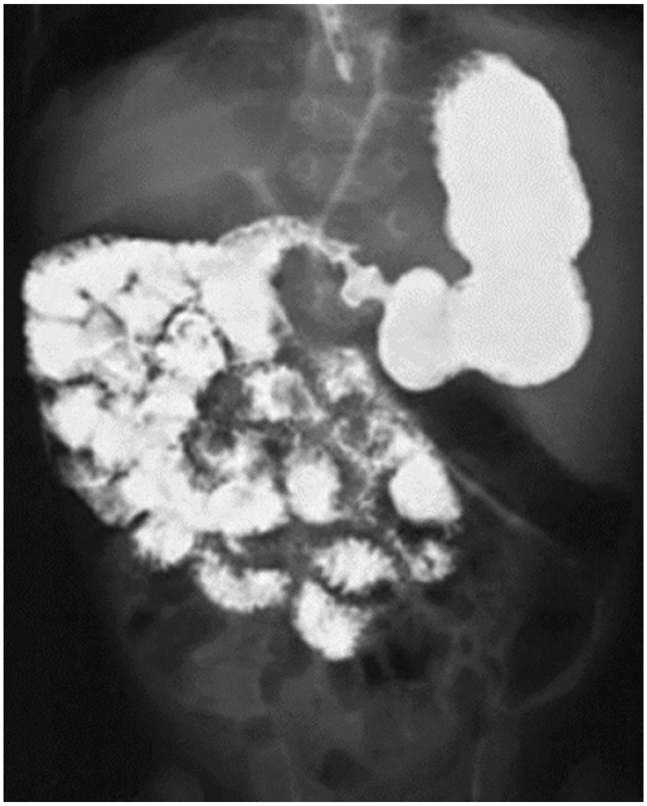

Figure 47–30. Upper gastrointestinal contrast study in patient with malrotation without volvulus. Note location of duodenal-jejunal junction and small intestine to right of midline.

Ultrasonography can be used to determine the orientation of the superior mesenteric vessels and thus may be helpful in the diagnosis of malrotation. Normally, the superior mesenteric vein lies to the right of the superior mesenteric artery. If the superior mesenteric vein lies either anterior or to the left of the superior mesenteric artery, malrotation may be present. However, this is inconsistent and does not lead to a definitive diagnosis.

An acutely ill child with the presumed diagnosis of volvulus requires urgent operative intervention even at the expense of full resuscitation. As the operation gets underway, intravenous fluids continue, bladder and stomach catheters can be placed, blood is drawn for type and crossmatch, and broad-spectrum antibiotics are administered. Time is critical. In patients with malrotation without volvulus or obstruction, urgency is somewhat less. As long as all caregivers are vigilant for the development of volvulus, early operation (within a day or two of diagnosis) would appear to be justified. Older individuals with intermittent symptoms can be treated more electively.

The surgical treatment of these patients involves seven aspects: evisceration of the bowel, detorsion of a volvulus, division of Ladd bands, widening the mesenteric base, relieving duodenal obstruction, incidental appendectomy, and nonrotational return of the bowel to the abdomen. Ladd bands extend from the ascending colon (on the medial aspect of the duodenum in patients with malrotation) across the duodenum and attach to the posterior aspect of the right upper quadrant. They presumably represent the attempt of the ascending colon to become retroperitoneal, as it is in the normally rotated individual. They must be completely divided. Techniques to widen the mesenteric base and relieve duodenal obstruction are then used. Incidental appendectomy and nonrotational return of the bowel to the abdomen may seem unusual. It would seem logical to try to rotate the bowel properly or to try to fix it in place. However, this does not work in practice. Experience has shown that returning the bowel with the small bowel on the right and the large bowel on the left (total nonrotation) is effective. Unfortunately, this typically leaves the appendix in the left upper quadrant, so it is removed to avoid possibly confusing clinical presentations of appendicitis in the future.

Mortality for the operative correction of malrotation ranges from 3% to 9% and is increased in patients with volvulus, intestinal necrosis, prematurity, and other abnormalities. Recurrent volvulus is relatively infrequent (less than 10%) but must always be considered. Gastrointestinal motility disturbances are not uncommon after operative correction of malrotation. Other complications can occur as a result of compromised bowel from ischemia caused by volvulus, such as reperfusion injury with hemodynamic instability and delayed stricture formation. Adhesive bowel obstruction is possible in any patient after abdominal exploration. Finally, midgut volvulus accounts for nearly 20% of the cases of short gut syndrome in the pediatric population.

MECONIUM SYNDROMES

Meconium syndromes are associated with intestinal obstruction resulting from thick, inspissated meconium. These syndromes are broadly characterized by several patterns of clinical presentation, including meconium ileus, meconium plug syndrome, meconium peritonitis, and meconium ileus equivalent. In meconium ileus, which is almost always associated with cystic fibrosis, the inspissated meconium typically obstructs the small bowel, usually at the level of the distal jejunum or the proximal ileum. Meconium plug syndrome is observed more frequently in preterm infants and involves obstruction at the level of the colon. It is thought to occur as a result of poor intestinal motility, but it can be associated with cystic fibrosis in a minority of infants. Meconium peritonitis results from bowel perforation, usually intrauterine, which is secondary to meconium-related obstruction. Meconium ileus equivalent is a condition associated with stool-related bowel obstruction in older children with cystic fibrosis.

Meconium Ileus

Meconium ileus occurs in approximately 10% to 20% of newborns with cystic fibrosis. Cystic fibrosis is caused by mutations in the gene that codes for a protein called *cystic fibrosis transmembrane conductance regulator* (CFTR), which regulates chloride transport across epithelia.[17,82] Luminal epithelial cells of patients with cystic fibrosis either lack or have defective CFTR, and are relatively impermeable to chloride and excessively reabsorb sodium. This leads to dehydration and hyperviscosity of secretions with secondary obstruction of the lumina that these cells line, including the mucus-secreting glands of the bowel wall and the ductal cells of the exocrine pancreas.

The hyperviscosity of mucosal cell secretion leads to the formation of thick, tarlike meconium, which becomes increasingly inspissated farther along the small bowel lumen, eventually resulting distally in the formation of small, dense meconium pellets and a microcolon. Resultant small bowel obstruction is usually present at birth and can even be diagnosed antenatally on ultrasonic examination of the maternal abdomen. Postnatal clinical signs of bowel obstruction usually evolve within 24 to 48 hours, including increased abdominal distention associated with failure to defecate and eventual bilious vomiting. Bowel loops, which have a pliant, doughlike quality, can often be palpated on abdominal examination. Abdominal radiographs may have a granular, soap-bubble appearance as a result of air bubbles in the meconium. This clinical picture is classically used to characterize *simple meconium ileus*. However, luminal bowel obstruction of this sort can progress to volvulus, necrosis, and perforation, and these clinical situations constitute *complicated meconium ileus*. If bowel necrosis and perforation have occurred in utero, a pseudocyst may form and present as a palpable mass on abdominal examination at birth. Volvulus can also present as a palpable abdominal mass. In addition to the classic features of intestinal obstruction (i.e., multiple distended bowel loops), abdominal radiography may reveal a large mass containing calcified material (pseudocyst) or calcifications distributed throughout the peritoneal cavity (meconium peritonitis) in association with this process. Ascites, free air, or a granular, soap-bubble appearance caused by air bubbles in the meconium may also be present. The absence of any or all of these radiographic findings does not necessarily rule out meconium ileus. However, a contrast enema almost always demonstrates a microcolon, usually associated with small, "rabbit-pellet" meconium concretions seen proximally. The differential diagnosis includes meconium plug syndrome, small bowel and proximal colonic atresia, total colonic Hirschsprung disease, and congenital hypothyroidism.

Management options to treat meconium ileus depend on the type of presentation. General management principles always include prompt rehydration with adequate fluid and electrolyte support, gastric decompression with a dual-lumen sump nasogastric tube, and appropriate antibiotic coverage.

Simple meconium ileus can be treated either nonoperatively or operatively. Nonoperative intervention requires that other causes of distal bowel obstruction be ruled out and that complicated meconium ileus (volvulus, necrosis, perforation, pseudocyst, or peritonitis) does not exist. A hyperosmolar solution (typically Gastrografin) is administered as an enema and allowed to reflux into the ileum. The hypertonic solution (1900 mOsm/L) establishes a concentration gradient across the bowel wall that draws fluid into the lumen and promotes passage of the meconium. It is extremely important that the infant receive adequate intravenous fluid therapy before and during this procedure to compensate for the rapid fluid shift out of the plasma compartment as a result of the intestinal osmotic load. This procedure should be performed by an appropriately trained and experienced pediatric radiologist, with a pediatric surgeon available. Although the technique is successful a little over 50% of the time, there is also an 11% perforation rate.[80] Furthermore, necrotizing enterocolitis can result from the exposure of the bowel to the hyperosmolar solution. Surgical treatment involves evacuation of the meconium from the intestine. This can be accomplished by creating an enterotomy and irrigating the bowel with 2% to 4% N-acetyl-L-cysteine, which helps to partially dissolve the inspissated meconium, making it easier to flush through the lumen. In addition, the bowel can be partially diverted using a variety of techniques (Bishop-Koop, Santulli-Blanc, or Mikulicz procedures), which allow for evacuation of the meconium over a longer term with gradual resumption of distal bowel utilization.

Complicated meconium ileus requires an exploratory laparotomy. Volvulus can be relieved by untwisting the bowel. Bowel resection is usually required to treat atresia, necrotic and perforated bowel, and in some instances, remarkably dilated bowel. Partial or complete temporary intestinal diversion is usually required along with the irrigation techniques previously mentioned. Initial postoperative care involves adequate fluid and electrolyte support, continued nasogastric sump tube decompression of the stomach, and appropriate antibiotic therapy. Careful ostomy irrigation by the pediatric surgeon can be continued postoperatively to facilitate further meconium evacuation if needed. Bowel function usually returns within 3 to 5 days, at which time oral nutritional support can be initiated, first with elemental formulations if the inflammation encountered at exploration was extensive or if surgery was complicated by intra-abdominal infection. Pancreatic enzyme supplementation should also be considered. If bowel function does not return within this period, parenteral nutritional support should be initiated. Early postoperative recovery is usually good. Proper ostomy care is essential and surgical closure is usually carried out 4 to 6 weeks after the initial surgery. Because long-term mortality in patients with cystic fibrosis is most frequently associated with respiratory complications, aggressive pulmonary toilet during the initial postoperative period is mandatory.

Meconium Peritonitis

Intestinal obstruction from a variety of causes, including, but not limited to, meconium ileus, volvulus, atresia, peritoneal bands, and internal hernia, can result in bowel necrosis and perforation during the fetal period. Meconium escaping into the peritoneal cavity combined with intestinal necrosis can cause an inflammatory reaction, leading to calcification and extensive scarring (fibroadhesive peritonitis), which seals the perforation; cystic meconium peritonitis (if a seal does not form and meconium continues to leak into the peritoneal cavity); or meconium pseudocyst (when loops of bowel and necrotic tissue are encased in scar tissue and surround the extramural meconium). Meconium ascites presents as a large amount of liquid meconium, presumably resulting from a recent perforation just before birth, which fills the peritoneal cavity.

Asymptomatic patients with radiographic evidence of intraperitoneal calcification can be managed conservatively; however, babies with meconium peritonitis who present with bowel obstruction usually require surgical intervention. Surgical management is based on the findings at laparotomy and may include resection of necrotic bowel or temporary intestinal diversion, or both. Every attempt should be made to preserve as much bowel length as possible to decrease the risk of developing short gut syndrome. The principles of postoperative care are similar to those for meconium ileus.

Meconium Plug Syndrome

Meconium plug syndrome is believed to relate to colonic hypomotility. It is more frequently observed in preterm infants and in infants of diabetic mothers, and it has been alternatively termed *functional inertia of prematurity* or *neonatal small left colon syndrome* (see also Chapter 49, Part 1). Several factors known to affect bowel motility have been implicated. These include hypermagnesemia and hypoglycemia. A hypermagnesemia-associated decrease in the release of acetylcholine can result in myoneural depression. This mechanism has been used to explain meconium plug syndrome observed in preterm neonates whose mothers received magnesium to treat eclampsia. Furthermore, immature development of the myenteric plexus of preterm infants may impair intestinal motility, accounting for the increased observation of meconium plug syndrome in this patient population. Hypoglycemia, frequently observed in infants of diabetic mothers, is thought to induce increased glucagon secretion, and may be associated with intestinal hypomotility.

Meconium ileus is seen in preterm infants who present with abdominal distention associated with minimal passage of meconium. Multiple dilated bowel loops are present on abdominal radiography. Although a digital rectal examination can sometimes result in the passage of the obstructing meconium, a water-soluble contrast enema is valuable both for diagnostic purposes (usually demonstrating a microcolon distal to the obstruction) and for therapy (to induce passage of the obstructing meconium plug). Surgical therapy is infrequently required to relieve the blockage. Because of the association of meconium plug syndrome with cystic fibrosis and Hirschsprung disease, patients with this disorder may need to be evaluated for cystic fibrosis and undergo a rectal biopsy.

JEJUNOILEAL ATRESIA AND STENOSIS

The potential pathogenesis of small bowel atresia is varied and includes events during the second and third trimester of intrauterine life such as intussusception, internal herniation of bowel, volvulus, bowel perforation, vascular constriction in association with gastroschisis (and, less frequently, omphalocele), mesenteric thrombosis, and possibly excessive resorption of the intestinal attachment of the omphalomesenteric remnant. The suggestion of in utero vascular compromise as an etiologic factor was first demonstrated in beagle puppies by Christian Barnard and colleagues, who observed that the late-gestational ligation of mesenteric vessels resulted in a classic V-shaped mesenteric defect in association with a noncontiguous gap atresia (most likely caused by resorption of the ischemic bowel supplied by the ligated vessels).[52]

These observations have subsequently been confirmed in a number of different animal models. The notion that the etiologic events occur after the 12th week of embryonic life is supported by the frequent clinical finding of bile pigments and lanugo hairs in the postatretic bowel segment, because secretion of bile into the bowel lumen and fetal swallowing of amniotic fluid begin during the 11th to 12th week of gestation. Another potential etiologic factor is linked to the concept of epithelial plugging. From the 5th to 8th week of gestation, the intestine undergoes a period of epithelial growth so rapid that it can completely obliterate the intestinal lumen (solid-cord stage). After the 8th week, the intestinal lumen is reestablished through a process termed *revacuolization*. Lack of complete revacuolization has been postulated to account for the development of intestinal stenoses and webs (membranous atresias).

The classification of jejunoileal atresia is as follows. Operative management of intestinal atresia and stenosis is based on pathologic findings.

Type I: Mucosal (membranous) web
Type II: Blind ends connected by a fibrous cord
Type IIIa: Blind ends separated by a V-shaped mesenteric defect
Type IIIb: Apple-peel or Christmas-tree deformity (blind ends; distal small bowel segment forms corkscrew around ileocecal artery terminus)
Type IV: Multiple atresias (string of sausages)

The anatomic distribution is approximately 50% in the jejunum (proximal 30%, distal 20%) and 50% in the ileum (proximal 15%, distal 35%). Approximately 90% of all small bowel atresias are single. Type IV atresias more often involve the proximal jejunum.

The initial diagnosis is often entertained when pregnant mothers present with polyhydramnios resulting from the inability of the fetus to absorb amniotic fluid via the obstructed bowel. Prenatal ultrasonography shows distended loops of fetal bowel consistent with obstruction. Newborn infants typically present with the abdominal distention and bilious vomiting often associated with failure to pass meconium. A more proximal (higher) location of the obstruction is characterized by an earlier onset of bilious vomiting and less abdominal distention in comparison with a more distal (lower) obstruction. On plain abdominal radiography, distended air-filled bowel loops are usually observed. The lower the obstruction, the greater is the number of distended loops and air-fluid levels. Often, a markedly distended loop (relative to other bowel loops) is visualized, which may help to identify the location of the blind end of the obstructed bowel. A contrast enema typically reveals a microcolon, which results from the fact that little or no succus has passed distal to the obstruction.

The differential diagnosis includes malrotation (with or without volvulus), meconium syndromes, duodenal or colonic atresia, internal hernia, intestinal duplication, and total colonic Hirschsprung disease. The particular distinguishing features of these conditions are discussed elsewhere in this chapter; however, jejunoileal atresia may coexist with malrotation (10% to 18%), meconium peritonitis (12%), meconium ileus (10%), and, less frequently, with other comorbid obstructive conditions. Intestinal ileus secondary to sepsis can also present with abdominal distention and bilious vomiting. When the level and pattern of obstruction suggest the possibility of malrotation, a limited upper gastrointestinal contrast study should be performed to demonstrate a normally positioned ligament of Treitz (located to the left of the vertebral column at the level of the pylorus).

Initial treatment should include prompt adequate intravenous hydration and orogastric decompression of the stomach with a sump tube placed at intermittent suction with frequent regular irrigation of the tube to ensure patency. The operative management of the child should not be undertaken until the fluid and electrolyte status is within normal range. Bilious drainage from the stomach should be replaced with equal amounts of intravenous lactated Ringer's solution every 4 hours. Fluid management should be administered to maintain a urine output of 3 to 4 mL/kg per hour.

Operative intervention is based on the type of atresia, the presence of associated surgical comorbidities, and the condition of the bowel at the time of surgical exploration. Abdominal exploration is usually carried out through a transverse incision above the level of the umbilicus. In considering the most appropriate operation, a general strategy is to preserve as much viable bowel as possible. Although dilation of the bowel proximal to the obstructing blind end is always present, a marked and relatively abrupt increase in the caliber of dilation is often found at the terminus itself, creating a large, bulbous pouch (Fig. 47-31). Because peristalsis of massively dilated bowel is thought to be ineffective, a primary anastomosis between such a pouch and the small-caliber, unused distal bowel should not be attempted. Instead, the pouch should be surgically tapered (or resected, if the involved segment is appropriately limited to avoid creating short gut syndrome) to allow for better postoperative peristalsis and to facilitate a more appropriately proportioned end-to-oblique end anastomosis. Side-to-side anastomoses are not generally used because of the association with blind-loop syndrome.

Before creation of the anastomosis, the distal lumen of the bowel is gently irrigated (inflated) to ensure that no further

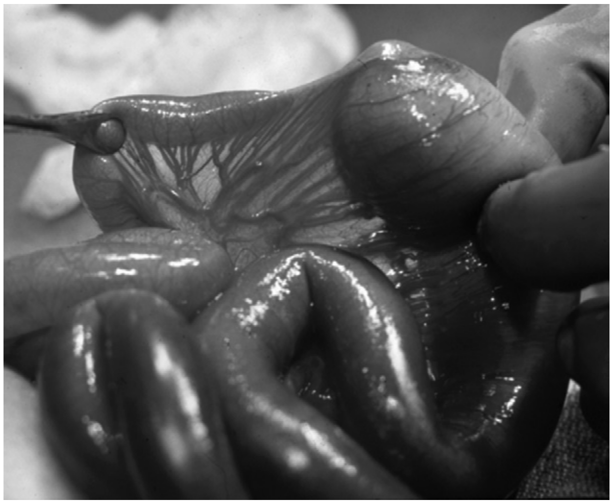

Figure 47–31. Operative photograph of a type II ileal atresia.

atretic segments or webs are present. Multiple atresias can be managed either by multiple resections and anastomoses or by intramural stenting.[11] This latter method may help to preserve intestinal length. Particular care is required in handling the distal bowel involved in the fragile apple-peel deformity, as the entire length of the segment is based on a delicate, easily injured ileocecal artery terminus. If the bowel is compromised by inflammation or ischemia, a primary anastomosis is postponed and the bowel is diverted.

Postoperative care involves adequate nutritional support, often administered parenterally until adequate bowel function is present. Elemental formulas may be useful to transition over to a full regular-formula diet. The most serious postoperative complications usually involve anastomotic leakage and sepsis. Over the longer term, anastomotic stricture can be problematic.

HIRSCHSPRUNG DISEASE

Congenital intestinal aganglionosis (Hirschsprung disease) is the result of arrested fetal development of the myenteric nervous system (see Small Intestine in Part 1). Hirschsprung disease is the most common cause of intestinal obstruction in the neonate. It occurs in about 1 in 5000 live births with a male-to-female ratio of 3.4:1. Total-colon Hirschsprung disease, noted in up to 8% of cases, favors females at a ratio of 1.6:1. More than 75% of the time, the transition zone from normal to involved colon is located in the rectosigmoid region. Down syndrome is the most commonly associated anomaly, occurring in 8% to 16% of patients. Approximately 5% of patients with Down syndrome have Hirschsprung disease. Family history is important because the risk of a sibling having Hirschsprung disease is 1% to 5% for short-segment disease and 9% to 33% with long-segment disease. Familial Hirschsprung disease occurs in 4% to 8% of patients.[36,77,81,101] Hirschsprung disease or tumors of neural crest origin (neuroblastoma, ganglioneuroblastoma, and ganglioneuroma) occur in association with congenital central hypoventilation syndrome in approximately 20% and 6% of cases, respectively.[7]

Approximately 80% to 90% of patients present in the neonatal period with complete intestinal obstruction characterized by abdominal distention, emesis, and failure to pass meconium. Approximately 95% of normal full-term infants pass meconium in the first 24 hours, whereas an equal number of patients with Hirschsprung disease do not. Physical examination shows a distended, soft abdomen, but rectal examination can produce an explosive stool. A contrast examination can be diagnostic in 80% of newborns. Findings may include a rectum with a smaller diameter than the sigmoid colon, a transition zone, normal caliber in the majority of the colon, and failure to completely evacuate on a 24-hour delayed film. Contrast enemas in all age groups are performed on unprepared bowel if the diagnosis of Hirschsprung disease is being considered. The definitive diagnosis of Hirschsprung disease, however, rests on demonstration of aganglionosis and hypertrophy of the nerve trunks on biopsy. In newborns, adequate biopsy specimens can often be obtained by the suction technique in the nursery.

Hirschsprung-associated enterocolitis occurs in 10% of patients overall and is more common beyond the neonatal period. This can be fatal and can happen even after treatment for Hirschsprung disease has been completed. All practitioners should be aware of this complication and treat for it whenever it is suspected. Enterocolitis is associated with abdominal distention, fever, emesis, and spontaneous diarrhea or an explosive diarrheal stool with gas during and after rectal examination. Enterocolitis is treated with decompression of the rectum with a large catheter and with warm saline irrigations using 20 mL/kg three or four times per day, volume resuscitation, and administration of broad-spectrum antibiotics.

The initial goal of treatment is decompression. Traditionally, this was performed with a leveling ostomy. Leveling here refers to the intraoperative determination of where on the bowel the ganglion cells make an appearance. This is done by taking seromuscular biopsies and having the pathologist review the frozen sections. The ostomy is then placed proximal to this to ensure its adequate function. Primary pull-through procedures are being performed with much greater frequency. Here, instead of the traditional three stages (ostomy, definitive repair, ostomy takedown), the operation is done in one stage, and without a protective stoma. Occasionally, a primary repair with a protective ostomy is performed—a two-stage operation, in that ostomy takedown is still required.

If a primary procedure is to be performed, the bowel must be decompressed and not too dilated. In the newborn, this is easily accomplished with rectal irrigations of saline at a volume of 20 mL/kg three times daily via a large catheter located high in the rectum or sigmoid colon. These irrigations can be performed by competent caregivers for a few days to a few weeks before the definitive pull-through procedure. Perioperative broad-spectrum antibiotics are recommended.

The three traditional surgical methods used to treat Hirschsprung disease are (1) Swenson, (2) Soave, and (3) Duhamel. No statistically significant difference has been shown between the outcomes of any of these procedures if they are performed properly. In the Swenson procedure, the aganglionic bowel is removed completely and the ganglionic bowel is anastomosed full-thickness to full-thickness rectum just above the dentate line. In the

Soave, only the distal mucosa of the bowel is removed, from just above the dentate line to about the level of the peritoneal reflection. The remaining aganglionic bowel is removed. The ganglionic bowel is then brought down into the sleeve of bowel left behind and anastomosed full-thickness to partial-thickness rectum just above the dentate line. The Duhamel leaves the last segment of aganglionic distal bowel in place and brings the ganglionic segment down behind it. The two segments are then stapled and sewn together to create a common channel above the dentate line, with aganglionic bowel anteriorly and ganglionic bowel posteriorly. Most laparoscopic procedures done today are slight variants based on the Soave technique. Total colonic Hirschsprung disease requires much more involved and less successful procedures. Many variants have been proposed and are performed, with the goal of all surgical procedures being to bring ganglionated bowel down the anorectal junction, with or without the formation of a reservoir.

Regardless of the procedure performed, these patients must be followed for years postoperatively. Postoperative care and long-term issues are similar to those for patients with anorectal malformations. Mandatory dilations are not necessary in Hirschsprung disease, as a neorectum is not created. However, strictures are not uncommon, and these patients need to be diligently followed during the first year. If any narrowing is noted, a full dilation program is started. As there appears to be no detriment to dilations, some surgeons start a dilator program in all patients. Also, enterocolitis is not typically seen in patients with anorectal malformations but can absolutely occur after repair in a patient with Hirschsprung disease. All patients with Hirschsprung disease, at any time in their lives, should have enterocolitis included in their differential diagnosis whenever they have abdominal pain, distention, or diarrhea. Also unique to patients with Hirschsprung disease is the possibility of a retained aganglionic segment contributing to ongoing, postoperative constipation. This occurs when poorly vascularized, poorly ganglionated, or frankly aganglionic bowel is brought down in the pull-through. Repeat biopsy is necessary. Anal sphincter achalasia can also occur, and injection with botulinum toxin can help make this diagnosis. If suspected, an anal myomectomy can provide a permanent solution. All the potential complications, however, must be balanced by the long-term results, which indicate that approximately 90% of these patients ultimately achieve normal or near-normal bowel function.

ANORECTAL ANOMALIES

Anorectal malformations, or imperforate anus, are a class of congenital malformations that covers a wide spectrum of defects.[35,72,75] They can be quite minor in appearance—for example, a mildly anteriorly displaced anus—or quite severe. Overall, most patients do reasonably well, with more than 75% attaining a good degree of bowel control when they have adequate treatment.[76] The most severe forms of pelvic malformations, such as cloacal exstrophy, are not discussed here; this discussion is limited to malformations of the anus and rectum alone.

Imperforate anus occurs in 1 of every 4000 to 5000 newborns. The estimated risk for a couple having a second child with an anorectal malformation is approximately 1%. The frequency of this defect is slightly higher in male than in female patients.

Traditionally, the terms *high, intermediate*, and *low* were used to describe various degrees of imperforate anus. However, terminology should relate to the location of the rectal fistula for both prognostic and therapeutic implications.

More than 80% of male patients with imperforate anus have a fistulous connection between the rectum and the urinary tract. This can go from the rectum to the bladder (rectovesical), to the prostatic urethra (rectoprostatic), and to the bulbar urethra (rectobulbar). When the rectal fistula opens onto the perineal skin, it is called a *perineal fistula*. An unusual form of imperforate anus occurs when the rectum ends blindly in the pelvis. More than 50% of these patients have Down syndrome and almost all patients with Down syndrome and imperforate anus have this variant.

In female patients, there are three main types of malformations: perineal fistulas, vestibular fistulas, and complex malformations called *cloacae*. In the perineal fistula, the rectum opens on the perineal skin anterior to the anal dimple. A vestibular fistula opens in the posterior aspect of the introitus but outside the hymen. A cloaca is a malformation in which the rectum, vagina, and urethra all open into a common channel of variable length, which then opens onto the perineum. A rectovaginal fistula is extremely uncommon; these are usually rectovestibular fistulas.

Anorectal malformations may be associated with malformations of the sacrum and spine. One missing vertebra does not appear to have prognostic significance; however, two or more missing sacral vertebrae is a poor prognostic sign in terms of bowel continence and, sometimes, urinary control. Hemivertebrae in the thoracic and lumbar spine are also associated with imperforate anus.

Tethered cord is a defect frequently associated with imperforate anus, seen in up to 25% of cases. The actual repercussions of tethered cord are more difficult to determine. It usually coincides with very high anal defects, a very abnormal sacrum, or spina bifida. Cause and effect is unclear, as is the benefit of surgical treatment of the tethered cord, but the current standard of care is to look for tethered cord in all patients with imperforate anus and surgically treat if discovered.

The frequency of associated genitourinary defects varies from 20% to 50%. The width of the range is most likely related to how diligently the defects are sought. The higher the malformation, the more frequent are the associated urologic abnormalities. Patients with a persistent cloaca or rectovesical fistula have a 90% chance of an associated genitourinary abnormality. Conversely, children with perineal fistulas have less than a 10% chance of an associated urologic defect. Hydronephrosis, urosepsis, and metabolic acidosis from poor renal function are the main sources of mortality and morbidity in newborns with anorectal malformation. In fact, a thorough urologic evaluation should take precedence over the colostomy itself in patients with high lesions. In patients with lower lesions such as perineal fistulas, the urologic evaluation can be performed on an elective basis. This evaluation must include an ultrasonographic study of the kidneys and the entire abdomen to rule out the presence of hydronephrosis or any other obstructive process.

Approximately 5% of patients with imperforate anus have associated esophageal atresia, and up to 10% have significant cardiac malformations such as tetralogy of Fallot, ventricular septal defect, or patent ductus arteriosus.

The initial diagnosis of imperforate anus is almost always made during the first newborn physical examination. Occasionally, a mild perineal fistula is missed. Two important questions need to be answered within the first 24 hours. The first is whether a colostomy will be needed, deferring definitive repair until later in life, or whether to proceed with definitive repair. The second is to determine whether associated defects, such as urologic abnormalities, require more urgent treatment. It should be stressed that imperforate anus is not a surgical emergency and rarely needs to be operated on within the first 24 hours of life. This time should be used to complete the workup and discuss options with the family. On the other hand, some associated abnormalities can carry morbidity and mortality risks in the first 24 hours, and these must be addressed. Intravenous fluids, antibiotic coverage, an abdominal ultrasound, a radiograph of the spine, anteroposterior and lateral radiographs of the sacrum, a cardiac evaluation, and a nasogastric tube are indicated.

The decision to perform a colostomy or to proceed with the definitive repair can be answered within the first 24 hours by physical examination alone in more than 80% of male patients and 95% of female patients (Figs. 47-32 and 47-33). In the male, the presence of a well-developed midline groove between the buttocks, a prominent anal dimple, and meconium exiting through a small orifice located anterior to the sphincter in the midline of the perineum are evidence of a perineal fistula. Occasionally, there is a prominent skin bridge that an instrument can be passed beneath (known as a “bucket handle”) or a midline raphe “black ribbon” of subepithelial meconium. These malformations can be repaired via a perineal approach during the newborn period without a colostomy. On the other hand, flat buttocks with no evidence of a perineal opening and the presence of meconium in the urine are indications of a rectourethral fistula. A small gauze pad over the tip of the penis can be helpful in spotting meconium in the urine. Most surgeons place a colostomy in these patients.

It can take up to 24 hours for enough pressure to build up in the colon to push meconium out a perineal fistula. So, unless meconium is definitely seen in the urine, waiting is appropriate. If the diagnosis is still in doubt after 24 hours, a cross-table lateral radiograph of the abdomen and pelvis with the infant in the prone position is indicated. By identifying the anal dimple with a lead marker, the distance between the

end of the dilated bowel and the skin can be estimated. If this distance is less than 1 cm, a primary repair can be attempted. It is important to wait 24 hours before obtaining this radiograph, because pressure within the colon is necessary for its prognostic value. Fewer than 20% of male patients need this radiograph.

In the female patient, physical examination alone can lead to the proper initial surgical treatment in more than 95% of cases. If a single perineal opening is observed where the urethra is normally located, the diagnosis of cloaca is established and a colostomy is indicated. A girl with a normal urethra and an opening within the vestibule of the female genitalia but outside of the hymen confirms the diagnosis of rectovestibular fistula. Initial treatment of this defect is the most variable. Pediatric surgeons experienced in its repair often either temporarily dilate the fistula and perform a definitive repair in a few weeks or proceed directly to definitive repair. The most conservative option is to place a colostomy and perform the repair at a later date. This is by far the most common defect seen in girls.

A fistula tract located anterior to the center of the sphincter but posterior to the vestibule of the genitalia establishes the diagnosis of perineal fistula. These babies undergo primary anoplasty without a protective colostomy. In the absence of any fistulous tract in the female patient, imperforate anus without fistula is the diagnosis, particularly in patients with Down syndrome. The cross-table film is needed for fewer than 5% of female patients.

The surgical care of patients with anorectal malformations often involves a complex interplay between clinical judgment and technical expertise. Surgical strategies include the creation of a temporizing or palliative colostomy and various types of corrective repairs. Some of the principles that influence surgical decisionmaking follow.

Colostomy

The main purpose of a colostomy is to provide immediate relief of bowel obstruction related to imperforate anus. It also allows the medical and surgical team time to plan the definitive repair, and it permits other medical and surgical issues, some of which may be more pressing, to be properly addressed. A colostomy is nearly always a temporary measure, as patients with imperforate anus very rarely require permanent diversion.

Most colostomies are placed at the junction of the descending and sigmoid colon in the patient's left lower quadrant. This limits the amount of prolapse that can occur and leaves adequate colon to perform the pull-through in the future. A divided colostomy is required, as loop colostomies can provide incomplete diversion. Overflow of stool into the distal limb exposes the patient to fecal contamination of the genitourinary tract and can lead to massive distention of the distal colon, compromising the ability to perform a successful pull-through. The stoma appliance should not include both stomas to avoid this same problem. A technical point is that the distal colon should be irrigated of all meconium at the time of the colostomy. An exception to the descending/sigmoid colostomy placement is that in the female patient with a persistent cloaca, a divided transverse colon colostomy is performed, despite its greater risk of prolapse, because more distal colon may be needed to perform a vaginal reconstruction.

It is extremely important that the surgeon know the exact location of the fistula before undertaking the definitive repair. A distal colostogram must be obtained for all male patients who undergo a colostomy and all female patients with a cloaca. This study accurately shows the location of the fistula between the rectum and the genitourinary tract, the length of available colon from the colostomy to the fistula site, the distance from the rectum to the anal dimple, its relationship with the sacrum, the characteristics of the urethra in the male patient, the characteristics of the vagina in a female patient, and the presence or absence of vesicoureteral reflux. It is important that the radiologist apply some pressure to the contrast material to get full benefit from the examination.

Definitive Repair

The goal of the definitive repair is to place a neoanus in the appropriate location allowing control by the patient. The vast majority of patients with imperforate anus can be approached via the posterior sagittal route by a posterior sagittal anorectoplasty. Male patients with a bladder neck fistula and female patients with a long common channel (greater than 2.5 cm) require combined abdominal and posterior sagittal approaches. In the posterior sagittal approach, the patient is placed in the prone position with the pelvis elevated. An incision is made from above the coccyx to below the anal dimple. Fine-tip cautery is used, and an electrical stimulator is critical to determine the location of the sphincter mechanism. Dissection proceeds exactly on midline until the rectum is found. In male patients, fistulas to the urethra must be isolated and divided, and the rectum freed. Perineal fistulas in both sexes and vestibular fistulas in female patients are tracked directly to the rectum, which must still be freed from the common wall it may have with other genitourinary structures. The now mobilized rectum is then brought down to the perineum into the proper location within the sphincter mechanism as determined by electrical stimulation. The rectum occasionally needs to be tapered at this time. The surrounding muscle and soft tissue is then appropriately closed in layers. In the male patient, a Foley catheter must be placed at the start of the operation and left in place for 4 to 7 days postoperatively.

Postoperative Care

After colostomy, broad-spectrum antibiotics are continued for 2 to 3 days. A stoma appliance is fitted, and the mucous fistula is typically left exposed. Once the colostomy is productive, feedings are begun. Recovery after posterior sagittal anorectoplasty is typically quite rapid—patients can often eat on the day of surgery. Broad-spectrum antibiotics are continued for 2 days. Patients can often go home after 2 days, but male patients should have their Foley catheters left in until postoperative day 4 to 7. If the catheter accidentally comes out, it should not be replaced until the patient is given ample opportunity to void spontaneously, because replacing the Foley can cause significant injury.

Two to 3 weeks after surgery, dilations are begun using Hegar dilators. That this procedure is critical for success must be impressed on the patient's caregivers. Dilations continue for 6 to 12 months postoperatively. If this process is interrupted, there is a high likelihood that a stricture will develop. If a colostomy is present, it can be closed once the desired anal size is reached, typically a 14 Hegar dilator in a 6-month-old child. The importance of dilation cannot be overstated.

After colostomy closure or primary definitive repair, the usual multiple bowel movements frequently produce severe perianal excoriations. These may take time to heal and caregivers should be forewarned. Every attempt to prevent prolonged contact of stool and skin should be made. Barrier products are frequently used, but it is most helpful to avoid using a diaper on the patient as much as possible.

Special Considerations for Cloaca Patients

In patients with a cloaca, certain characteristics of the common channel determine the various operative approaches. As noted earlier, a cloaca is a common opening in the perineum, seen in female patients only, into which the bladder, vagina, and rectum typically enter. It is not to be confused with cloacal exstrophy, a defect seen in both sexes in which the incomplete hindgut, genitals, and bladder are exposed in conjunction with a deformed pelvis. Cloacal exstrophy is not discussed in this chapter. In cloacal malformations, the major treatment determinant is the length of the common channel. A *common channel* is defined as the distance from the introitus to the first fistula tract, that is, bladder, bowel, or vagina. Most pediatric surgeons believe that a common channel of more than 3.5 cm changes the technical aspects of the repair from performing a urogenital mobilization from below to requiring a combined abdominoperineal approach that may include an interposition graft of bowel to create a neovagina. In a urogenital mobilization, the rectal fistula is divided from the cloaca and placed appropriately in the muscle complex, as is done for all anorectal malformations described earlier. The common bladder and vagina complex is then extensively mobilized and brought down to the introitus. By not dividing the urethra and vagina, many complications can be avoided. With a long common channel, both an abdominal and perineal approach is required. Frequently in these cases, inadequate vaginal tissue is available and a neovagina of colon or small bowel is required. Despite the complexity of these reconstructions, with meticulous surgical care and careful operative planning, these patients can do very well and a number have gone on to have children of their own. All should achieve some level of social continence and be able to be sexually active.

Long-term Follow-up

These patients need life-long follow-up. Constipation is the most common sequela in patients with anorectal malformations, and it can be most severe in the benign group of malformations.

The more complex malformations have a poorer prognosis in terms of bowel control but less chance for constipation. Constipation must be treated aggressively, and prolonged use of laxatives in this population is indicated.

Twenty-five percent of patients with anorectal malformations suffer from some level of fecal incontinence and require some form of bowel management.[72,75,76] Urinary incontinence is not common in boys—99% enjoy control. In females with cloacae, 50% to 60% have control, 20% require a continent diversion, and the rest remain dry with intermittent catheterization.

PART 4

Neonatal Necrotizing Enterocolitis: Clinical Observations, Pathophysiology, and Prevention

Michael S. Caplan

Neonatal necrotizing enterocolitis (NEC) is a common and devastating gastrointestinal emergency that primarily afflicts premature infants in neonatal intensive care units (NICUs) worldwide. Despite advances in neonatal care and significant clinical and basic science investigation, the etiology remains incompletely understood, specific treatment strategies are lacking, and morbidity and mortality from this disease remain high. This section reviews the epidemiology and classic clinical features of NEC, describes the current understanding of the pathophysiology, and relates new, exciting approaches to prevention.

EPIDEMIOLOGY

The incidence of NEC varies among US centers and across continents, but ranges between 3% and 28% with an average of approximately 6% to 10% in infants born weighing less than 1500 g.[126] There is an inverse correlation between gestational age/birthweight and incidence of NEC; the incidence increases dramatically in the smallest and most premature infants, and intrauterine growth restriction confers a higher risk of disease than that of a normally grown preterm infant. Whereas there appears to be a slightly increased prevalence in boys, some data suggest higher NEC rates in African Americans compared with whites or Hispanic neonates.[106] Most (90% to 95%) preterm infants in whom NEC develops are previously fed, although the onset of disease may be several weeks after enteral nutrition begins. Although most neonates in whom NEC develops are preterm, 5% to 10% of cases occur in babies born greater than or equal to 37 weeks' gestation.[136] In this population, NEC is almost always associated with a specific risk factor such as asphyxia, intrauterine growth restriction (IUGR), polycythemia/hyperviscosity, exchange transfusion, umbilical catheters, gastroschisis, congenital heart disease, or myelomeningocele. In these situations, overt intestinal ischemia is often suspected, and therefore the pathophysiology may differ from that in the preterm neonate with NEC (see Pathophysiology). Despite significant advances in neonatal care, the mortality resulting from NEC has not improved over the last three decades, with reports of NEC mortality ranging between 10% and 30%.[49]

CLINICAL FEATURES

Presentation

NEC can present with a variety of symptoms and signs; preterm neonates may demonstrate symptoms of hematochezia, emesis or increased gastric residuals, abdominal distention, lethargy, apnea, and bradycardia, as well as signs of neutropenia, thrombocytopenia, metabolic acidosis, tachycardia, abdominal tenderness, abdominal discoloration, respiratory failure, and, if severe, shock.[134] Guaiac-positive stools are quite common in nasogastric tube-fed preterm neonates (60% to 75%) and therefore are not a useful indicator of NEC. Feeding intolerance occurs frequently in this population of preterm neonates, but studies indicate that intolerance is not a reliable marker for the development of intestinal injury.

Diagnosis

The diagnosis is typically made by the identification of pneumatosis intestinalis (air in the bowel wall) or portal venous gas on abdominal radiograph, although in some cases of NEC, commonly in unfed patients, pneumatosis is not appreciated (Fig. 47-34). In these situations, NEC may be diagnosed surgically or pathologically, or in some instances by ultrasound appreciation of portal venous air. Bell and colleagues suggested a classification scheme that differentiates suspected NEC (stage I) from proven NEC (stage II) and advanced NEC (stage III with peritonitis or perforation) (Table 47-8).[6] In this scheme, stage I NEC includes mild systemic signs, abdominal distention with changes of feeding intolerance, but no confirmatory radiographic evidence. Stage II or proven NEC has similar symptoms or signs with pneumatosis and/or portal venous gas, and stage III demonstrates significant systemic signs with radiographic evidence of intestinal perforation (pneumoperitoneum). This classification scheme is useful in occasional circumstances, especially when one analyzes studies that evaluate NEC; readers should be wary of interventions that appear to influence stage I suspected disease without altering definitive NEC.

Treatment

No specific treatment approaches have influenced the outcome of NEC; therefore interventions are supportive and include fluid resuscitation, withholding feedings with gastric decompression; antibiotics to cover likely enteric pathogens; correction of acidosis, anemia, and thrombocytopenia; and blood pressure support. Whereas blood cultures are positive in approximately 30% of NEC cases and are thought to reflect a breakdown in the mucosal barrier leading to bacterial translocation, intraluminal enteric bacterial pathogens are thought to contribute to the pathophysiology (see later).[66] Antibiotic coverage in this condition typically includes ampicillin and an aminoglycoside or third-generation cephalosporin, although only occasionally. Staphylococcal species are heavy colonizers of the intestinal tract, and nafcillin or vancomycin should be considered. In situations with suspected or proven intestinal perforation, aggressive anaerobic coverage with clindamycin is often added. Although routine treatment with NPO and antibiotics in uncomplicated medical NEC usually proceeds for 7 to10 days, length of treatment has not been carefully studied, and a recent report has suggested earlier refeeding after ultrasonographic evidence of portal venous air has resolved.[16]

Surgical intervention for NEC is required in 30% to 50% of cases reported, although the approach and timing of these procedures remain controversial. Most physicians agree that intestinal perforation in a patient with NEC requires surgery, but based on three recent clinical trials, patients treated with a peritoneal drain had similar rates of death and short-term intestinal function as those undergoing definitive laparotomy.[15,80,101] In surgical trials for NEC treatment, almost 50% of cases treated with a drain never required a second procedure.[37] In patients without perforation but with worsening disease as manifested by abdominal discoloration and distention, persistent thrombocytopenia and acidosis, and respiratory failure, exploratory laparotomy is often undertaken to remove a discrete segment of necrotic bowel, or to confirm the viability of enough remaining intestine to sustain life. Nonetheless, the timing and utility of these procedures in these complex cases has not been adequately studied.

Outcome

Approximately 30% of patients with radiologic evidence of pneumatosis intestinalis have mild disease and require a period of bowel rest but no surgical intervention. Another 30% of patients eventually die of the disease, with most presenting acutely with rapid deterioration and death. Survivors of NEC have a significant risk for intestinal stricture; in some reports, partial bowel obstruction will develop in as many as 25% in weeks or months following the initial presentation. Short bowel syndrome from NEC develops in some patients; postsurgical patients have an incidence of short bowel syndrome as high as 11%, and these patients are an extremely difficult group to care for. Novel medical and surgical interventions have made only modest improvements in the morbidity and mortality rates associated with this dreaded complication. Of concern, accumulating data suggest that the neurodevelopmental outcome of NEC patients is significantly worse than their gestational age/birthweight-matched controls with similar respiratory disease.[129] The morbidity includes mental retardation as well as an increased incidence of cerebral palsy, hypothetically related to white matter injury from cytokine mediators involved in the systemic inflammatory cascade.[130] Further studies are needed to confirm this association and to clarify the significance of these important results. Nonetheless, NEC is a major financial burden nationwide, with increased initial hospital costs (due primarily to longer length of stay) of \$60,000 for a case of medical NEC and up to \$200,000 per patient for surgical disease.[14] Based on the current epidemiology, this projects an annual cost burden of \$1 billion to the US health care industry without taking into account the long-term care issues associated with impaired survivors.

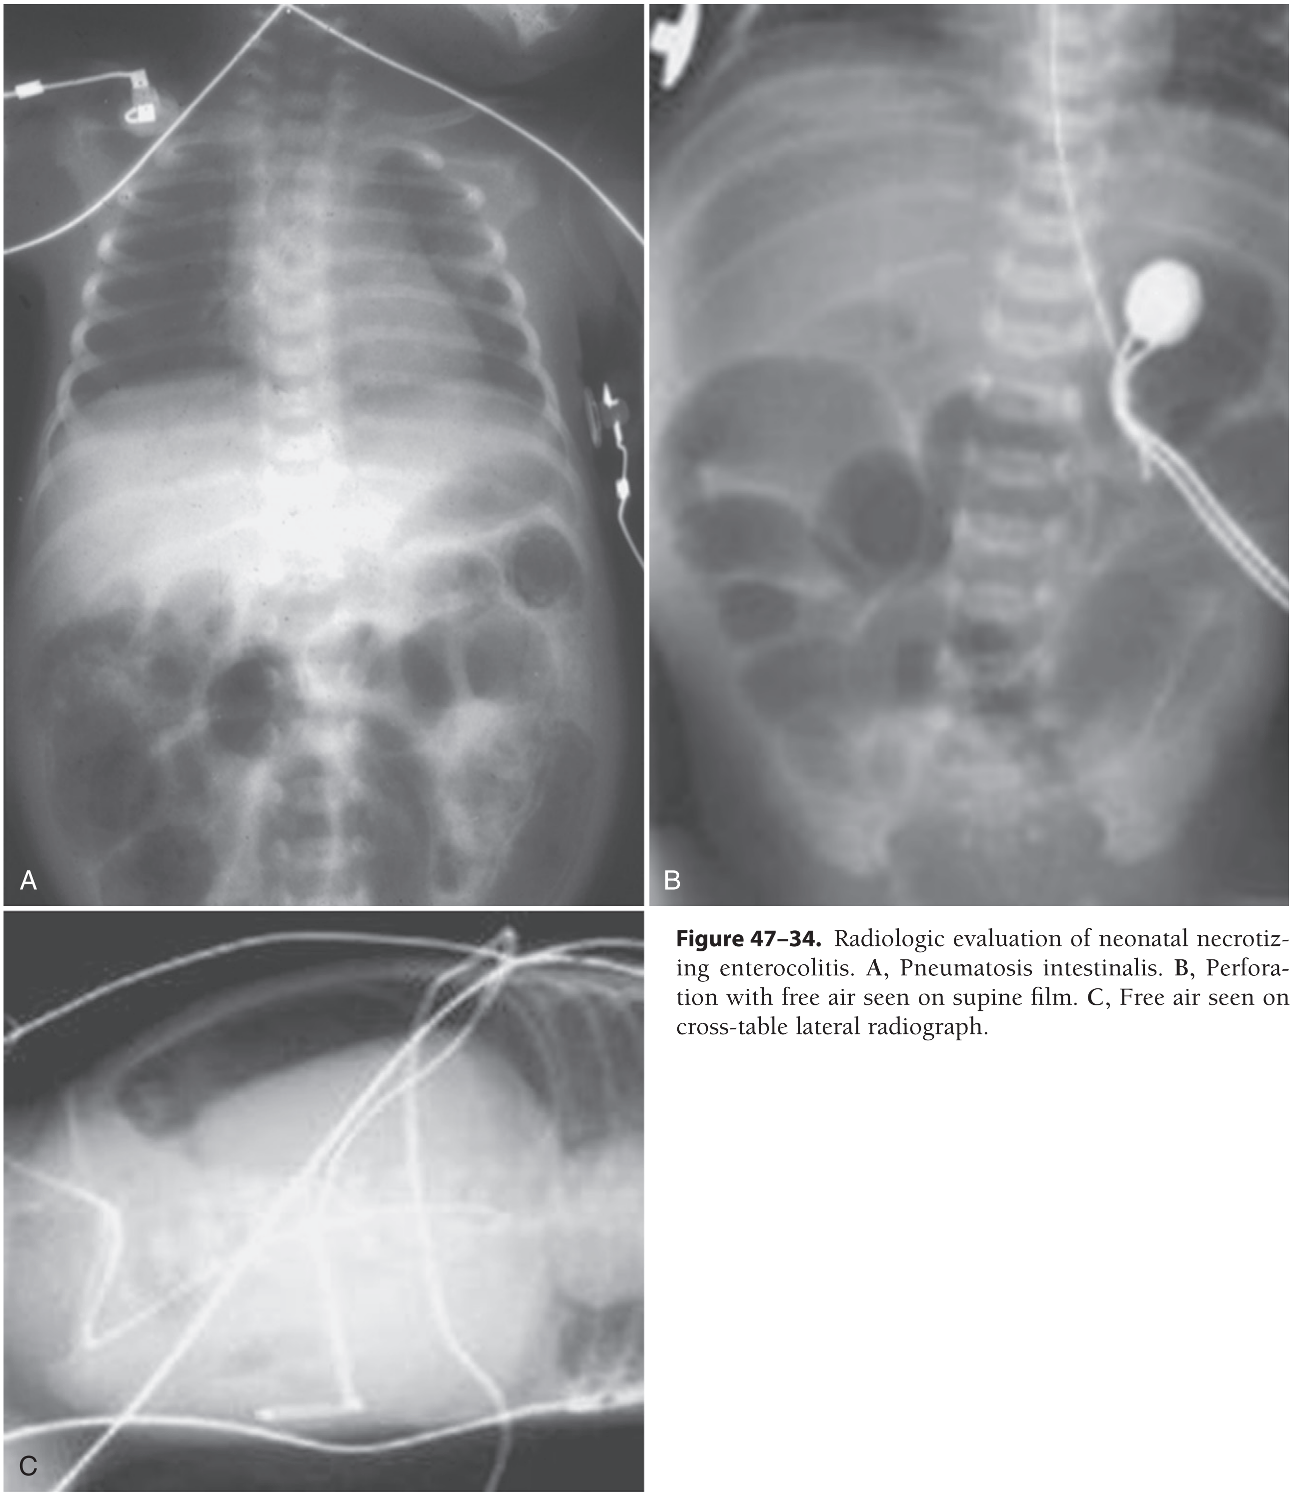

Figure 47–34. Radiologic evaluation of neonatal necrotizing enterocolitis. **A**, Pneumatosis intestinalis. **B**, Perforation with free air seen on supine film. **C**, Free air seen on cross-table lateral radiograph.

Pathology

Clues to the etiology are suggested by the pathologic changes observed in surgical specimens and autopsy material, including coagulation necrosis (suggesting some component of ischemic injury), inflammation (acute and/or chronic), and less commonly, ulceration, hemorrhage, reparative change, bacterial overgrowth, edema, and pneumatosis intestinalis.[5]

PATHOPHYSIOLOGY

Although the specific etiology of NEC is still controversial, epidemiologic analyses of this disease have identified key risk factors of prematurity, enteral feeding, intestinal ischemia/asphyxia, and bacterial colonization. Studies have begun to delineate the mechanisms that link these risk factors to the final common pathway of bowel necrosis. It has been

TABLE 47–8 Modified Bell Staging Criteria for Necrotizing Enterocolitis

Stage	Classification	Clinical Signs	Radiologic Signs
I	Suspected NEC	Abdominal distention Bloody stools Emesis/gastric residuals Apnea/lethargy	Ileus/dilation
II	Proven NEC	As in stage I, plus: Abdominal tenderness ±Metabolic acidosis Thrombocytopenia	Pneumatosis intestinalis and/or portal venous gas
III	Advanced NEC	As in stage II, plus: Hypotension Significant acidosis Thrombocytopenia/disseminated intravascular coagulation Neutropenia	As in stage II, with pneumoperitoneum

Modified from Walsh MC, Kliegman RM: Necrotizing enterocolitis: treatment based on staging criteria, *Pediatr Clin North Am* 33:179, 1986.

suggested that mucosal injury associated with impaired host defense leads to the activation of the inflammatory cascade with subsequent intestinal injury, occasionally associated with the systemic inflammatory response syndrome.

Prematurity

Greater than 90% of NEC cases occur in premature infants; there is consistently a higher risk with lower gestational age and birthweight,[77,106,126] and prematurity is the most consistent and important risk factor. Even though there are many known differences between preterm and full-term neonates, the specific underlying mechanisms responsible for this predilection of NEC in the premature condition remain incompletely elucidated. Studies in humans and animals have identified alterations in multiple components of intestinal host defense,[11,46,131] motility,[8,17] bacterial colonization,[20,25,34,38,39] bloodflow regulation,[87] and inflammatory response[19,41,84] that may contribute to the development of intestinal injury in this unique population.

Enteral Feeding

Because most cases of NEC occur after feedings have been introduced (>90%), enteral alimentation is a significant risk factor for disease in premature infants. Historical reports identified the onset of NEC several days following the first feeding, but in studies of infants with extremely low birthweight, NEC may be diagnosed several weeks after initiating enteral supplementation.[126] This change may reflect current neonatal practice, which typically uses early trophic or hypocaloric feedings, characterized by small volumes and slow rates of increase, without a significant impact on the development of NEC.[40,124] While the precise relationship between enteral feedings and NEC remains poorly understood, studies have identified the importance of breast milk (versus formula), volume and rate of feeding advancement, osmolality, and substrate fermentation as important factors.[36,65,125]

Breast milk feeding appears to reduce the incidence of NEC in human studies and in carefully controlled animal models.[20,53,77] Breast milk contains multiple bioactive factors that influence host immunity, inflammation, and mucosal protection, including secretory IgA, leukocytes, lactoferrin, lysozyme, mucin, cytokines, growth factors, enzymes, oligosaccharides, and polyunsaturated fatty acids, many of which are absent in neonatal formula preparations (Table 47-9). Specific intestinal host defense factors acquired from breast milk such as epidermal growth factor (EGF), polyunsaturated fatty acid, platelet-activating factor (PAF)-acetylhydrolase, IgA, and macrophages are effective in reducing the incidence of disease in animals,[23,26,41,98] and some have been effective in limited human trials.[43] Nonetheless, breast milk is not completely protective against NEC in premature infants; the largest prospective trial identified a reduction by 50% in most birthweight-specific groups, although there was not a statistically significant reduction in disease observed in a randomized subset from this cohort.[67,77] Due to ethical considerations, it seems unlikely that such an investigation will be accomplished, although there is renewed interest in evaluating donor milk samples and alternative human milk preparations in this context.[110] Because most premature infants receive breast milk via the nasogastric route after artificial collection by mothers and subsequent freezing, it has been suggested that the lack of the normal maternal-infant physical interaction during feeding interferes with specific milk immunity, thereby reducing the protection against the neonate's unique microbial flora. The particular microbial profile in the neonate's intestinal environment may contribute to initiation of NEC (see later).

TABLE 47–9 Factors in Breast Milk That May Influence Pathophysiology of Necrotizing Enterocolitis

Molecule	Effective in Animal Model	Effective in Human Trial

Erythropoietin	±	NA

NA = not applicable

Specific components of milk feedings have been implicated to cause mucosal injury in the high-risk neonate and to subsequently stimulate the development of NEC. Studies have shown that hyperosmolar formulas resulted in disease and that addition of medication to feedings can markedly increase osmolality.[135] Animal studies have shown that short chain fatty acids such as propionic or butyric acid can cause damage to developing intestine, and that colonic fermentation leading to production of these acids by the host microflora may occur in situations of carbohydrate malabsorption.[18,30,75]

This pathway may be especially problematic in the premature infant who is partially deficient in lactase activity and other brush border enzymes. Finally, an intriguing new hypothesis suggests that bile acid accumulation may lead to mucosal injury in the unique environment of the preterm neonate.[54]

Different approaches to feeding have been associated with the initiation of NEC. Early studies suggested that rapid volume increases with full-strength formula increased the incidence of disease, and protocols were designed to limit feeding advancement. Several studies have shown that early hypocaloric or trophic feedings are safe and improve gastrointestinal function in infants with very low birthweight.[40,111,124] Feeding advancement has been evaluated, and the results suggest that judicious volume increase may be safer.[9,65] It has been postulated that overdistention of the stomach with aggressive volumes may compromise splanchnic circulation, leading to intestinal ischemia. Nonetheless, there remains little clarity on the safety of differing feeding practices on the incidence of NEC, and additional trials are needed to answer this challenging question.

Intestinal Ischemia/Asphyxia

Early observations on the pathophysiology of NEC suggested that profound intestinal ischemia led to intestinal necrosis in unusual clinical situations.[3,122] Similar to the "diving reflex" observed in aquatic mammals, it was hypothesized that in periods of stress, bloodflow was diverted away from the splanchnic circulation resulting in bowel injury. While early epidemiologic observations identified asphyxia as an important risk factor, subsequent studies have shown that the majority of NEC cases are not associated with profound impairment in intestinal perfusion.[134] In animal models, studies have shown that the reperfusion following intestinal ischemia is required in the initiation of bowel necrosis[112]; occlusion of the mesenteric artery for a prolonged period of time results in only mild histologic changes atypical for full-blown NEC.

Neonatal animals have been shown to have differences in the intestinal circulation that may predispose them to NEC. The basal intestinal vascular resistance is elevated in the fetus, and soon following birth decreases significantly, allowing for rapid increase in intestinal bloodflow that is necessary for robust intestinal and somatic growth. It has been shown that this change in the resting vascular resistance is dependent on *the balance between* the dilator (nitric oxide), constrictor (endothelin) molecules, and the myogenic response,[82] and altered levels of these vasoactive mediators have been identified in human NEC samples.[88,89] Perhaps more relevant than basal vascular tone, studies have shown that the newborn has alterations in response to circulatory stress, resulting in compromised intestinal flow and/or vascular resistance. In response to hypotension, newborn animals (3-day-old but not 30-day-old swine) appear to have defective pressure-flow autoregulation, resulting in compromised intestinal oxygen delivery and tissue oxygenation.[87] In addition, in the face of arterial hypoxemia, the newborn intestinal circulatory response differs from that in older animals. Even though intestinal vasodilation and increased intestinal perfusion occur following modest hypoxemia, severe hypoxemia causes vasoconstriction and intestinal ischemia or hypoxia, mediated in part by loss of nitric oxide production. There are multiple chemical mediators (nitric oxide, endothelin, substance P, norepinephrine, and angiotensin) that impact on intestinal vasomotor tone, and in the stressed newborn, abnormal regulation of these may result in compromised circulatory autoregulation, leading to perpetuation of intestinal ischemia and tissue necrosis.[83,90]

Bacterial Colonization

Although reports have documented isolated epidemics of NEC associated with specific bacteria (e.g., *Clostridium* sp., *Escherichia coli*, *Klebsiella* sp., *Staphylococcus epidermidis*), most cases occur endemically and demonstrate a variety of bacterial isolates from stool cultures that are similar to the flora isolated from patients without intestinal symptoms.[39,97] Blood cultures are positive in only 20% to 30% of affected cases, and this likely occurs from mucosal damage and subsequent bacterial translocation. At birth, the intestine is a sterile environment, and no cases of NEC have been described in utero, supporting the importance of bacterial colonization in the pathophysiology. Healthy breast-fed infants develop colonization with several organisms by 1 week of age, including a predominance of anaerobic species of *Bifidobacterium* and *Lactobacillus*, while the hospitalized, extremely premature infant intestine has less species diversity and fewer or absent anaerobes.[47,105,121,137] This imbalance may allow for pathologic proliferation, binding, and invasiveness of otherwise nonpathogenic intestinal bacteria, and a reduction in anti-inflammatory effects and mucosal defense that has been attributed to probiotic organisms.[132] Evidence suggests that contamination or colonization of nasogastric feeding tubes in formula-fed premature infants predisposes some infants to develop NEC.[79] The specific mechanisms by which bacteria initiate NEC remain unclear; mounting evidence suggests that bacterial cell wall products (e.g., endotoxin and lipoteichoic acids) activate specific toll-like receptors on intestinal epithelium and activate the inflammatory cascade leading to the final common pathway of intestinal injury.[13,34,35,138] Nonetheless, certain bacteria such as adherent *E. coli* produce disease in a rabbit model of NEC, whereas nonpathogenic strains of gram-positive organisms prevent disease.[95] Furthermore, accumulating evidence suggests that early colonization by probiotics (facultative anaerobes, e.g., bifidobacteria and lactobacilli) reduces the risk of NEC in animal and human studies, which is discussed further in a subsequent section.[25,56] In summary, bacterial colonization is an important factor in the initiation of intestinal injury, but the specific events in the pathophysiology are not well delineated.

FINAL COMMON PATHWAY: IMBALANCE BETWEEN MUCOSAL INJURY AND HOST DEFENSE/REPAIR WITH ACTIVATION OF THE PROINFLAMMATORY CASCADE

It has been suggested that mild or moderate stress or injury to intestinal epithelium (e.g., from feeding, intestinal ischemia, or bacterial products) without adequate host defense and repair can activate the inflammatory response leading to intestinal injury and NEC.

Host Defense

Gastrointestinal host defense is markedly impaired in the preterm infant, and this imbalance further increases the risk for injury in this population. This intricate system includes (1) physical barriers such as skin, mucous membranes, intestinal epithelia and microvilli, epithelial cell tight junctions, and mucin, (2) immune cells such as polymorphonuclear leukocytes, macrophages, eosinophils, and lymphocytes, and (3) multiple biochemical factors.* Intestinal permeability to macromolecules including immunoglobulins, proteins, and carbohydrates is known to be greater in the neonate than in older children and adults, and in premature infants this permeability may be more pronounced. Intestinal mucus, a complex gel consisting of water, electrolytes, mucins, glycoprotein, immunoglobulins, and glycolipids, protects against bacterial and toxin invasion, and is abnormal in developing animals and perhaps premature infants.[68,114] Additionally, key bacteriostatic proteins are secreted from epithelium that bind to or inactivate the function of invading organisms. Intestinal trefoil factor is one such molecule that appears to be developmentally regulated and, therefore, deficient in the premature neonate.[74,109,119] Human defensins (or cryptidins) are bacteriostatic proteins synthesized and secreted from paneth cells that protect against bacterial translocation and are altered in premature infants and those with NEC.[92,107]

Immunologic host defense is abnormal in developing animals.[50,96,102] It is known that intestinal intraepithelial lymphocytes (IEL) are decreased in neonates (B and T cells), and do not approach adult levels until 3 to 4 weeks of life. Newborns have markedly reduced secretory IgA in salivary samples, reflecting the decreased activity presumed in intestine.[43,104] Breast milk feeding provides significant supplementation; formula fed neonates have impaired intestinal humoral immunity, and this deficiency may predispose to the increased incidence of infectious diseases and NEC noted in this population.[128,137]

Several biochemical factors that are present in the intestinal milieu play an important role in the maintenance of gut health and integrity. Substances such as lactoferrin,[71] glutamine,[85] growth factors such as EGF,[41] HB-EGF,[44] TGF,[86] insulin-like growth factor (IGF),[103] and erythropoietin,[62,70] gastric acid, oligosaccharides,[32] polyunsaturated fatty acids,[26] and nucleotides,[120] among others, affect mucosal barrier function, intestinal inflammation, and the viability of intraluminal bacteria. Many of these factors are deficient or absent in the preterm neonate, especially in those patients not receiving breast milk feedings.

Based on a growing body of evidence, mucosal stress coupled with inadequate host defense and repair can result in a final common pathway of intestinal injury involving the activation of the inflammatory cascade.[22,24,57] This cascade involves a complex balance of pro- and anti-inflammatory endogenous mediators, receptors, signaling pathways, second messengers, and a variety of downstream effects that ultimately results in end-organ damage in certain clinical circumstances. *Inflammation can be* initiated by a variety of factors, the prototype most commonly described by exposure to the bacterial cell wall product, endotoxin. It has now been clearly shown that bacterial pathogens initiate downstream events following the binding of specific pathogen-associated molecular patterns to a series of human toll-like receptors (TLRs) that are expressed on most cells in the body.[1,2] For example, endotoxin or lipopolysaccharide, the cell wall product of gram-negative bacteria, binds to and activates TLR4, which is normally downregulated on the surface of intestinal epithelium but which has been shown to be abundantly expressed in stressed animals and human neonates.[61,69] Additional work has shown that TLR4 dysfunction reduces the risk of experimental NEC in neonatal mice. Following TLR4 activation, a series of signaling events occurs, allowing for activation of nuclear factor kappa B (NFκB) and translocation into the nucleus with subsequent production of a variety of cytokines including PAF, tumor necrosis factor (TNF), IL-1, and IL-8.[7,78,84,91,100,123] In intestine, subsequent events lead to chemotaxis, transmigration, and activation of leukocytes, as well as synthesis and release of many products from epithelial and inflammatory cells such as IL-6, IL-8, IL-10, IL-18, arachidonic acid metabolites, thromboxanes, leukotrienes, prostaglandins, nitric oxide, endothelin-1, and oxygen free radicals.* If counter-regulatory responses are insufficient (e.g., with decreased or absent IL-1 receptor antagonist, IL-11, IL-12, PAF-acetylhydrolase, IκB leading to increased NFκB), pathologic changes to gut mucosa occur and may include accentuated apoptosis of epithelial cells, perturbation of tight junctional proteins and complexes, increased mucosal permeability, bacterial translocation, alterations of vascular tone and microcirculation, and additional neutrophil infiltration and accumulation (Fig. 47-35). This process may then be perpetuated by the activation of the secondary inflammatory response, and the final common pathway will result in intestinal necrosis. While these events remain localized in some cases, in others this activation results in the systemic inflammatory response syndrome, in which patients develop capillary leak, hypotension, metabolic acidosis, thrombocytopenia, renal failure, respiratory failure, and often, death.[117] In summary, proinflammatory signaling follows TLR4 activation on the intestinal epithelium and leads to a cascade culminating in intestinal necrosis in neonatal animals, similar to that in humans, neonatal NEC.

---

Although endotoxin is a well-characterized activator of inflammation, additional factors may play a role in stimulating the NEC cascade in premature infants. Asphyxia or ischemia-reperfusion activate the early mediators of inflammation in many tissues including intestine. Neonatal animal studies have shown that the stress of formula feeding stimulates phospholipase A_2 gene expression, intestinal PAF production, and stimulation of apoptosis and the inflammatory response with resulting NEC.[21,22] Therefore many of the purported risk factors for NEC may activate the inflammatory response, which results in the final common pathway described earlier.

The evidence suggests that the premature neonate may have an abnormal balance between proinflammatory and anti-inflammatory mediator regulation, thereby increasing the predisposition for diseases such as NEC. PAF is a potent phospholipid inflammatory mediator that is associated with NEC in several experimental models and human analyses.[28,29,48,58,99] PAF infusion causes intestinal necrosis in animals, and PAF receptor antagonists prevent injury following hypoxia, endotoxin challenge, TNF infusion, and ischemia-reperfusion.[27,81,116] It has been shown that neonates are markedly deficient in their ability to degrade PAF due to decreased activity of the PAF-specific enzyme PAF-acetylhydrolase.[19] PAF-acetylhydrolase is present in breast milk but absent in commercial formula, which may in part account for the beneficial effects of breast milk feeding. IL-10 is an anti-inflammatory cytokine thought to be important in reducing intestinal inflammation and possibly NEC in animals and humans.[42,76] In neonatal rats, maternal milk feedings increased IL-10 and reduced the incidence of NEC, while in human milk specimens, a significant percentage of NEC patient-pairs were deficient in this

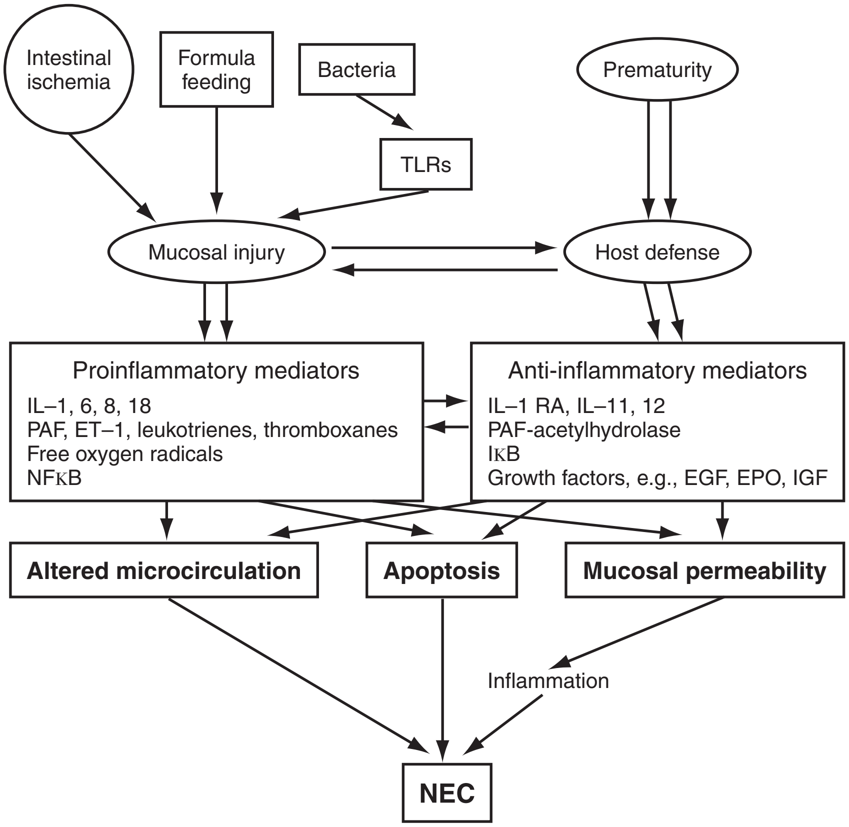

Figure 47–35. Hypothetical events in the pathophysiology of neonatal necrotizing enterocolitis (NEC). EGF, epidermal growth factor; EPO, erythropoietin; ET, endothelin; IGF, insulin-like growth factor; IL, interleukin; PAF, platelet activating factor; TLR, toll-like receptors.

important cytokine. Studies have compared proinflammatory response to endotoxin and/or IL-1 in different cell lines and have found that IL-8 response is significantly higher in fetal intestinal epithelium compared with mature, adult intestine.[84] These results suggest that the neonatal balance of the inflammatory response may be weighted toward the proinflammatory side and may be more likely to result in the pathologic outcome of NEC.

PREVENTION OF NEONATAL NECROTIZING ENTEROCOLITIS

Based on the unique epidemiologic features and understanding of the pathophysiology, there have been multiple approaches attempted to prevent NEC in animal and human studies. Human prevention trials with sufficient power to demonstrate a reduction in NEC incidence from 10% to 5% (e.g., in babies born weighing less than 1500 g) would require a large number of patients, approximating 350 patients per treatment group. Reduction of disease in animal models has been shown with breast milk feeding, IgA supplementation, antibiotic prophylaxis, steroids, probiotics, polyunsaturated fatty acids, PAF antagonists, PAF-acetylhydrolase, EGF, trefoil factor, leukocyte depletion, and oxygen radical scavengers. In human studies, there remains no standard effective alternative for NEC prevention, although careful enteral feeding with breast milk is the best approach that neonatologists have to offer. Prevention trials with IgA/IgG,[43] steroids,[51] polyunsaturated fatty acids, arginine,[4] and antibiotics[113] have been conducted with limited success, but because of various problems including poor study design, risks of intervention, lack of reproducibility, and weak statistical power, these approaches have yet to become routine strategies in the neonatal intensive care unit for preterm infants.

Probiotic supplementation is a promising approach for the prevention of NEC in infants with very low birthweight. There have now been several international prospective randomized trials that demonstrate efficacy for probiotic prophylaxis for this indication, and additional trials in the United States are planned to confirm these findings (Table 47-10).* As described earlier, probiotic colonization in infants with very low birthweight appears inadequate, and studies have defined multiple plausible mechanisms whereby probiotics could improve gastrointestinal health and prevent proinflammatory signaling and disease. As seen in Table 47-10, five of the six recent studies showed a reduction in NEC, and although the specific probiotic species and dosing varied somewhat, the cumulative results identified a reduction in NEC from 142 in 2143 controls (6.6%) to 53 in 2093 treated (2.5%, $P < .01$). Of additional importance, probiotics reduced the incidence of death in this vulnerable population ($P < .05$), and there were no reported cases of probiotic sepsis in any of these cohorts.

Although there is much excitement and appropriate optimism regarding this promising strategy, there are several important reasons why additional studies are warranted before clear standard-of-care can be recommended. First, different probiotic species have differing effects, and the optimal probiotic combination and optimal dosing strategy are not clearly elucidated. Second, probiotic preparations have not been rigorously regulated, and because some studies have shown inaccuracies in the reported organism species and content, appropriate quality control measures are warranted. Finally, although probiotic sepsis has not been observed in this unique population, additional safety concerns have been raised with recent reports demonstrating increased death in an adult population of patients in intensive care units, and increased wheezing and asthma in pediatric patients treated in the newborn period.[10,64] Nonetheless, after a large, multicenter trial with similar efficacy and safety in infants with very low birthweight has been reported as in other countries, it is likely that in the United States this approach will soon become routine in neonatal intensive care units.

SUMMARY

In conclusion, NEC is an increasing clinical burden to patients, families, and the neonatology health care team. Although the diagnosis is straightforward, the morbidity and mortality associated with the disease are not improving. Risk factors of prematurity, formula feeding, intestinal ischemia/hypoxia, and bacterial colonization accentuate the imbalance toward mucosal stress with impaired host defense, in some cases leading to uncontrolled intestinal inflammation and necrosis. The premature infant differs from term infants and older patients in multiple ways, including enteral feeding characteristics, bacterial colonization patterns, autoregulation of splanchnic bloodflow, host defense, and the regulation of the inflammatory cascade.

TABLE 47–10 Randomized Trials for Probiotic Prophylaxis

	Hoyos 1999	Dani 2002	Lin 2005	Bin-Nun 2005	Lin 2008	Samanta 2008

Although several strategies to prevent NEC have been tested in humans and animals, most have had limited success. Recent results from studies using probiotic supplementation have been exciting, and following additional investigation, this novel approach may significantly impact the incidence, morbidity, and mortality associated with neonatal NEC.

CHAPTER 48

Neonatal Jaundice and Liver Disease

Michael Kaplan, Ronald J. Wong, Eric Sibley, and David K. Stevenson

Bilirubin is one of the biologically active end products of heme catabolism. Its clinical significance in the neonate relates to its propensity for deposition in the skin and mucous membranes, producing easily identifiable jaundice (French *jaune*, yellow) or icterus (Greek *ikteros*). The yellow color, or the serum (or plasma) total bilirubin (TB) concentration at any point in time, represents the combined processes of bilirubin production minus bilirubin elimination from the body, the latter primarily due to bilirubin conjugation. As long as these processes remain in balance, a moderate degree of jaundice should develop, which should not endanger an otherwise healthy, nonhemolyzing infant. An imbalance between bilirubin production and its elimination may result in increasing jaundice or hyperbilirubinemia. In rare cases, the degree of bilirubin production relative to bilirubin elimination may be so great that bilirubin may deposit in the brain, where it may cause transient dysfunction (acute bilirubin encephalopathy, or ABE) and, occasionally, chronic bilirubin encephalopathy with resultant permanent neuronal damage known as kernicterus. Because as many as 60% of otherwise healthy, term newborns develop some degree of elevated TB levels, whereas, in contrast, severe hyperbilirubinemia with its potentially devastating sequelae is rare, it is important to distinguish between normal processes of bilirubin physiology from pathologic conditions. All those caring for newborns should possess a thorough understanding of normal bilirubin physiology, on the one hand, and a healthy respect for the potential complications of severe hyperbilirubinemia, on the other.

BILIRUBIN METABOLISM

Bilirubin Biochemistry

Throughout life, there is a continuum of bilirubin production and elimination from the body. Ongoing lysis of red blood cells (RBCs) or hemolysis, whether physiologic or at increased rates, releases iron protoporphyrin (heme), the oxygen-carrying component of hemoglobin. Catalyzed by heme oxygenase (HO), heme is then converted to biliverdin from which bilirubin is derived. This unconjugated bilirubin is transported to the liver bound to albumin (Fig. 48-1). In the hepatocyte, bilirubin is conjugated to glucuronic acid by the enzyme uridine diphosphoglucuronate (UDP)-glucuronosyltransferase 1A1 (UGT1A1). This water-soluble conjugated bilirubin can be now excreted into the bile, from which it reaches the bowel and is eliminated from the body.[182] This simplified overview of bilirubin biochemistry will be reviewed in greater detail in the pages to come.

Heme oxygenase-1 (HO-1), the inducible isoform of HO, a membrane-bound enzyme found in cells of the liver and other organs, catalyzes the first step in the pathway by which heme is converted to biliverdin through oxidation of the former molecule's α-methene bridge carbon (Fig. 48-2). This rate-limiting step produces free iron (which can be reutilized for hemoglobin synthesis) and carbon monoxide (CO) (which is excreted in the lungs) in equimolar amounts. Biliverdin is a blue-green water-soluble pigment that can be readily excreted by the liver and kidneys. In amphibians, reptiles, and certain avian species, the major pigmented end product of heme catabolism is biliverdin. In mammals, however, biliverdin is converted to bilirubin by biliverdin reductase in the cytosol.

The degradation of 1 g of hemoglobin forms 34 mg of bilirubin. The isomeric form of bilirubin formed by this two-step process is IX-α (the Z,Z isomer), defining the relative positions of the four pyrrole rings and the hydrogen molecules on the two linking lateral carbons. This form of bilirubin is insoluble owing to tertiary structural changes that internalize the keto and carboxy groups that would otherwise interact with water molecules. Intramolecular hydrogen bonding maintains this folded bilirubin structure.

Because bilirubin is a weak acid and is neither water soluble nor readily excreted at pH 7.4, it must be conjugated to

Figure 48–1. Metabolic pathway of the degradation of heme and the formation of bilirubin. Heme released from the hemoglobin of red blood cells or from other hemoproteins is degraded by heme oxygenase (HO), the first and rate-limiting enzyme in a two-step reaction requiring nicotinamide adenine dinucleotide phosphate (NADPH) and oxygen, and resulting in the release of iron and the formation of carbon monoxide (CO) and biliverdin. Metalloporphyrins, synthetic heme analogues, can competitively inhibit HO activity (indicated by the *X*). Biliverdin is further reduced to bilirubin by the enzyme biliverdin reductase. CO can activate soluble guanylyl cyclase (sGC) and lead to the formation of cyclic guanosine monophosphate (cGMP). It can also displace oxygen from oxyhemoglobin or be exhaled. The bilirubin that is formed is taken up by the liver and conjugated with glucuronides to form bilirubin monoglucuronide or diglucuronide (BMG and BDG, respectively), in reactions catalyzed by uridine diphosphoglucuronate glucuronosyltransferase (UGT). The bilirubin glucuronides are then excreted into the intestinal lumen but can be deconjugated by bacteria so that the bilirubin is reabsorbed into the circulation, as shown. Figure 48–2. Catabolism of heme to bilirubin by microsomal heme oxygenase and biliverdin reductase. (*From Tenhunen R, et al: The enzymatic conversion of hemoglobin to bilirubin,* Trans Assoc Am Physicians *82:363, 1969.)*

glucuronic acid before excretion by the specific hepatic enzyme isozyme (UGT1A1).[112] What evolutionary advantage is derived by mammalian species in the development of such an intricate energy-dependent system that first produces bilirubin from a water-soluble precursor and then converts it back to a water-soluble form for excretion is presently uncertain. The mammalian placenta is capable of removing unconjugated bilirubin, but not biliverdin. Biliverdin accumulation in the mammalian fetus would presumably result in the accumulation of large amounts of potentially toxic heme metabolites. Evidence has shown that bilirubin and even CO may be biologically useful molecules.[144,205] The inducibility of HO-1 would appear to indicate that bilirubin production is helpful to cells when they are stressed.[69] Bilirubin is an antioxidant that readily binds to membrane lipids and is capable of limiting membrane damage by preventing their peroxidation. Biologic evidence of potentially beneficial effects of bilirubin, on the one hand, is tempered by the association of high levels of unconjugated bilirubin with neuronal dysfunction and necrosis, on the other. Although cells may be potential beneficiaries of small amounts of bilirubin, in greater circulating quantities the same bilirubin molecule may be a causative factor of severe neuronal damage. The dilemma that faces the clinician is determining the desirable or "safe" level of bilirubin appropriate for any particular neonate.

The CO formed by heme degradation binds to hemoglobin to form carboxyhemoglobin (COHb) and is then transported in the circulation to the lung. Here, the CO separates from hemoglobin and is excreted in exhaled breath. Although there are other potential endogenous and exogenous sources of CO, such as lipid peroxidation and photo-oxidation,[236] the main source of endogenous CO is derived from heme catabolism. Therefore, quantitative estimation of its synthesis or excretion (in infants without significant lung disease or oxygen exposure) offers a reasonably accurate assessment of the rate of heme degradation from which the rate of bilirubin synthesis can be derived. It is believed that other hemoproteins undergo the same degradative process.

Bilirubin Production

The pathway of bilirubin synthesis, transport, and metabolism is summarized in Figure 48-3. In the normal adult, bilirubin is derived primarily from the degradation of heme, which is released from senescing RBCs, in the reticuloendothelial cells. Normally, about 20% of the bilirubin excreted into bile is derived from erythrocyte precursors and other hemoproteins (mainly cytochromes, catalase). Carbon monoxide excretion in humans and more direct measurements in animals have demonstrated that, on the first day of life, bilirubin production is increased two to three times the rate of adults, to an estimated average of 8 to 10 mg/kg of body weight per day.[204,232] Bilirubin production decreases rapidly during the first 2 postnatal days.[114] Several factors may explain this increased production in the newborn. The circulating RBC life span is shortened to 70 to 90 days compared with 120 days in the adult. Increased heme degradation arises from the very large pool of hematopoietic tissue, essential to intrauterine wellbeing, but which ceases to function shortly after birth. An additional factor may possibly include an increased turnover of cytochromes. Another major addition to the bilirubin pool in the neonate, in addition to increased synthesis, is an increase

in bilirubin absorbed from the bowel as part of the enterohepatic circulation. This mechanism results from both reformation of unconjugated bilirubin from conjugated bilirubin in the bowel and enhanced absorption of unconjugated bilirubin by the intestinal mucosa (see "Enterohepatic Absorption of Bilirubin," later).

Transport of Bilirubin in Plasma

Unconjugated bilirubin is almost insoluble in water at pH 7.4, with a solubility of less than 0.01 mg/dL, and when released into the circulation by the reticuloendothelial cells, it is rapidly bound to albumin. Each molecule of adult albumin is capable of binding at least two molecules of bilirubin; the first molecule is more tightly bound than the second. Additional binding sites with weaker affinities may also exist but are probably of little clinical importance. On average, 7 to 8 mg/dL of unconjugated bilirubin can be bound to each gram of albumin. Physiologically, newborns have a lower plasma-binding capacity for bilirubin compared with adults or older children. This occurs because of reduced neonatal serum albumin concentrations and reduced molar binding capacities. Binding of unconjugated bilirubin by albumin is believed to be of some importance in determining bilirubin toxicity to the brain and neural tissue (acute bilirubin encephalopathy or kernicterus and auditory neuropathy). The unbound bilirubin concentration is thought to be a more sensitive predictor of bilirubin neurotoxicity than the clinically used TB.[249] However, there is currently no reliable and clinically available measurement to make determination of unbound concentrations a useful clinical tool in evaluating the risk to the newborn for developing bilirubin toxicity.

Bilirubin exists in four different forms in circulation: (1) unconjugated bilirubin reversibly bound to albumin, which makes up the major portion; (2) a relatively minute fraction of unconjugated bilirubin not bound to albumin (known as free or unbound bilirubin); (3) conjugated bilirubin, comprising mainly monoglucuronides and diglucuronides, which have effluxed from the hepatocyte to the circulation and which are readily excretable through the renal or biliary systems; and (4) conjugated bilirubin covalently bound to albumin, known as δ-bilirubin. The latter has a plasma disappearance rate similar to that of serum albumin (Fig. 48-4).[33] Conjugated bilirubin, but not δ-bilirubin, gives a "direct" reaction with standard diazo reagents, whereas bound or unbound unconjugated bilirubin yields an "indirect" reaction. The terms indirect and direct bilirubin tend to be used interchangeably with unconjugated and conjugated bilirubin, respectively. δ-Bilirubin can be measured only with newer techniques. It is found in detectable amounts in normal older neonates and children, and in significantly increased concentrations in those with prolonged conjugated hyperbilirubinemia resulting from various liver disorders.[34] However, it is virtually absent from the serum during the first 2 weeks of life.[129]

Hepatic Uptake of Bilirubin

Bilirubin dissociates from circulating albumin before entering the liver cell. The latter process occurs partly by a passive process of carrier-mediated diffusion, and partly by mediation by organic anion transporter proteins (OATP). In the liver cell cytoplasm, the unconjugated bilirubin is bound to glutathione-S-transferase A, also known as ligandin, or with B-ligandin (Y protein). These are major intracellular transport proteins, and their bilirubin binding ability helps keep the potentially toxic unbound portion low. Z protein, another hepatic cytoplasmic carrier, also binds bilirubin but with a lower affinity. The equilibrium between the rates of bilirubin entry into the circulation, from de novo synthesis, enterohepatic recirculation and tissue shifts, on the one hand, and hepatic cell bilirubin uptake, conjugation of bilirubin and conjugated bilirubin excretion, on the other, determines the TB concentrations under both normal and abnormal circumstances.

A reduced capacity of net hepatic uptake of unconjugated bilirubin has been implicated in the development of physiologic jaundice. In the newborn monkey, deficiency of B-ligandin and reduced clearance of sulfobromophthalein were demonstrated in the first 3 days of life, the period during which this animal frequently has physiologic jaundice. Studies in the human indicate that deficiency of bilirubin uptake is probably of less importance in the pathogenesis of unconjugated hyperbilirubinemia than immaturity of the bilirubin conjugation system during the first 3 or 4 days of life. However, the relative contribution of uptake deficiency may be greater during the second week of life when the rate of bilirubin conjugation increases and approaches that of normal adults.[199]

Conjugation of Bilirubin

In order for bilirubin to be excreted into the bile, the nonpolar, water-insoluble unconjugated bilirubin must be converted to a more polar, water-soluble substance. The aim of this process is to alter the bilirubin molecule by solubilizing bilirubin IX-α. Bilirubin is presumed to be transported by hepatic ligandin from the liver cell plasma membrane to the endoplasmic reticulum, at which site the conjugating enzyme, UGT1A1, is situated. The conjugation process comprises a two-step enzymatic process, in which each molecule of bilirubin is conjugated with two molecules of glucuronic acid. Glucuronic acid derives from activated uridine diphosphoglucuronic acid (UDPGA), itself synthesized by the soluble cytoplasmic enzyme uridine diphosphoglucose dehydrogenase from uridine diphosphoglucose, which, in turn, is synthesized from free glucose. The UGT1A1 enzyme first catalyzes the transfer of one glucuronic acid molecule from one of the two propionic acid side groups on one of the central pyrrole rings of bilirubin, in an ester linkage, to form bilirubin monoglucuronide. A reduction in enzyme activity to less than 1% of normal may result in unconjugated hyperbilirubinemia.

Although bilirubin monoglucuronide is water soluble and capable of being excreted into bile without further alteration, about two thirds of the total bilirubin excreted into bile in the adult human is in the form of a diglucuronide. The second step of the enzymatic conjugation process involves the esterification of a second glucuronide molecule to the now monoconjugate. This process is catalyzed primarily by the same UGT1A1 enzyme on the endoplasmic reticulum, although a second enzyme, located in the canalicular portion of the hepatocyte plasma cell membrane, UDP-glucuronate glucuronosyltransferase (transglucuronidase), may also play a role. The substrate for the canalicular transglucuronidation is believed to be bilirubin monoglucuronide. The enzyme transfers one molecule of glucuronic acid from one molecule of bilirubin monoglucuronide to another, resulting in the formation of one molecule of bilirubin diglucuronide. The latter molecule is excreted into the bile canaliculus, whereas the remaining molecule of now unconjugated bilirubin is returned to the endoplasmic reticulum for subsequent reconjugation. In circumstances such as severe chronic hemolysis, increased loads of bilirubin are delivered to the liver, which results in retention of conjugated bilirubin in the form of bilirubin monoglucuronide.

The result of the esterification is to disrupt the intramolecular hydrogen bonds, thereby opening the molecule and rendering the conjugated bilirubin water soluble. The water-soluble form of bilirubin is excretable in the bowel. Water solubility also decreases the amount of bilirubin reabsorbed from the bowel because hydrophilic agents do not pass through the intestinal wall easily.[72]

In the normal adult, glucuronide conjugation accounts for the disposal of about 90% of all bilirubin. The remaining portion is converted to water-soluble substances by conjugation with substances other than glucuronic acid, or by oxidation, hydroxylation, or reduction. In humans, bilirubin forms a conjugate with glucose, xylose, possibly other carbohydrates, sulfates, and taurine. These nonglucuronide conjugates account for no more than 10% of the total bilirubin conjugates excreted in the bile.

A number of in vitro studies have demonstrated the existence of deficiencies in hepatic UGT activity in newborns of many species, including the human. In newborn rhesus monkeys, hepatic bilirubin conjugating capacity is extremely low during the first hours of life, and functions at about 5% of adult capacity (Fig. 48-5). However, by 24 hours of age, UGT activity increases sufficiently to process the bilirubin load presented to the liver, and the TB concentration begins to fall. In 1-day-old rats, the proportion of both xylose and glucose conjugates of bilirubin equals that of glucuronide conjugates. Total conjugating capacity increases to the adult level by the fourth day of life, when a mature pattern of glycoside distribution is present, with 75% of all conjugates being glucuronides. In human newborns, the monoglucuronide conjugate is the predominant bile pigment conjugate. UGT activity in term infants is about 1% of that of healthy adults, and increases at an exponential rate until 3 months of age, when adult levels are reached.[172] Nonglucuronide conjugates are insignificant in this period.[124]

Excretion of Bilirubin

Excretion of the now polar, water-soluble bilirubin appears to be an energy-dependent concentrative process. The bilirubin conjugates are incorporated into mixed micelles along with bile acids, phospholipids, and cholesterol.[72] The conjugates are excreted against a concentration gradient, and as a result, bile bilirubin concentration is about 100-fold that of the hepatocyte cytoplasm. Although the capacity for bilirubin excretion into bile is limited in newborn rhesus monkeys (Fig. 48-6), excretory deficiency is not a rate-limiting factor in the overall hepatic elimination of bilirubin in the human newborn. In newborn babies, bilirubin uptake into the hepatocyte and the enzyme-mediated conjugation processes are the more restrictive steps and may result in a "bottleneck" effect. By contrast, in older humans and in the mature rhesus

monkey and other mammals beyond the newborn period, hepatic excretion of conjugated bilirubin into bile predominates as the rate-limiting step in the presence of a large bilirubin load. At any age, in the presence of hepatic cell injury and biliary obstruction, hepatic excretory transport is the step most severely restricted, resulting in efflux of conjugated bilirubin from the hepatocyte to the serum with resultant conjugated hyperbilirubinemia. Thus, the hepatic excretory step may have the least reserve capacity of all the processes contributing to bilirubin elimination.

Enterohepatic Absorption of Bilirubin

Conjugated bilirubin is not absorbed from the intestine. However, the monoglucuronides and diglucuronides of bilirubin are relatively unstable conjugates that are readily hydrolyzed to unconjugated bilirubin. Having reverted to this form, unconjugated bilirubin may now be readily absorbed across the intestinal mucosa, contributing, through the enterohepatic circulation, to the circulating unconjugated bilirubin pool, and again being presented to the liver for conjugation. Of importance in the mechanism of the enterohepatic circulation is the enteric mucosal enzyme β-glucuronidase, which is present in both term and premature neonates in high concentrations. Mild alkaline conditions present in the duodenum and jejunum contribute to the deconjugation process.

A study in adult rats demonstrates that enteric absorption of unconjugated bilirubin occurs predominantly in the duodenum and colon.[79] The extent of absorption varies widely, depending on diet and caloric intake (Fig. 48-7). Although quantitative estimates of the disposal of bilirubin have been performed only for adult humans, these data do indicate that about 25% of the TB excreted into the intestine is reabsorbed as unconjugated bilirubin. About 10% of the total is excreted in stool as unaltered bilirubin. The remaining pigment is converted to urobilinoids, most of which are excreted in stool, with a small portion being reabsorbed in the colon for subsequent excretion by both the liver and kidney.

Neonates have relatively high concentrations of unconjugated bilirubin in the intestine that contribute to the enterohepatic circulation. Intestinal bilirubin is derived from increased bilirubin production, exaggerated hydrolysis of bilirubin glucuronide, and high concentrations of bilirubin found in meconium. The relative lack of bacterial flora in the newborn bowel to reduce bilirubin to urobilinogen further increases the intestinal bilirubin pool in comparison with that of the older child and adult. The increased hydrolysis of bilirubin conjugates in the newborn is enhanced by high mucosal β-glucuronidase activity and the excretion of predominantly monoglucuronide conjugates (in the newborn) rather than diglucuronides (in the adult). Oral administration of nonabsorbable bilirubin-binding substances, such as agar, activated charcoal, or a lipase inhibitor (e.g., Orlistat),[92,166] may retain bilirubin in the bowel, thereby further increasing stool bilirubin content and reducing bilirubin reabsorption, in this way decreasing TB. Studies of intestinal bilirubin binding contribute to our understanding of the contribution of the enterohepatic circulation to unconjugated hyperbilirubinemia of the newborn.[58]

GENETIC CONTROL OF BILIRUBIN ELIMINATION

Genetic Control of Uptake of Bilirubin into the Hepatocyte

This process by which unconjugated bilirubin is taken up from the hepatic sinusoids and crosses the hepatocyte membrane to enter into that cell is facilitated by a carrier molecule, organic anion-transporting polypeptide-2 (OATP2, gene *SLC21A6*). Human OATP2 may play an important role in the metabolism of bilirubin and in the prevention of hyperbilirubinemia by facilitating the entry of bilirubin into hepatocytes.[57] A mutation in the *SLC21A6* gene leading to an impaired maturation of the protein with reduced membrane localization and abolished transport function has been described,[151] and a number of single-nucleotide polymorphisms have been identified, some of which are associated with an altered in vitro transport capability.[213]

Genetics of Diminished Bilirubin Conjugation

Perhaps one of the most important advances in our understanding of the genomics of bilirubin metabolism is the elucidation of the *UGT* gene encoding the bilirubin conjugating enzyme, UGT1A1. Next we provide a short overview to allow the reader to comprehend mutations of this gene and interactions of these mutations with genetic or environmental factors in the mechanism of jaundice.[31,40,50,125,134,189,215]

The *UGT* Gene

The *UGT* gene is a superfamily of genes whose function is to encode a biochemical reaction leading to the conjugation of glucuronic acid to certain target substrates in order to facilitate their elimination from the body. The *UGT2* genes are located on chromosomes 4q13 and 4q28. The enzymes encoded by this family preferentially conjugate endobiotic substances, such as steroids and bile acids, and although of physiologic and pharmacologic importance, they are of little relevance to bilirubin metabolism. In contrast, the UGT1A1 gene isoform, which belongs to the UGT1 gene family, is of major importance to the conjugation, and therefore elimination, of bilirubin. This gene isoform has been mapped to chromosome 2q37.[225] *UGT1A1* was cloned by Ritter and associates in 1991.[181] The gene encodes isoform 1A1 of the UGT enzyme, which is of paramount importance in the conjugation of bilirubin. The gene consists of four common exons (exons 2, 3, 4, and 5) and 13 variable exons, of which only variable exon A1 is of any importance regarding bilirubin conjugation; the remaining exons play a role in the detoxification of a diverse range of chemical substances (Fig. 48-8). The variable exon A1 functions in conjunction with common exons 2 to 5: in response to a specific signal, transcription processing splices messenger RNA from the variable exon to the common exons. This process provides a template for the synthesis of an individual enzyme isoform. Upstream of each variable exon is a regulatory noncoding promoter that contains a TATAA box sequence of nucleic

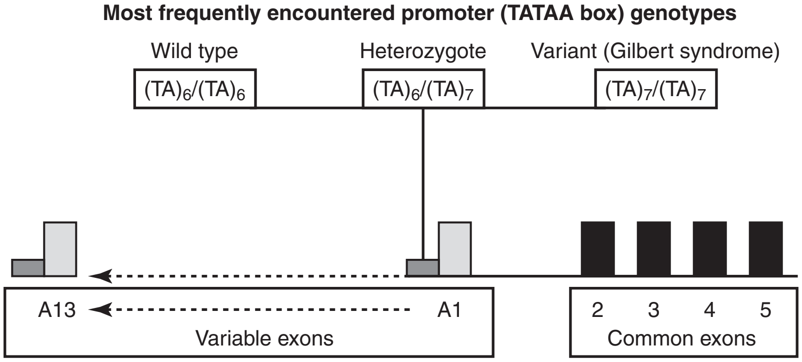

Figure 48–8. The human *UGT1* gene locus. Schematic representation of the genomic structure of the *UGT1* gene complex. Variable exon 1A1 and common exons 2 to 5 of the gene complex have been identified as those sites encoding the bilirubin conjugating enzyme, UDP-glucuronosyltransferase. Variable exons 1A2 to 1A13 do not participate in bilirubin metabolism. Genetic mutations associated with absent or decreased enzyme activity, which cause deficiencies of bilirubin conjugation, have been localized to this variable exon 1A1 (light gray box), its promoter (dark gray box), or the common exons 2 to 5 (black boxes). The *upper section* of the diagram demonstrates the common exon 1A1 promoter TATAA box genotypes. (*Redrawn from Kaplan M, Hammerman C: Bilirubin and the genome: the hereditary basis of unconjugated neonatal hyperbilirubinemia,* Curr Pharmacogenom *3:30, 2005.)*

acids. Mutations of variable exon A1, its promoter, or the common exons 2 to 5, may result in deficiencies of bilirubin conjugation. Polymorphisms of the noncoding promoter area affect bilirubin conjugation by diminishing expression of a normally structured enzyme, whereas mutations of the gene coding area may affect enzyme function by altering the structure of the enzyme molecule. Further information is supplied in the section on "Conjugated Hyperbilirubinemia," later.

NONPATHOLOGIC UNCONJUGATED HYPERBILIRUBINEMIA

In contrast with the older pediatric and adult patient, elevations in unconjugated bilirubin occur ubiquitously in the human neonatal population. In a sense, this "normal" increase in TB levels is not true hyperbilirubinemia when compared with a reference group of all newborns. A more appropriate term that would add to our understanding of the phenomenon and distinguish the normal or physiologic state with the pathologic entity implied in the term *hyperbilirubinemia* may be *physiologic bilirubinemia*.[136] A study of the hour-of-life specific bilirubin nomogram (Fig. 48-9) will reflect the natural increase in TB during the first days of life, reaching a peak at about 5 days.

Unconjugated hyperbilirubinemia in the human, regardless of age, is defined as an indirect-reacting bilirubin concentration of 2.0 mg/dL (34 μmol/L) or greater, depending on the standard used in calibration of the reaction. Nearly all adults and older children normally have indirect-reacting bilirubin concentrations in circulation of less than 0.8 mg/dL (14 μmol/L) and δ-bilirubin of 0.2 to 0.3 mg/dL (3 to 5 μmol/L). Conjugated hyperbilirubinemia is defined as an elevation of the direct-reacting fraction in the van den Bergh diazo reaction of greater than 1.5 mg/dL (26 μmol/L) provided it comprises more than 10% of the TB concentration. The latter portion of the definition is added to guard against overinterpretation of direct reactions in newborns with markedly elevated indirect-reacting bilirubin concentrations because up to 10% of the unconjugated pigment behaves as direct-reacting pigment in the van den Bergh-type methods.

Clinical situations in which the direct-reacting bilirubin concentration is equal to or close to the TB concentration are extremely rare, especially in the newborn period. In the neonate with conjugated hyperbilirubinemia, the hyperbilirubinemia is usually "mixed," the elevated direct-reacting fraction accounting for 20% to 70% of the total pigment. Thus, a neonate with mixed hyperbilirubinemia should be considered primarily to have *conjugated* hyperbilirubinemia, and pathology resulting from interference with hepatic cell excretion and bile transport, rather than from abnormalities of increased bilirubin production or deficient hepatic bilirubin uptake or conjugation, should be sought.

Fetal Bilirubin

During the last stages of human gestation, the normal degradation of erythrocytes formed earlier in fetal life results in about a 150% increase in bilirubin production per unit of body weight compared with adults. The mammalian fetus of all species appears to be capable of degrading heme without limitation, through the two enzymatic steps responsible for the formation of unconjugated bilirubin IX-α, HO and biliverdin (see Fig. 48-2). However, notable species differences exist in the pattern of development of hepatic bilirubin conjugation. Marked deficiency in the conjugating enzyme (UGT) activity is noted in rat, rabbit, guinea pig, sheep, dog, monkey, and human fetuses. At term, UGT activity in the rhesus monkey is only 1% to 5% of that in the adult. In the human fetus, UGT activity is extremely low before 30 weeks of gestation at about 0.1% of adult activity, and gradually increases to about 1% at term.

Diminished UGT activity is the central rate-limiting step that, in conjunction with additional processes including increased bilirubin production, enhanced enterohepatic circulation, and diminished uptake into the hepatocyte, manifests as physiologic jaundice in monkeys and humans.

Significant hyperbilirubinemia is unusual in the human fetus because the placenta transports unconjugated bilirubin from the fetus to the mother. Administration of radioactive unconjugated bilirubin into the fetal circulation of a dog,

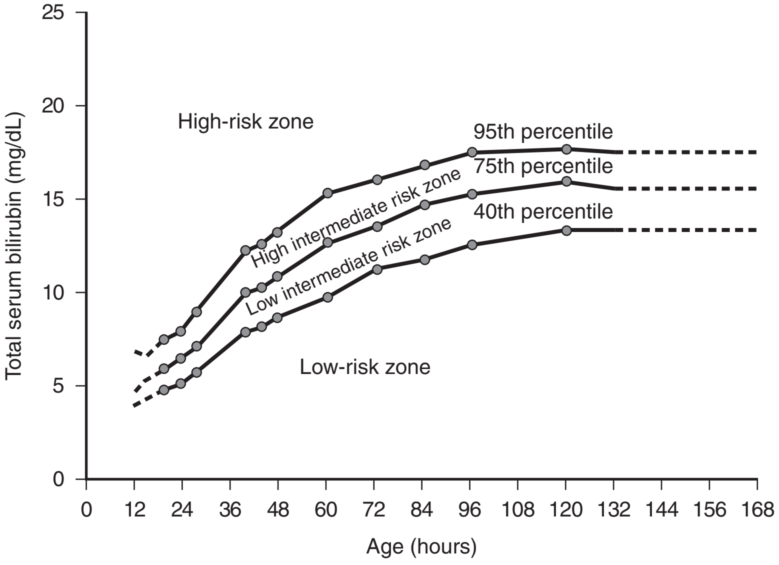

Figure 48–9. Zones of risk for pathologic hyperbilirubinemia based on hour-specific serum bilirubin levels. (*From Bhutani VK, et al: Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns,* Pediatrics *103:6, 1999.)*

guinea pig, or monkey shows a rapid disappearance from the fetal side and recovery in the maternal bile. Even in states of severe intrauterine hemolysis from conditions such as Rh isoimmunization, the degree of anemia by far exceeds the level of hyperbilirubinemia, and clinical jaundice is usually mild at birth.[29] After delivery and separation of the placenta from the infant, rapid increases in TB may be expected. By contrast, the placenta is barely permeable to conjugated bilirubin. Thus, in the absence of evidence of hemolytic disease, if clinical jaundice is present at birth, a conjugated hyperbilirubinemia, caused by intrauterine hepatic pathology, should be suspected.

A large amount of bilirubin is found in meconium, indicating appreciable activity of fetal hepatic bilirubin conjugation. A significant level of β-glucuronidase activity is found in meconium, suggesting that conjugated bilirubin in the fetal intestine can be hydrolyzed back to unconjugated bilirubin and then absorbed from the bowel into the portal circulation. This absorbed bilirubin may reenter the hepatocyte for subsequent reconjugation and re-excretion, or may be transferred through the placenta into the maternal circulation. The efficiency of this process is protective to the fetus against severe hyperbilirubinemia, even when hemolysis is severe.

Conjugated hyperbilirubinemia in the mother, which may occur in hepatitis or recurrent jaundice of pregnancy, is not reflected in the cord blood. Severe hemolytic disease in the fetus results in small, but significant, increases in amniotic fluid bilirubin concentrations. How bilirubin enters the amniotic fluid pool is not known, but suggestions have ranged from direct transfer across the placenta from the maternal circulation, to transudation of pigment across the amniotic membranes or cord vessels, to secretion of bilirubin in the pulmonary fluids flowing from the fetal lung into the fetal pharynx and oral cavity and then into the amniotic fluid. Although to a great extent replaced by noninvasive measurement of anterior cerebral artery flow as an index of fetal anemia, in recent decades, measurement of amniotic fluid bilirubin concentrations by spectrophotometry, combined with percutaneous umbilical blood sampling allowing for serial hematocrit determinations and fetal intravascular transfusions, resulted in markedly improved outcome for the now rare fetus and infant with Rh erythroblastosis (see Chapter 21).

Neonatal Hyperbilirubinemia

TERM NEONATE

In the full-term newborn, physiologic jaundice is characterized by a progressive rise in TB concentration from about 2 mg/dL (34 μmol/L) in cord blood to a mean peak of 5 to 6 mg/dL (86 to 103 μmol/L) between 48 and 120 hours of age in white and African-American babies, with most infants peaking at 72 to 96 hours of age, and 10 to 14 mg/dL (171 to 239 μmol/L) between 72 and 120 hours of age in Asian-American babies. This is followed by a rapid decline to about 3 mg/dL (51 μmol/L) by the 5th day of life (Fig. 48-10) in white and African-American neonates and by the 7th to 10th day in Asian-American neonates. This early period of physiologic jaundice has been designated as *phase 1* physiologic jaundice. During the period from the 5th to 10th day of life in white and African-American infants, TB concentrations decline slowly, reaching the normal adult value of less than 2 mg/dL (34 μmol/L) by the end of that period. This late neonatal period of minimal, slowly declining hyperbilirubinemia has been designated as *phase* 2 physiologic jaundice. The epidemiology is dependent, in part, on the prevalence of breast feeding in a population because lower peak TB values will be found among predominantly formula-fed infants.

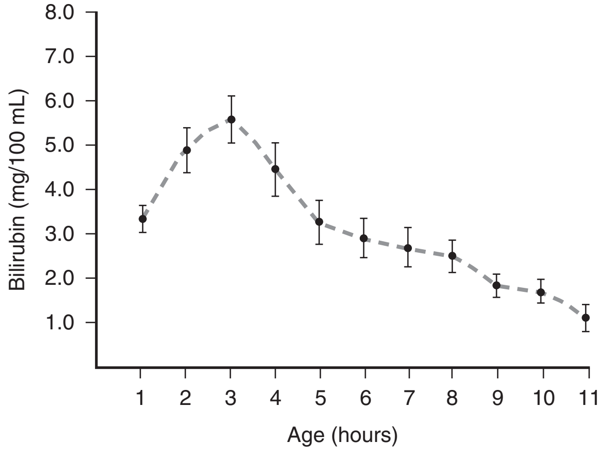

Figure 48–10. Mean total bilirubin (TB) concentrations in 22 full-term normal white and African-American infants during the first 11 days of life. *Vertical bars* represent standard error of the mean. *(From Gartner LM, et al: Development of bilirubin transport and metabolism in the newborn rhesus monkey,* J Pediatr *90:513, 1977.)*

Studies in the newborn rhesus monkey, an animal with a pattern of physiologic jaundice of the newborn that is similar to that in humans, show that phase 1 results from the combination of a sixfold postnatal increase in the load of bilirubin presented to the liver combined with a markedly diminished UGT activity. The presence of either of these factors alone would result in retention of unconjugated bilirubin to a lesser extent than when in combination. Hepatic uptake and excretion of bilirubin are also decreased during this period, although their function as rate-limiting steps in the transport of bilirubin from plasma into bile is dwarfed by the combination of increased bilirubin load to the liver and diminished conjugative capacity. The very large increase in bilirubin load appears to result from both increased de novo bilirubin synthesis and enteric reabsorption of unconjugated bilirubin. In the newborn monkey, the markedly increased load persists for 3 to 6 weeks, primarily because of enhanced intestinal bilirubin absorption. Similar data are not yet available for the human neonate.

In the human, UGT activity is extremely low in the fetal period. After birth, UGT activity increases at an exponential rate, reaching the adult level by 6 to 12 weeks of age (Fig. 48-11). The early deficiency in enzyme activity may result from insufficient enzyme synthesis, inhibition of enzymatic activity by naturally occurring substances, deficient synthesis of the glucuronide donor UDPGA, or a combination of these factors. Phase 2 physiologic jaundice appears to result from an imbalance in which hepatic uptake of bilirubin remains diminished while the increased bilirubin load presented to the liver persists. Developmental deficiency of B-ligandin may contribute to deficient uptake of bilirubin.

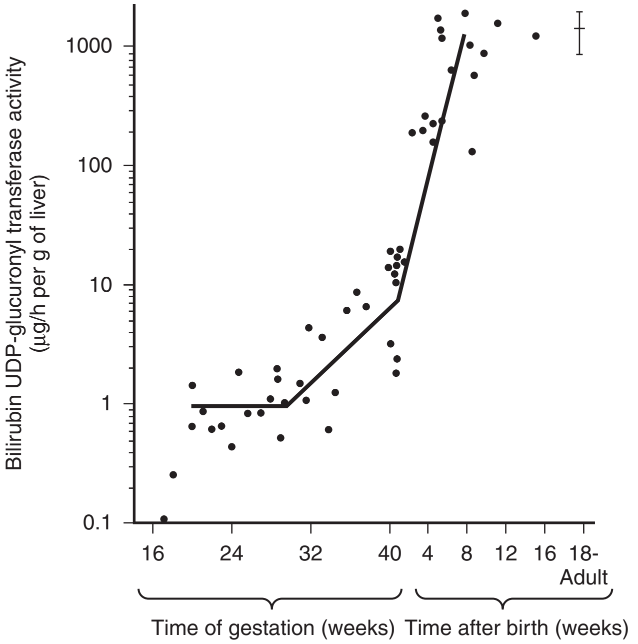

Figure 48–11. Developmental pattern of hepatic bilirubin uridine diphosphoglucuronate (UDP)-glucuronosyltransferase activity in humans. *(From Kawade N, Onishi S: The prenatal and postnatal development of UDP-glucuronyltransferase activity towards bilirubin and the effect of premature birth on this activity in the human liver,* Biochem J *196:257, 1981. Reprinted by permission of the Biochemical Society, London.)*

Despite the development of physiologic jaundice of some degree in nearly every newborn, only half of all white and African-American term newborns become visibly jaundiced during the first 3 days of life. Cutaneous icterus in the newborn will not become evident until TB concentrations exceed 5 to 6 mg/dL (86 to 103 µmol/L). This situation contrasts with that of the older child and adult, in whom jaundice may be noticeable in the sclerae and skin at TB concentrations as low as 2 mg/dL (34 µmol/L). Variations in duration of hyperbilirubinemia, in skin color, and in perfusion may account for these differences. As the intensity of jaundice increases, clinical icterus progresses in a caudal direction. At lower levels of TB, only the head and sclerae may be affected, with the chest, abdomen, legs, and feet becoming jaundiced in parallel to increasing TB concentrations. Because routine daily TB determinations are not usually performed on full-term or even premature newborns, careful scrutiny of the nursery population several times a day by experienced personnel is essential to detect infants who are becoming jaundiced. Some of these may subsequently develop significant hyperbilirubinemia and require further TB testing. Visual assessment of jaundice, however, is largely subjective, inaccurate, and dependent on observer experience. Development of transcutaneous devices intended to measure the skin color objectively and noninvasively may improve on the reliability of visual estimation and facilitate daily bilirubin determinations (see section on "Transcutaneous Bilirubinometry" later in this chapter). This is especially important in predischarge assessment of newborns, especially those discharged before 72 hours of age.

PRETERM NEONATE

Physiologic jaundice in premature neonates is more severe than in term neonates, with mean peak TB concentrations reaching 10 to 12 mg/dL (171 to 205 µmol/L) by the fifth day of life. This delay in reaching the maximal concentration compared with term neonates primarily reflects the delay in maturation of hepatic UGT activity. Because mean peak unconjugated bilirubin concentrations as low as 10 to 12 mg/dL (171 to 205 µmol/L) may be associated with acute bilirubin encephalopathy or kernicterus in certain high-risk, low-birthweight neonates, all degrees of visible jaundice in premature neonates should be monitored closely and investigated fully.[44]

Despite lower UGT activity in premature neonates than in term neonates at birth, UGT activity increases rapidly, far exceeding the expected maturational rate noted in utero (Fig. 48-12). This observation indicates that there are two components in the maturational process of hepatic UGT: (1) chronologic maturation and (2) accelerated maturation related to birth. Nevertheless, normal TB concentrations in

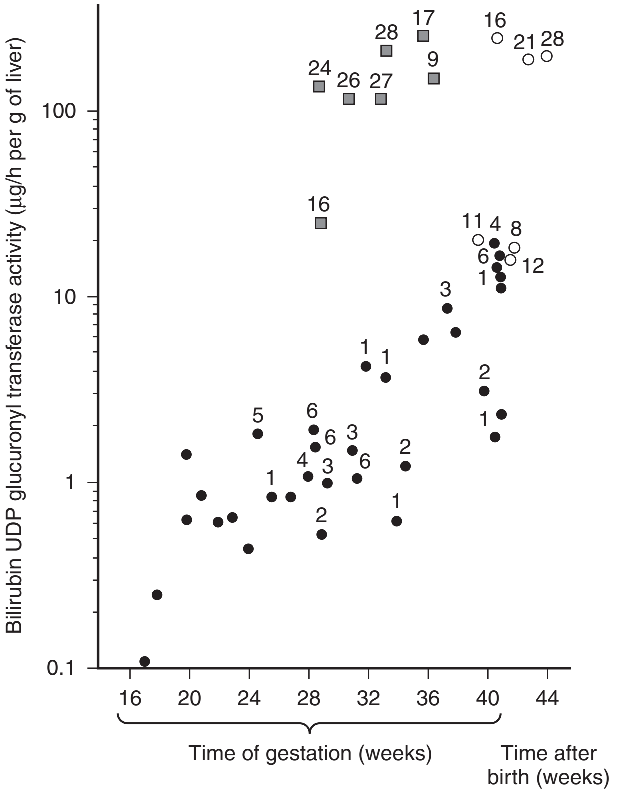

Figure 48–12. Effect of premature birth on development of hepatic bilirubin uridine diphosphoglucuronate (UDP) glucuronosyltransferase (UGT) activity in humans. Numbers beside symbols represent age (days) at which activities were measured. Symbols represent enzyme activities for premature (*squares*) and full-term (*open circles*) infants who lived more than 8 days after birth, and for fetuses and premature and full-term infants who died within 7 days of delivery (*filled circles*). *(From Kawade N, Onishi S: The prenatal and postnatal development of UGT activity towards bilirubin and the effect of premature birth on this activity in the human liver,* Biochem J *196:257, 1981. Reprinted by permission of the Biochemical Society, London.)*

premature neonates may not be reached in many cases until the end of the first month of life.[124]

LATE PRETERM NEONATE

Late preterm gestation (newborns born between 34 and 36 completed weeks) is an important risk factor for the development of severe neonatal hyperbilirubinemia and kernicterus. At this point of gestation, hepatic conjugative capacity is still immature and may contribute to the greater prevalence, severity, and duration of neonatal jaundice in these infants. Many of these infants will be feeding with human breast milk. Additional factors that may increase the incidence of severe hyperbilirubinemia include large for gestational age status, male sex, and glucose-6-phosphate dehydrogenase (G6PD) deficiency. Scrupulous attention to screening for jaundice in the newborn nursery, adequate lactation support, parental education, and appropriate postdischarge follow-up should facilitate institution of treatment when clinically indicated.[245]

POST-TERM NEONATE

Nearly all postmature neonates and about half of all term neonates who are small for gestational age (SGA) may be expected to have little or no physiologic jaundice, with peak TB concentrations of less than 2.5 mg/dL (43 μmol/L). The mechanism for this acceleration of hepatic maturation is unknown. Similarly, neonates of mothers treated with phenobarbital, a drug known to stimulate hepatic UGT activity and the concentration of ligandin,[171] and neonates of heroin users have less than the anticipated severity of physiologic jaundice. Other drugs, less well investigated, also may have similar "maturing" effects.[220,243]

GENETIC, ETHNIC, AND CULTURAL EFFECTS

The severity of physiologic jaundice varies significantly among different ethnic populations. Mean maximal TB concentrations in Chinese, Japanese, Korean, American-Indian, and other Asian term newborns are between 10 and 14 mg/dL (171 to 239 μmol/L), about double those of the white and African-American populations. The incidence of bilirubin toxicity as defined by autopsy-proven kernicterus is also increased significantly in Asian newborns. There is no clinical evidence for increased hemolysis in Asian newborns to account for these dramatic differences,[74,130] although some studies of CO production have suggested that bilirubin synthesis may be slightly increased compared with that in white or African-American neonates. A mutation (Gly71Arg) in the gene for UGT frequently found in Japanese, Koreans, and Chinese, but rare in whites, is associated with Gilbert syndrome in Asian populations has been shown to be associated with an increased incidence of neonatal hyperbilirubinemia in these groups.[8] In contrast, variation in the number of thymidine-adenine (TA) repeats in the promoter for *UGT1A1* gene are commonly encountered in whites and are associated with Gilbert syndrome in that population group (see section on "Genetic Control of Bilirubin Conjugation," earlier). The promoter polymorphism is rare in Asian communities.[24] Thus, there is mounting evidence that the phenotypic variability in neonatal TB levels seen in different populations results in part from genotypic heterogeneity.

Certain geographically distinct populations may demonstrate a markedly increased incidence of neonatal unconjugated hyperbilirubinemia without associated hemolysis. The most dramatic of these are from certain Greek islands, especially the islands of Lesbos and Rhodes. Although the incidence of G6PD deficiency in these populations is markedly increased compared with the remainder of the Greek population and the world incidence, the incidence of hyperbilirubinemia was not directly correlated with the frequency of G6PD deficiency, suggesting interaction of additional icterogenic factors.[219] Unless aggressively treated with phenobarbital prophylaxis, phototherapy, and exchange transfusion, the incidence of kernicterus was also much greater in the newborns from these Greek islands than in those of the mainland population.[220]

It has been speculated that the increased incidence of neonatal unconjugated hyperbilirubinemia in Asian and geographically identifiable populations may result either from environmental influences, such as the maternal ingestion of certain ethnically characteristic herbal medications or foods, or from a genetic predisposition to slower maturation of bilirubin metabolism and transport. Asian-origin infants born in the United States, and Greek newborns born in Australia, appear to be at similar risk for neonatal jaundice as natives of Asia and Greece, respectively, suggesting that geographic factors alone are not determinant. Differentiating the influence of drugs, foods, or traditional practices from that of genetic factors requires further investigation. Severe hyperbilirubinemia can result from hemolysis associated with sepsis or, if genetically vulnerable (e.g., in G6PD deficiency), exposure to chemicals (such as naphtha in mothballs) or pharmaceutical agents (such as antimalarials, sulfonamides, sulfones, antipyretics, and analgesics). In some societies with a high incidence of G6PD deficiency, application of henna to the skin or use of menthol-containing umbilical potions may precipitate severe hyperbilirubinemia and potentiate bilirubin encephalopathy. Even though some of these agents and stressors have received public attention, others represent generally unsuspected dangers, such as the intramuscular (IM) injection of vitamin K_3 (menadione) or the inhalation of paradichlorobenzene, which is used in moth repellents, air fresheners, and bathroom deodorizers.[197,221] In addition, newborn exposure to a hemolytic agent, especially in the presence of G6PD deficiency, can occur transplacentally or through breast milk, through both of these as in the case of maternal ingestion of fava beans, or directly by inhalation, ingestion, or injection.

PATHOLOGIC UNCONJUGATED HYPERBILIRUBINEMIA

Elevated concentrations of unconjugated bilirubin are of concern because of the danger of bilirubin encephalopathy or neuropathy associated with this fraction of bilirubin. Although there have been some reports of bilirubin encephalopathy associated with elevated levels of conjugated bilirubin, the role of conjugated hyperbilirubinemia in the mechanism of bilirubin encephalopathy is not clear. Most studies of kernicterus have related to the TB concentration, of which the conjugated fraction usually comprises a small fraction. Elevated levels of conjugated bilirubin frequently indicate disease processes of hepatic origin. The following discussion therefore relates primarily to unconjugated, or indirect, hyperbilirubinemia, and is followed by a section on conjugated hyperbilirubinemia.

The TB level at any point in time reflects a multiplicity of forces in delicate balance. Processes including bilirubin production, transport, uptake, conjugation, excretion, and reabsorption are not only interdependent but are also influenced by tremendous physiologic flux present in this complex system in the first few days of the neonatal period. Examples of such changes include differences in the rate of heme catabolism and progressive maturation of the bilirubin conjugation system. Physiologically, the net result is an increase in TB up to about the fifth day of life, after which point it levels off and then gradually decreases. Superimposed on these physiologic alterations of bilirubin metabolism may be specific disorders that may further exaggerate or prolong the normal pattern of elevated TB. These conditions may affect the entire spectrum of bilirubin metabolism and include disorders of bilirubin production as well as bilirubin conjugation and elimination.

Causes of Unconjugated Hyperbilirubinemia

DISORDERS OF PRODUCTION

Although increased bilirubin production could result from pathologic states in which degradation of nonhemoglobin heme (i.e., hemoproteins such as cytochromes, catalase) and erythrocyte hemoglobin precursor heme are increased, such disorders in fact have not been identified in the newborn period. The most common pathologic causes of unconjugated hyperbilirubinemia in the newborn include isoimmune hemolytic disease caused by blood group incompatibility between mother and fetus, and G6PD deficiency. Disorders associated with increased erythrocyte destruction are listed in Box 48-1 (see Chapter 21).

BOX 48–1 Conditions Associated with Increased Erythrocyte Destruction

ISOIMMUNIZATION
- Rh incompatibility
- ABO incompatibility
- Other blood group incompatibilities

ERYTHROCYTE BIOCHEMICAL DEFECTS
- Glucose-6-phosphate dehydrogenase deficiency
- Pyruvate kinase deficiency
- Hexokinase deficiency
- Congenital erythropoietic porphyria
- Other biochemical defects

STRUCTURAL ABNORMALITIES OF ERYTHROCYTES
- Hereditary spherocytosis
- Hereditary elliptocytosis
- Infantile pyknocytosis
- Other

INFECTION
- Bacterial
- Viral
- Protozoal

SEQUESTERED BLOOD
- Subdural hematoma and cephalohematoma
- Ecchymoses
- Hemangiomas

Neonates who are acutely hemolyzing appear to be at a higher risk for developing bilirubin-induced brain damage compared with those without hemolysis. Indeed, the first association to be recognized between increasing bilirubin levels and the risk for kernicterus was made in newborns with Rh isoimmunization.[99] Subsequently, some reports suggested that kernicterus in hyperbilirubinemic newborns with hemolytic disease may occur more frequently than that in counterparts without evidence of hemolytic disease, as reviewed by Newman and Maisels.[163] Surveying the literature up to 1983, Watchko and Oski[248] reinforced the concept that hyperbilirubinemia among neonates without hemolytic disease was less dangerous with regard to the development of kernicterus than in cases in which hemolysis was present. A similar stand was taken by Newman and Maisels[164] several years later. However, there are few data to substantiate this view. A study shedding some light on this question was performed by Ozmert and colleagues.[174] In 102 children aged 8 to 13 years, indirect hyperbilirubinemia ranging from 17 to 48 mg/dL (291 to 821 µmol/L) associated with a positive direct Coombs test, presumed to reflect ongoing hemolysis, was associated with lower intelligence quotient (IQ) scores and a higher incidence of neurologic abnormalities. In these same children, the incidence of detected neurologic abnormalities increased as the time of exposure to high bilirubin levels became more prolonged. Similarly, in Norway, Nilsen and coworkers[165] found that of males born in the early 1960s who developed neonatal hyperbilirubinemia, those with a positive Coombs test and hyperbilirubinemia for greater than 5 days had significantly lower IQ scores than average for that country.

Although there is to date no hard evidence demonstrating higher levels of unbound bilirubin in hemolyzing neonates, many believe hemolysis to be a potential factor increasing the risk for bilirubin-related brain damage. Although a TB concentration of 20 to 24 mg/dL (342 to 410 µmol/L) may be associated with kernicterus in a neonate with Rh isoimmunization, a healthy, term infant without an obvious hemolytic condition will rarely be endangered by TB concentrations in this range. Conditions associated with hemolysis, including direct Coombs-positive Rh and ABO immunization or other isoimmunizations and G6PD deficiency, may pose an increased threat to an otherwise healthy newborn. The Subcommittee on Hyperbilirubinemia of the American Academy of Pediatrics (AAP) includes jaundice developing within the first 24 hours, blood group incompatibility with a positive direct antiglobulin test (DAT) (also known as the Coombs test), and other known conditions including G6PD deficiency, all associated with increased hemolysis, as major risk factors for the development of severe hyperbilirubinemia.[13] The AAP recommends initiating phototherapy or performing exchange transfusions at lower levels of TB in neonates with hemolytic conditions than in apparently nonhemolyzing counterparts. However, we do not propose that a hyperbilirubinemic newborn, but without an obvious hemolytic condition will be unaffected by bilirubin encephalopathy. Patients with kernicterus have been reported in whom no evidence of hemolysis was evident.[140] Crigler-Najjar syndrome, a condition not associated with increased hemolysis, is frequently complicated by bilirubin-induced neurologic dysfunction.

Hemolytic conditions in the newborn are generally divided into two major etiologic groups: immune and nonimmune.

Isoimmunization

The hallmark of isoimmunization is a positive DAT, also known as the Coombs test. This is indicative of maternally produced antibody that has traversed the placenta and is now found within the fetus. The test is termed *direct* if the antiglobulin is adhered to the RBCs. An *indirect* test refers to the antibody being detected in the serum.

Rh DISEASE

In past decades, Rh hemolytic disease was the most common cause of severe hemolytic hyperbilirubinemia and a frequent cause of kernicterus. However, maternal prophylaxis with high-titer anti-D immunoglobulin G (RhoGAM), combined with aggressive fetal surveillance and intrauterine blood transfusions, has greatly reduced the incidence and severity of this disease. Mothers sensitized before the development of immune serum prophylaxis are no longer commonly encountered. Those without access to preventive treatment, immigrants from countries in which prophylaxis was not widely available, or those who did not receive prophylaxis following abortion or invasive procedures may continue to deliver affected infants.

The Rh blood group proteins are a highly antigenic group of proteins capable of causing severe isoimmunization with a high risk for fetal hydrops and death. Although several systems of nomenclature exist, the CDE system is most commonly used. These three loci each contain two major alleles (C,c; D,d; E,e) and several minor alleles. The D antigen may produce maternal sensitization with a fetomaternal hemorrhage as small as 0.1 mL. Whereas C and E alleles are relatively uncommon causes of isoimmunization, they can, on occasion, lead to severe hemolysis and hyperbilirubinemia. Rh disease in pregnancy is highly associated with both intrauterine hemolysis and severe hemolytic disease following delivery. Untreated, the condition can lead to intrauterine anemia and severe *hydrops fetalis*, with rapid postnatal evolvement of hyperbilirubinemia with the potential of kernicterus.

The immunization process may begin if an Rh-negative woman, usually D negative, is exposed to a D antigen. This usually occurs by antepartum or intrapartum transplacental fetomaternal transfusion of fetal RBCs containing a D antigen, or by transfusion of Rh-positive RBCs during abortion, blood administration, or procedures including amniocentesis, chorionic villus sampling, or fetal blood sampling. Following exposure to the D antigen on the fetal RBCs, the mother's immune system responds by forming anti-D immunoglobulin G (IgG) antibodies. The IgG then crosses the placenta and adheres to fetal RBCs containing the D antigen. The subsequent antigen-antibody interaction leads to hemolysis and anemia. The immune response may become more severe and more rapid with progressive pregnancies. Resultant anemia causes bone marrow stimulation, with increased numbers of immature RBCs appearing in the circulation (*erythroblastosis*) and extramedullary hematopoiesis. *Fetal hydrops*, a condition characterized by generalized tissue edema and pleural, pericardial, and peritoneal effusions, may result from a combination of hypoproteinemia, tissue hypoxia, and capillary leak. Anemia with resultant poor myocardial function may further exacerbate the hydrops by causing congestive cardiac failure and venous congestion.[154]

Elevated COHb levels, detected in blood obtained by cordocentesis in affected fetuses of nonsmoking isoimmunized mothers, demonstrate that destruction of erythrocytes begins in utero.[254] However, the primary manifestation of the in utero hemolysis is that of anemia. Although large amounts of bilirubin are produced concomitantly, erythroblastotic infants are not severely icteric at birth. TB concentrations are usually kept below 5 mg/dL (86 μmol/L) by transfer of unconjugated bilirubin across the placenta. Jaundice may appear, however, within 30 minutes after delivery. Classically, the serum bilirubin is all indirect reacting, although small amounts of conjugated bilirubin have been noted. After some days of excessive bilirubin load, the excretory system may become overwhelmed with efflux of conjugated bilirubin into the serum, and an increasing conjugated bilirubin fraction is not uncommonly seen. Hepatic conjugation may mature more rapidly than excretory function as a result of stimulation by chronic exposure to high concentrations of bilirubin in utero. Furthermore, hepatic excretory function may also be adversely affected by development of hepatic congestion secondary to heart failure and swelling caused by extramedullary hepatic hematopoiesis, anemia, and poor hepatic perfusion.

ABO HETEROSPECIFICITY

With the reduction of the incidence of Rh isoimmunization by immune prophylaxis, DAT-positive ABO incompatibility is now the single most prominent cause of immune hemolytic disease in the neonate. The clinical picture is usually milder than that of Rh disease, although infrequently severe hemolysis with hyperbilirubinemia may occur.

By ABO blood group heterospecificity, we refer to the situation in which a blood group A or B baby is born to a group O mother, a setup occurring in about 12% of pregnancies. In some instances, women with blood group O have a high titer of naturally occurring anti-A or anti-B antibodies. High titers of anti-A or anti-B antibodies can sometimes be found in blood group O women even before their first pregnancy. This contrasts to Rh isoimmunization, in which immune sensitization occurs progressively with subsequent pregnancies.[90] In contradistinction to blood group A or B individuals, in whom their respective anti-B or anti-A antibodies are IgM molecules with limited ability to cross the placenta, the respective antibodies of blood group O individuals are predominantly smaller IgG molecules and may cross the placenta. Attachment to corresponding fetal RBCs may follow, provided these cells have the A or B antigen. Extravascular hemolysis of the IgG-coated RBCs is thought to be mediated within the reticuloendothelial system by Fc-receptor–bearing cells. As with Rh isoimmunization, the immune process may commence in utero. However, unlike the Rh situation, there is little danger of severe hyperbilirubinemia, anemia, or hydrops in utero, and prenatal intervention is not indicated. Infants may sometimes be born with moderate anemia. After delivery, there is a potential danger of hyperbilirubinemia.

About one third of blood group A or B neonates born to a blood group O mother will have a positive direct Coombs test.[175] Measurements of endogenous formation of CO, reflective of heme catabolism, have demonstrated, overall, an increased rate of heme catabolism in affected babies compared with controls.[71,203,204,217] Not all DAT-positive neonates, however, develop severe hyperbilirubinemia. In one study, only 20% of DAT-positive neonates actually developed TB values greater than 12.8 mg/dL (219 µmol/L),[175] whereas in another study, only 19.6% required phototherapy.[149] Despite this apparent clinical mildness, newborns with severe hyperbilirubinemia of early onset who do not respond to phototherapy are occasionally encountered. At the extreme end of the spectrum, kernicterus has been described.[28,193] ABO blood group incompatibility with a negative DAT, not usually predictive of hemolysis or hyperbilirubinemia, may sometimes cause early and rapidly progressing jaundice, reminiscent of DAT-positive hemolytic disease.

Paucity of A and B antigenic sites on neonatal RBCs or weak expression of these antigens in neonates, compared with adults, may explain, in part, absence of clinical disease in most DAT-positive newborns. A or B antigenic sites situated in sites other than the RBC may bind with transplacentally acquired antibodies, limiting their availability to the RBC.

Because many ABO-incompatible, direct Coombs-positive neonates have no evidence of ongoing hemolysis and do not develop early jaundice or hyperbilirubinemia, ABO heterospecificity with a positive DAT does not necessarily indicate ABO *hemolytic disease*. Some or all of the following criteria are necessary to support the diagnosis of ABO hemolytic disease:

1. Indirect hyperbilirubinemia, especially during the first 24 hours of life
2. Mother with blood group O, infant with blood group A or B
3. Spherocytosis on blood smear
4. Increased reticulocyte count
5. Evidence of hemolysis based on increased endogenous production of CO. Unfortunately, a readily available clinical tool for determining end-tidal CO, corrected for ambient CO (ETCOc) levels, is no longer available.

In DAT-negative ABO-heterospecific newborns, an interaction with polymorphism for the $(TA)_7$ sequence in the promoter of the gene encoding UGT1A1, significantly increasing the incidence of TB of at least 15 mg/dL (257 µmol/L) compared with controls, has been described.[113]

It is essential to closely observe any newborn born to a blood group O mother and to perform a TB measurement at the first appearance of jaundice. Routine blood group and DAT determination on umbilical cord blood is an option, which may allow for additional risk determination.

ISOIMMUNIZATION DUE TO ANTIBODIES OTHER THAN RhD

More than 50 RBC antigens may cause hemolytic disease of the newborn.[153] The most important of these with regard to prenatal hemolysis include anti-c, anti-Kell, and anti-E,[91,107] although others may also, infrequently, be problematic. Alloimmunization due to these autobodies can sometimes cause severe hemolytic disease of the fetus requiring prenatal intervention. Fetal surveillance protocols and clinical strategies developed for RhD alloimmunization are useful in monitoring all alloimmunized pregnancies. Similarly, the postnatal management should be based on the principles outlined in the management of the RhD-immunized newborn (see "Therapy for Unconjugated Hyperbilirubinemia" section that follows). Anti-Kell isoimmunization warrants special mention because fetal anemia often predominates the clinical picture. This may be due to erythropoietic suppression in addition to a hemolytic process.[226]

Nonimmune Hemolysis

ERYTHROCYTE ENZYMATIC DEFECTS

The mature human erythrocyte lacks a nucleus and the organelles necessary for protein and lipid synthesis. Most of the protein present within its cell membranes is hemoglobin. Because the uptake and release of oxygen and carbon dioxide by hemoglobin in the tissues does not require energy, the erythrocyte relies on glycolysis (through the anaerobic Embden-Meyerhof pathway and the aerobic pentose phosphate pathway) and not on mitochondrial oxidative phosphorylation to generate adenosine triphosphate (ATP). Thus, defects in the glycolytic enzymatic machinery may have profound effects on erythrocyte function and life span.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

An entity that is highly associated with extreme neonatal hyperbilirubinemia and bilirubin encephalopathy is G6PD deficiency.[110] Because G6PD deficiency has major neonatal public health implications, it is discussed in some detail.

G6PD deficiency is a common enzyme deficiency estimated to affect hundreds of millions of people with a worldwide distribution.[23,253] From its original indigenous distribution, including areas in south Europe, Africa, the Middle East, and Asia, immigration patterns have transformed it into a condition that may now be encountered virtually in any corner of the globe. The condition has been overrepresented in reports of neonates with extreme hyperbilirubinemia and bilirubin encephalopathy, relative to the background frequencies of this condition among the populations of the United States, Canada, the United Kingdom, and Ireland.[28,143,193] In the United States–based Pilot Kernicterus Registry,[28] more than 20% of reported neonates had G6PD deficiency, whereas its overall frequency is estimated at less than 3%.[253]

Function of G6PD. G6PD plays a major part in stabilization of the RBC membrane against oxidative damage. The enzyme catalyzes the first step in the hexose monophosphate pathway, oxidizing glucose-6-phosphate to 6-phosphogluconolactone, thereby reducing nicotinamide adenine dinucleotide phosphate (NADP) to NADPH. NADPH is essential for the regeneration of reduced glutathione from oxidized glutathione, a substance that plays an integral part in the body's antioxidative mechanisms. The pathway is also instrumental in stimulating catalase, another important antioxidant. In the absence of G6PD, NADPH will not become available, reduced glutathione will not be regenerated, and cells may be rendered susceptible to oxidative stress. Unlike other body cells, no alternative source of NADPH is available in the RBC, which explains the extreme vulnerability of the G6PD-deficient RBC to oxidative damage. Oxidative membrane damage incurred may manifest as hemolysis.[253]

Genetics of G6PD Deficiency. Because G6PD deficiency is an X-linked condition, males may be normal hemizygotes or deficient hemizygotes, whereas females may be either normal or deficient homozygotes, or heterozygotes. Because of X-inactivation, heterozygotes have two RBC populations: one G6PD deficient, the other G6PD normal. As X-inactivation may be nonrandom, unequal ratios of normal and enzyme-deficient RBCs may coexist. Heterozygotes may, as a result, have either a normal, intermediate, or deficient phenotype.[70] It was previously thought that heterozygotes had sufficient enzyme activity to protect them from the dangers of G6PD deficiency.[253] However, reports suggest that heterozygotes may not be without risk, and fatal kernicterus has been described in a heterozygote.[97,109,115] The most commonly encountered mutations are G6PD A$^-$, found in Africa, southern Europe, and in African Americans. G6PD Mediterranean, regarded as a more severe type than G6PD A$^-$, is found in Mediterranean countries, the Middle East, and India. Another variant encountered primarily in Asia is G6PD Canton. Many other mutations have been documented.

G6PD Deficiency and Hemolysis. Most G6PD-deficient individuals lead perfectly normal lives and will, for the most part, be unaware of their inherited condition. However, G6PD deficiency may be associated with severe hemolytic episodes with resultant jaundice and anemia, following exposure to a hemolytic trigger. Classically, these episodes often occur after ingestion of or contact with the fava bean (favism). Medications and chemical substances may be implied, but sometimes no offending trigger may be identified. Beutler[23] has emphasized the role of infections in the pathogenesis of acute hemolysis.

In neonates, extreme hemolytic jaundice may develop suddenly and without previous warning. Some identifiable substances associated with neonatal hemolysis include naphthalene used to store clothes, herbal medicines, henna applications, or menthol-containing umbilical potions. Frequently, the trigger cannot be recognized. The hemolysis may be severe, and the TB concentration may increase exponentially to dangerous levels. G6PD deficiency may, therefore, be the one reason that kernicterus may not be completely preventable. Exchange transfusion may be the only recourse. Early hospital discharge with delayed follow-up may place these patients at risk for severe sequelae.[177,198]

Frequently, hematologic indices typical of hemolysis in older children and adults, including falling hemoglobin and hematocrit values and increasing reticulocyte count, may be absent, despite a clinical picture of hemolysis. However, studies of endogenous CO formation, reflective of the rate of heme catabolism, have demonstrated an important role of increased hemolysis in association with this condition.[162,198] Slusher and colleagues,[198] for example, demonstrated significantly higher levels of COHb in Nigerian G6PD-deficient neonates who developed kernicterus, compared with neonates who were hyperbilirubinemic but did not develop signs of kernicterus.

More frequently and less life-threatening, G6PD-deficient neonates may have a more moderate form of jaundice, which occurs at a rate several-fold that of controls. The jaundice usually responds to phototherapy, although exchange transfusion may also be necessary. These infants have a low-grade hemolysis, which cannot be implicated as the primary icterogenic factor.[116,120] Diminished bilirubin conjugation has been shown to be of major importance in the pathogenesis of the jaundice.[119] An intriguing interaction has been noted between G6PD deficiency and noncoding area $(TA)_7$ promoter polymorphism in the gene encoding UGT1A1.[118] This polymorphism, also known as UGT1A1*28, is associated with Gilbert syndrome. The incidence of hyperbilirubinemia, defined as a TB of at least 15 mg/dL (257 μmol/L), increased in a stepwise, dose-dependent fashion in G6PD-deficient neonates who were heterozygous or homozygous, respectively, for the polymorphism. This effect was not seen in the G6PD-normal control group. Furthermore, G6PD deficiency alone, in the absence of the promoter polymorphism, did not increase the incidence of hyperbilirubinemia over and above that of G6PD-normal counterparts. In contrast, in Asians, in whom the $(TA)_7$ promoter polymorphism is rare, a similar interaction was noticed between G6PD deficiency and coding area mutations of the *UGT1A1* gene.[100]

Unlike the acute hemolytic form of jaundice, this milder form of jaundice can be predicted by predischarge bilirubin testing. Neonates who had a predischarge TB concentration below the 50th percentile were unlikely to develop subsequent hyperbilirubinemia. However, as the predischarge TB increased progressively above the 50th percentile, the risk for subsequent hyperbilirubinemia increased in tandem.[111]

Testing for G6PD Deficiency. Many qualitative or quantitative screening tests are available that should accurately determine the hemizygous state in males or the homozygous state in females. Because many heterozygotes may have intermediate to normal enzyme activity, the heterozygote state is difficult to determine using standard biochemical tests. Females of high-risk groups (Mediterranean origin, African American, African, Middle Eastern or Asian, and Sephardic Jews) should have close follow-up to detect the development of jaundice despite a normal screening. Also, biochemical tests may give a false-normal result if performed during an acute hemolytic episode because older RBCs may be destroyed, leaving younger cells with higher enzyme activity intact.[96] In such cases, G6PD testing should be performed several weeks after the acute hemolysis has subsided. An alternative method is to analyze DNA for the specific suspected mutation. Some countries have introduced neonatal screening for G6PD deficiency combined with parent education in the hope that identification of an infant with G6PD deficiency should lead to avoidance of known triggers of hemolysis and speed the process of evaluation and treatment should an affected neonate become jaundiced.

The treatment of neonatal hyperbilirubinemia associated with G6PD deficiency should follow the guidelines of the AAP[13] for neonates with hemolytic risk factors.

Pyruvate kinase catalyzes the conversion of phosphoenolpyruvate to pyruvate and the formation of ATP from adenosine diphosphate in the Embden-Meyerhof pathway. Deficiency of this enzyme results in a lack of ATP for erythrocytic metabolic activity and in chronic anemia. Pyruvate kinase deficiency, a condition prevalent in northern European peoples and inherited in an autosomal recessive manner,[150] results in a lack of ATP, an important source of energy for RBC metabolism.[263] In the newborn period, anemia, reticulocytosis, and severe jaundice may ensue, requiring exchange transfusion on occasion. Kernicterus has been reported.[222]

Four isozymes are encoded by two genes, among which 180 mutations have been described.[263] Diagnosis is determined by enzyme assay, which should be performed in cases of hemolysis and hyperbilirubinemia not associated with a positive direct Coombs test or spherocytosis. Molecular studies may also confirm the diagnosis.

Hexokinase catalyzes the conversion of glucose to glucose-6-phosphate, the initial step in glycolysis. Hexokinase deficiency predisposes the erythrocyte to oxidant damage and thus is another cause of hemolysis and neonatal hyperbilirubinemia. Inheritance is autosomal recessive, and the gene has been localized to chromosome 10.

Congenital erythropoietic porphyria is an extremely rare, recessively inherited disorder of heme metabolism in which deficient uroporphyrinogen III cosynthase activity inhibits the conversion of hydroxymethyl bilane to type III uroporphyrinogen. Normal heme synthesis can occur only in the presence of greatly elevated levels of type I uroporphyrinogen and type I coproporphyrinogen. These porphyrins are deposited in massive quantities throughout the cells of the body, including the erythrocytes. The disease may present at birth with anemia, jaundice, and splenomegaly. Pink to brown staining of diapers soaked with porphyrin-rich urine is an early clue to the diagnosis. Because porphyrins are photoreactive, the diapers readily fluoresce under ultraviolet light. The same photoreactive properties of porphyrins lead to hemolysis, hyperbilirubinemia, and cutaneous photosensitivity with subepidermal bullae formation.

Deficiencies of other enzymes in the glycolytic pathway, including glucose phosphate isomerase, are capable of producing severe hemolysis and hyperbilirubinemia in the neonatal period.[222]

ERYTHROCYTE STRUCTURAL DEFECTS

See also Chapter 46.

Defects in erythrocyte membrane and cytoskeletal structure alter the shape and deformability of the cell and result in sequestration within the narrow splenic sinusoids. Hemolysis, hyperbilirubinemia, and splenomegaly are the clinical hallmarks of these disorders.

Hereditary Spherocytosis. Of the hereditary RBC membrane defects that may lead to acute hemolysis and hyperbilirubinemia in the newborn, hereditary spherocytosis is probably the most common.[102] In spherocytosis, the normal biconcave shape of the erythrocyte is altered such that the cell assumes a spherical shape—the shape with the smallest possible diameter for its volume. In addition to a reduction in surface area with consequential diminished oxygen uptake and delivery, the limitation in deformability may result in massive splenic sequestration. This condition may be inherited in both an autosomal dominant and recessive fashion, and frequently there may be a history of acute hyperbilirubinemia in a sibling or a parent. Microvesiculization of the RBC membrane results from deficiency of proteins including ankyrin, band 3, α-spectrin, β-spectrin, and protein 4.2 in that membrane. These osmotically fragile RBCs are trapped in the spleen, the microvesicles aspirated by macrophages, and the cell destroyed. The diagnosis can be made microscopically by demonstrating spherocytes in the peripheral blood smear, with confirmation by the osmotic fragility test. The latter test may be especially important in differentiating babies with hereditary spherocytosis from those with direct Coombs-positive ABO isoimmunization, a condition that may also result in microspherocytosis. Mutations of at least five genes encoding the previously mentioned proteins have been recognized.

Hereditary spherocytosis is frequently associated with neonatal hyperbilirubinemia. Of 178 affected Italian term, predominantly breast-fed newborns, 112 (63%) developed neonatal hyperbilirubinemia requiring phototherapy. The incidence of hyperbilirubinemia was even higher in those who also had a genetic variation in the promoter of the bilirubin *UGT1A1* gene, similar to that described in G6PD deficiency.[102] Kernicterus has been described.[22]

Hereditary Elliptocytosis, Hereditary Pyropoikilocytosis, Hereditary Ovalocytosis, and Hereditary Stomatocytosis. These are rare conditions affecting the erythrocyte membrane. The diagnosis may be made by microscopic examination of the peripheral blood smear. Hemolysis may occur in the neonatal period and result in anemia and hyperbilirubinemia.

Infantile pyknocytosis is a transient abnormality of erythrocyte morphology associated with hemolysis and neonatal jaundice. Small, irregular, dense RBCs with spiny projections are seen in the peripheral smear and account for more than 5% of the total RBC population. Anemia and hemolysis persist throughout the first month of life and often into the second and third months. Jaundice is most severe during the first 2 weeks of life.

INFECTION

Bacterial infection is a known cause of hemolysis and hyperbilirubinemia. Sepsis causes hyperbilirubinemia by increasing bilirubin concentrations through hemolysis, or by impairing conjugation, thereby resulting in decreased excretion of bilirubin. Several theories have been proposed for the mechanism of hyperbilirubinemia in the septic neonate. Neonatal erythrocytes are particularly susceptible to cell injury and Heinz body formation in response to oxidative stress. In addition, heme oxygenase can be induced by oxidants, which could lead to increased catabolism of heme to bilirubin. Because bilirubin is a protective antioxidant, initially in infection, bilirubin levels may be decreased as a result of its consumption. However, the frequent manifestation of hyperbilirubinemia associated with sepsis suggests that this protective mechanism may be overwhelmed in septicemia. Furthermore, disseminated intravascular coagulation resulting from sepsis may produce hemolysis as erythrocytes traverse the depositions of fibrin within the microvasculature. In addition, conjugated hyperbilirubinemia may result from hepatitis secondary to bacterial, viral, fungal, and protozoal infections.

SEQUESTRATION

Sequestration of blood within body cavities can result in increased bilirubin production as the body metabolizes and recycles the heme released as erythrocytes are catabolized. Birth trauma resulting in the collection of RBCs within the layers of tissue covering the skull and brain (cephalohematoma, subdural hematoma, subgaleal hematoma) or elsewhere (bruising associated with precipitous or instrument-assisted delivery) has the potential to produce hyperbilirubinemia (see also Chapter 28).

Large hemangiomas, as in Kasabach-Merritt syndrome, may be associated with hemolysis and hyperbilirubinemia in addition to thrombocytopenia and depletion of fibrinogen and other clotting factors.

POLYCYTHEMIA

An increase in RBC mass with resultant increased breakdown of these cells has the potential to overload the already immature capacity of the newborn to eliminate heme degradation products. Polycythemia may be associated with delayed cord clamping, maternal-fetal transfusion, and twin-twin transfusion. Infants of diabetic mothers, especially those who are large for gestational age, are known to be at risk for polycythemia. Although the mechanisms underlying polycythemia in this group are unclear, CO excretion studies have shown that increased RBC breakdown, even in the absence of polycythemia, is the source of the hyperbilirubinemia in these neonates (see Chapter 46).[39,202]

DISORDERS OF HEPATIC UPTAKE

Gilbert syndrome is a benign disorder that affects about 6% of the population and produces a chronic unconjugated hyperbilirubinemia. Both defective hepatic uptake of bilirubin and decreased hepatic UGT1A1 activity have been demonstrated. The basis of the reduced activity of UGT lies in the presence of additional TA repeats in the TATAA box in the promoter region of the gene.[32,157] Because the noncoding, rather than coding, area of the gene is affected, Gilbert syndrome individuals have a normally structured UGT1A1 enzyme, but with diminished expression. The latter leads to a decrease in UGT enzyme activity. Although this disease usually does not manifest until after the second decade of life, some neonates with Gilbert syndrome may exhibit hyperbilirubinemia secondary to diminished uptake of bilirubin.[20] When mutations in both the gene for G6PD and the promoter for UGT occur, the degree of neonatal hyperbilirubinemia has been shown to be dose dependent.[118] In addition, in G6PD-deficient infants who had the wild type $(TA)_6$ (normal) gene promoter, the incidence of hyperbilirubinemia was similar to that in infants who were G6PD normal, with the wild-type promoter (9.7% versus 9.9%). The variant UGT promoter, rather than the rate of heme catabolism as measured by blood COHb, was subsequently shown to be the crucial factor in determining the TB, and had a similar incidence of hyperbilirubinemia (>15 mg/dL [257 μmol/L]) to those infants with and without G6PD deficiency. However, in G6PD-deficient infants who were both heterozygous and homozygous for the Gilbert variant, hyperbilirubinemia was more frequent in a stepwise, dose-dependent sequence (32% versus 50%, respectively).[24,118]

DISORDERS OF CONJUGATION

As described earlier, UGT catalyzes the conjugation of bilirubin in the liver. Disorders of conjugation include both those in which there is a primary alteration in UGT and those in which UGT function is secondarily altered.[47]

Crigler-Najjar Syndrome Type I

Crigler-Najjar syndrome type I is a rare autosomal recessive disease characterized by an almost complete absence of hepatic UGT activity. Because the coding area of the *UGT* gene is mutated, the enzyme produced is structurally abnormal, with no bilirubin conjugating capacity. In the homozygous form, severe unconjugated hyperbilirubinemia develops during the first 3 days of life and progresses in an unremitting fashion, with TB concentrations reaching 25 to 35 mg/dL (428 to 599 μmol/L) during the first month of life. Kernicterus often occurs in the neonatal period, especially when the etiology of the disease is unsuspected and aggressive treatment is not initiated. Stools are pale yellow, and bile bilirubin concentrations are less than 10 mg/dL (171 μmol/L) (normal being 50 to 100 mg/dL [855 to 1710 μmol/L]), with total absence of bilirubin glucuronide in bile. Bilirubin glucuronide formation measured in vitro with liver obtained by biopsy is absent. Formation of most nonbilirubin glucuronides is either severely reduced or absent.

With either direct hepatic enzymatic assay or indirect measurement of glucuronide formation, both parents are found to have partial defects (about 50% normal). Enzyme activity reserve should be sufficient to keep TB concentrations within normal limits. Unless a family is known to be affected by the condition, during the first week of life, the recognition of this disorder may be difficult because of confusion with other types of exaggerated unconjugated hyperbilirubinemia. Persistence of unconjugated hyperbilirubinemia at TB concentrations of greater than 20 mg/dL (342 μmol/L) beyond the first week of life, or repeated need for phototherapy in the absence of obvious hemolysis, should prompt concern for this syndrome.

Indirect methods of diagnosis including microassay of UGT activity from a percutaneous liver biopsy specimen or analysis of bile conjugates have been largely replaced by gene analysis. Figure 48-8 includes many of the mutations associated with the condition. Occurrence of the identical mutation in both parents of an affected homozygous infant suggests parental consanguinity.

The management of these neonates requires maintenance of TB concentrations to less than 20 mg/dL (342 μmol/L) during at least the first 2 to 4 weeks of life. The risk for kernicterus persists into adult life, but aggressive management may diminish this risk while awaiting liver transplantation.[207] Today, nearly all neonates with this disorder are treated with phototherapy as initial therapy or after one or more exchange transfusions. Phototherapy is generally continued throughout the early years of life in the hope that this will prevent the development of kernicterus. Despite attempts to expose older children to phototherapy at the highest intensities and longest durations possible, the response to phototherapy progressively decreases with years of use. This may result from increased skin thickness or a changing distribution of the bilirubin pool. Prompt management of all intercurrent infections, febrile episodes, and other types of illness may help prevent later development of kernicterus. Inducers of UGT, such as phenobarbital, are not effective in Crigler-Najjar syndrome type I disease.

Liver transplantation offers the only definitive treatment for the disease. This procedure should not be delayed indefinitely because phototherapy may become less effective with the passage of time, and intercurrent illnesses may precipitate high levels of TB, with the potential of kernicterus, even in children whose TB concentrations had appeared to be under control and who had appeared to be neurologically intact. In a multicenter report of a world survey, 7 of 21 (33%) transplanted children had already developed some form of brain damage at the time of their transplantation. Average age at transplantation was 9.1 ± 6.9 years (range, 1 to 23 years).[224] Hepatocyte transplantation has been used,[48,75] whereas gene therapy may also have promise for these patients in the future.[185]

Crigler-Najjar Syndrome Type II

Crigler-Najjar syndrome type II (also known as Arias disease) is more common than type I and typically benign. Although unconjugated hyperbilirubinemia occurs in the first days of life, TB levels generally do not exceed 20 mg/dL (342 μmol/L). Fasting, illness, and anesthesia may cause temporary increases in bilirubin to above baseline. The occurrence of kernicterus is rare. Evidence of hemolytic disease is absent (although it may occur coincidentally), stool color is normal, and neonates are otherwise healthy.

Unconjugated hyperbilirubinemia persists into adulthood. Biochemically, hepatic UGT activity is nonexistent and indistinguishable from that found in type I disease. Less than 50% of the daily bilirubin production is excreted in bile, and the monoglucuronide is the predominant form.

Another difference between type II and type I diseases lies in the response to phenobarbital of patients with type II.[208] Jaundiced neonates and adults with type II disease respond readily to oral administration of phenobarbital with a sharp decline in TB concentrations, whereas individuals with type I disease demonstrate no such change. Phenobarbital may be used both as a simple clinical tool to differentiate the two syndrome types. Beyond the neonatal period, there should be no long-term risk for kernicterus unless there is coincidental hemolytic disease.

Crigler-Najjar syndrome type II occurs both as an autosomal recessive and dominant inheritance. The range of expression in one or both parents can be from an asymptomatic defect in conjugation on testing to severe icterus. Other members of the family also may either appear icteric or have detectable low-grade unconjugated hyperbilirubinemia. Screening of the parents and other close relatives for hyperbilirubinemia is a useful method for supporting the diagnosis when it is suspected. Testing of the neonate and the parents for the capacity to form glucuronides of bilirubin were used diagnostically in the past, but these methods have been largely replaced by sequencing of the *UGT* gene.[108]

Transient Familial Neonatal Hyperbilirubinemia (Lucey-Driscoll Syndrome)

Lucey-Driscoll syndrome is a rare familial disorder in which neonates of certain mothers may develop severe unconjugated hyperbilirubinemia during the first 48 hours of life. Kernicterus has been reported in untreated newborns. The sera of these neonates and their mothers contain high concentrations of an inhibitor of UGT when tested in vitro. The serum inhibitory effect gradually declines after delivery coincident with gradual decline in TB.

Pyloric Stenosis

Pyloric stenosis may be associated with unconjugated hyperbilirubinemia at the time vomiting begins. Hepatic UGT activity is markedly depressed in the jaundiced neonates. The mechanism of diminished UGT activity may be due to presence of the variant $(TA)_7$ *UGT1A1* gene promoter, which is associated in adults with Gilbert syndrome.[214]

Duodenal and jejunal obstruction are also associated with exaggerated unconjugated hyperbilirubinemia. Surgical relief of the obstruction results in a decline of TB concentrations to normal within 2 to 3 days. Lower intestinal obstruction, as in Hirschsprung disease, also may result in unconjugated hyperbilirubinemia, although usually of a milder degree than with upper intestinal tract disease. In this situation, as well as when there is upper intestinal tract obstruction, hyperbilirubinemia may result from increased reabsorption of unconjugated bilirubin from the intestine due to stasis of the intestinal contents (see Chapter 47).

Hypothyroidism

UGT activity in congenital hypothyroidism is deficient and may remain suboptimal for weeks or months. Because about 10% of congenitally hypothyroid neonates may develop prolonged, exaggerated jaundice, testing for thyroid function should be performed in these cases. Treatment with thyroid hormone promptly alleviates the hyperbilirubinemia. The mechanism of this association in the human newborn is unknown, but in rats, hypothyroidism impairs hepatic uptake and reduces hepatic ligandin concentrations. Thyroid hormone is also instrumental in many maturational processes. Its absence may delay hepatic bilirubin enzyme and transport development (see Chapter 49, Part 3). It has also been suggested that thyroid hormone can cause changes in UGT protein expression.[82]

DISORDERS OF EXCRETION

Impaired hepatic excretion of bilirubin from disorders such as hepatocyte injury results in conjugated hyperbilirubinemia and is discussed later in this chapter.

DISORDERS OF ENTEROHEPATIC CIRCULATION

Jaundice Associated with Breast Feeding

Jaundice associated with breast feeding is common. Two pathophysiologic mechanisms have been suggested for the early-onset association of jaundice with breast feeding, although this differentiation is not clear, and overlap may exist between these suggested entities. Breast-feeding failure jaundice or breast-feeding–associated jaundice has been so labeled to distinguish it from breast milk jaundice. Breast-feeding failure jaundice is so labeled because the cause appears to be associated with poor feeding practices and not with any change in milk composition. In contrast, breast milk jaundice is apparently related to a change in the composition or physical structure of the milk. Both types result in an exaggerated enterohepatic circulation of bilirubin—one through "starvation" and the other through altered milk chemistry.

BREAST-FEEDING FAILURE JAUNDICE

Breast-feeding failure jaundice occurs in the first weeks of life in breast-fed newborns. Establishing effective breast feeding may be difficult, especially in first-time mothers, who may find lactation to be an intricate process. Maternal factors, such as lack of proper technique, engorgement, cracked nipples, and fatigue may impair effective breast feeding. Neonatal factors such as ineffective suck also may hamper attempts at breast feeding. Even if the mother is experienced in breast feeding and her baby is interested, her milk supply is usually limited to small amounts of colostrum in the first 24 to 48 hours after birth. All these factors may act in combination, resulting in infrequent or ineffective breast feeding. As a result, there may be little stimulus for milk production. Formula supplementation may further impair successful lactation. Exclusively breast-fed neonates are therefore at risk for being relatively underhydrated and less well nourished than formula-fed counterparts. Poor enteral intake may lead to a state of relative starvation and delayed meconium passage. Intestinal content stasis may lead to increased enterohepatic reuptake of bilirubin, increasing the bilirubin load presented to the liver, leading to unconjugated hyperbilirubinemia. This process is similar to the "starvation jaundice" seen in older human patients as well as other animal species fasted for more than 24 hours.

Prevention of breast-feeding failure jaundice includes encouraging frequent (at least 8 to 12 times per day for the first several weeks)[16] breast feeding, avoiding supplementation with water or glucose solutions,[59] and accessing maternal lactation counseling. Intensive support of the breast-feeding mother is necessary, especially in view of early discharge policies in place at many hospitals. Both during birth hospitalization and after hospital discharge, the newborn should be closely monitored for weight gain, adequate urination and stool formation, and the development of jaundice.

BREAST MILK JAUNDICE

Late breast milk jaundice occurs after the first 3 to 5 days of life and may last into the third week of life or beyond. Epidemiologic studies report that 10% to 30% of breast-fed infants in the second to sixth week of life are affected, with some having hyperbilirubinemia into the third month.[78] Presence of the variant $(TA)_7$ *UGT1A1* gene promoter may be associated with prolonged breast milk jaundice.[156]

Typically, the TB level rises steadily, peaking at 5 to 10 mg/dL (86 to 171 μmol/L) at about 2 weeks of age, with a gradual decline over the first several months of life. More severely affected neonates may achieve peak levels as high as 20 to 30 mg/dL (342 to 513 μmol/L). There is no evidence of hemolysis, nor do these neonates appear ill; weight gain and intestinal function are normal. Pregnane-3-α,20-β-diol, a progesterone metabolite found in the breast milk fed to affected neonates, was historically thought to be the cause of this disorder because this substance was shown to be a competitive inhibitor of UGT in vitro. Although milk and urine of mothers of these neonates contain this pregnanediol isomer, the inhibitory effect of this hormone has been questioned. Studies have indicated that the milk associated with this syndrome also contains high concentrations of nonesterified long-chain fatty acids. This suggests that certain of these fatty acids act as inhibitors of hepatic UGT, causing retention of unconjugated bilirubin. It is unlikely that the nonesterified long-chain fatty acids would reach the sites of conjugation in smooth endoplasmic reticulum of hepatocytes without prior esterification. Triglycerides of these long-chain fatty acids do not inhibit in vitro activity of UGT. Neither the pregnanediol nor the fatty acids have ever been substantiated as an inhibitor of hepatic conjugation in vivo, and their role in the cause of the breast milk jaundice syndrome remains questionable.

Studies of the enterohepatic circulation of bilirubin in the rat suggest that milk from mothers of neonates with this syndrome contains β-glucuronidase, an enzyme that could deconjugate bilirubin and, consequently, enhance enteric reabsorption of bilirubin, thereby increasing the hepatic bilirubin load. The presence of this enhancer of intestinal bilirubin absorption in human milk correlates tightly with the presence of mild to moderate unconjugated hyperbilirubinemia in neonates during the second and third weeks of life. With more than 50% of all breast-fed neonates manifesting this effect of breast milk, this phenomenon may be a normal physiologic development comparable to, and an extension of, physiologic jaundice of the early newborn period.

Usually, other than jaundice, the neonates appear healthy, and no abnormal findings are noted. Although not recommended unless TB concentrations reach levels that might be of danger to the infant, interruption of nursing and substitution with formula feeding for 1 to 3 days usually causes a prompt decline of the TB concentration to about half or less of the original level. On resumption of nursing, the TB does not usually increase substantially. Brief interruption of nursing may be useful to confirm the diagnosis, thereby allaying parental anxiety. Failure to respond in this manner indicates that the neonate's jaundice may be unrelated to breast feeding, and other causes should be sought. Supplementation with milk formula may have an effect similar to complete cessation of nursing.[83] An alternative to temporary cessation of breast feeding would be to confirm that the TB is primarily unconjugated, that thyroid function tests are normal, and that there is no evidence of urinary infection. In the situation in which the infant is thriving and the TB does not reach dangerous levels, it may be prudent to observe the infant. It should not be forgotten, however, that rare disorders of bilirubin conjugation may occur in breast-feeding infants and may lead to erroneous diagnosis. Effective nursing practices that prevent early "starvation" in breast-fed newborns may reduce not only the incidence of breast-feeding failure jaundice, but also the severity of breast milk jaundice.[10,146]

Sequelae of Unconjugated Hyperbilirubinemia

The recognition that unconjugated bilirubin may penetrate the brain cell under certain circumstances and its association with neuronal dysfunction and death are reasons for carefully managing newborn infants with significant hyperbilirubinemia.[14,15] There is some evidence that, despite the publication of national guidelines for the prevention and management of hyperbilirubinemia in several countries (United States, Canada, South Africa, Israel and, very recently, the United Kingdom), kernicterus continues to occur in industrialized countries in which the condition was thought to have been "extinct."[28,65,142,193] Acute bilirubin encephalopathy (defined as the acute manifestations of bilirubin-induced neurologic dysfunction, or BIND) and its resultant sequela, kernicterus (defined as chronic and permanent sequelae of BIND) should, for the most part, be preventable conditions. Concerns that risks for acute bilirubin encephalopathy or kernicterus have been exaggerated with regard to term, otherwise healthy neonates have been outweighed by the perpetuation of cases up to present times.[12,164]

There is no single TB concentration that can be regarded as safe or categorically dangerous. The TB concentration, although used clinically to determine the need for phototherapy and exchange transfusion, is a poor predictor of subsequent neurodevelopmental outcome. It is unlikely that in an otherwise healthy, term infant with no obvious hemolytic condition, BIND will occur at TB concentrations below 25 mg/dL (428 μmol/L). In the presence of hemolysis, prematurity, or other risk factors (see later), or in the presence of poor relative health, the danger point may be reached at lower levels of TB.[55,105] In a term infant thought to be actively hemolyzing, a TB concentration of 18 to 20 mg/dL (308 to 343 μmol/L) should probably not be exceeded.[37,43] Until definitive scientific data indicate otherwise, hyperbilirubinemia should be seen as being capable of producing a spectrum of neurologic dysfunction in the newborn, ranging from transient mild encephalopathy to permanent severe neurologic impairment secondary to neuronal necrosis (kernicterus). In addition, it is important to understand that bilirubin metabolism is a dynamic process influenced by many factors. An isolated TB level obtained at one point in time is inadequate to fully assess the risk for sequelae for a particular neonate. Many other factors, including the gestational age and relative health of the newborn, need to be carefully evaluated.

TRANSIENT ENCEPHALOPATHY OR ACUTE BILIRUBIN ENCEPHALOPATHY

Early bilirubin toxicity is transient and reversible. This is suggested by clinical observations of increasing lethargy in tandem with rising TB concentrations, with reversal of lethargy after exchange transfusion. Brainstem auditory evoked response (BAER) may show changes in the wave latency and magnitude, characteristic of early signs of acute bilirubin encephalopathy.[196] BAER signs typically encountered in neonates with moderate unconjugated hyperbilirubinemia (10 to 20 mg/dL [171 to 342 μmol/L]) include prolongation of latencies of waves III and IV-V, and interpeak I-III and I-V, compared with neonates of similar gestational and postnatal ages without hyperbilirubinemia. Prolonged latencies in peak IV-V and interpeak I-V suggest interference with brainstem conduction. These changes in evoked responses reverse with either exchange transfusion or spontaneous decline in TB concentrations.

Long-term follow-up of children with neonatal abnormalities in brainstem responses believed to be due to hyperbilirubinemia are not yet available and the significance of abnormal BAER findings remains unknown.[194,250] An abnormal BAER suggests an injury of the VIII cranial nerve. Bilirubin auditory neuropathy may occur even in the context of normal cochlear function, as measured by otoacoustic emission (OAE), emphasizing the need to perform BAER testing, and not to rely on OAE, in neonates who are suspected of having auditory damage due to hyperbilirubinemia. During the early stages of BIND, a characteristic signal signature can be seen by magnetic resonance imaging (MRI) using T1- and T2-weighted imaging.[85,177] Consequently, the presence of an abnormal BAER, normal OAE, and focal changes in the globus pallidus and medial lobe of the hippocampus by MRI is highly suggestive of acute bilirubin encephalopathy (Fig. 48-13).

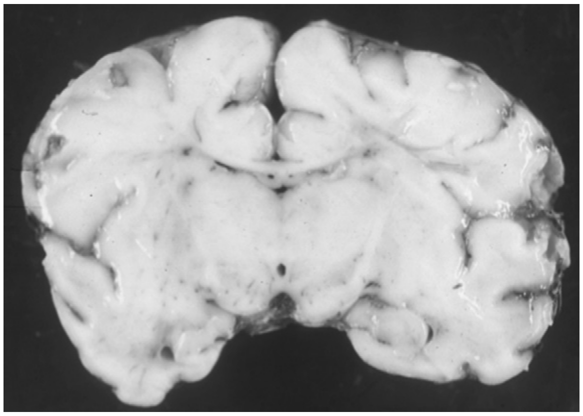

Figure 48–13. See color insert. Acute bilirubin encephalopathy. Coronal section through parietotemporal lobes. Note selective symmetric yellow discoloration in the hippocampus and subthalamic nuclei. Thalamus and globus pallidus are focally stained. *(From Zangen S, et al: Fatal kernicterus in a girl deficient in glucose-6-phosphate dehydrogenase: a paradigm of synergistic heterozygosity,* J Pediatr *154:616-619, 2009.)*

KERNICTERUS

If early acute bilirubin encephalopathy is unrecognized or untreated, it may progress to permanent neurologic impairment. The term *kernicterus* (German *kern*, kernel or nucleus, and *ikteros*, jaundice) has been traditionally used to describe the pathologic findings of bilirubin toxicity within the brain: staining and necrosis of neurons in the basal ganglia, hippocampal cortex, subthalamic nuclei, and cerebellum, followed by gliosis of these areas in survivors (Fig. 48-14). The cerebral cortex is generally spared. About half of all infants with kernicterus observed at autopsy also have extraneural lesions of bilirubin toxicity. These include necrosis of renal tubular cells, intestinal mucosa, and pancreatic cells in association with intracellular crystals of bilirubin. Gastrointestinal hemorrhage may accompany these lesions.[216]

Kernicterus is also used to describe the clinical presentation of worsening encephalopathy. In the term newborn, several phases of kernicterus have been classically described. Phase 1 is marked by poor sucking, hypotonia, and depressed sensorium. Fever, retrocollis, and hypertonia that may progress to frank opisthotonos are seen in phase 2. The hypertonia becomes less pronounced in phase 3, but high-pitched cry, hearing and visual abnormalities, poor feeding, and athetosis are manifest. Seizures may also occur. The usual time course for progression of the disease is about 24 hours. Long-term survivors often demonstrate the classic signs of kernicterus, including choreoathetoid cerebral palsy, upward gaze palsy, sensorineural hearing loss, and dental dysplasia during later infancy and childhood. The intellect may be spared, and mental retardation is not universally encountered. However, infants with normal intelligence frequently have severe physical handicaps, making rehabilitation, education, and independent living unlikely. These sequelae of bilirubin toxicity may also develop in neonates who never manifested clinical signs of acute bilirubin encephalopathy during the newborn period. In addition, earlier epidemiologic studies suggest that

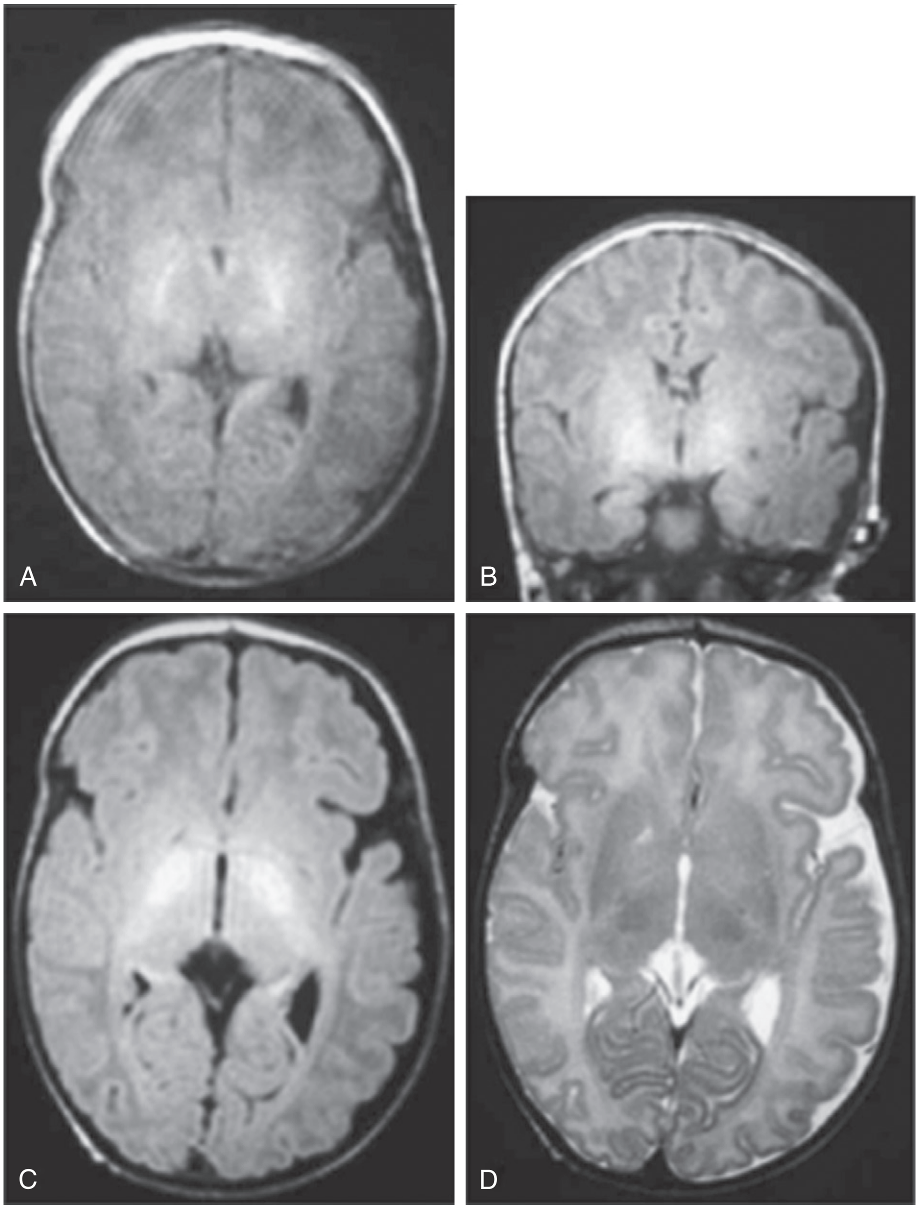

Figure 48–14. Magnetic resonance images of a 21-day-old, preterm male neonate with acute kernicterus. Axial (**A**) and coronal (**B**) T1-weighted and axial FLAIR (**C**) images at the level of the basal ganglia show symmetric, hyperintense globus pallidus involvement. This is not apparent on the axial T2-weighted (**D**) image. *(From Coskun A, et al: Hyperintense globus pallidus on T1-weighted MR imaging in acute kernicterus: is it common or rare?* Eur Radiol *15:1263, 2005.)*

some neonates may have sequelae of subclinical bilirubin encephalopathy characterized only by the later development of mild disorders of motor function or abnormal cognitive function, or both.[52,192]

Presentation in preterm neonates is less stereotypical, and these patients may simply appear ill without signs specific for kernicterus. Bilirubin may enter the brain at lower levels of TB than would be expected in term infants. Moreover, bilirubin staining of central nervous system (CNS) structures in premature neonates may not be indicative of overt kernicterus and may result from developmental differences in CNS permeability to bilirubin and in situ bilirubin metabolism. Mortality occurs in about 50% of term newborns but may occur more frequently in the preterm population with kernicterus.[4]

Bilirubin is thought to enter the brain through multiple mechanisms. These include: (1) bilirubin production that overwhelms the normal buffering capacity of the blood and tissues; (2) alterations in the bilirubin-binding capacity of albumin and other proteins resulting in the presence of unconjugated bilirubin in the circulation; (3) increased CNS permeability to bilirubin secondary to disruption of the blood-brain barrier; and (4) other factors that may affect those previously mentioned or act through novel independent mechanisms.

Unconjugated bilirubin is nonpolar and lipid soluble, and its aqueous solubility in plasma water is extremely small, mandating its binding in plasma primarily to albumin. Binding to other components of blood (β-globulin, RBC membranes, and platelets) may also occur when the albumin-binding capacity for bilirubin is exceeded. It has long been believed that bilirubin toxicity occurs when the albumin-binding capacity for bilirubin is saturated and the unbound or “free” bilirubin (bilirubin in aqueous phase) concentration rises in blood. Whether this is, in fact, the basic pathophysiologic mechanism of kernicterus remains unresolved.

The human albumin molecule is capable of binding at least two molecules of bilirubin, with the first molecule more tightly bound than the second. Additional classes of binding sites, if operative in vivo, have much lower affinities than the first two. At a molar ratio of 1, each gram of human albumin binds 8.2 mg of bilirubin. Thus, at an average albumin concentration of 3 g/dL, the first binding site should be capable of binding 25 mg of bilirubin per deciliter of serum or plasma. The second binding site should be capable of binding an additional 25 mg/dL for a total binding capacity of 50 mg/dL.

Various techniques have been proposed to measure albumin binding of bilirubin, but their application and interpretation in clinical management are not generally accepted. The dye-binding methods using 2-(4′-hydroxybenzeneazo) benzoic acid and direct-yellow-7 are based on the measurement of reserve binding sites on the albumin molecule and should be capable of indicating impending risk. The column chromatographic methods (Sephadex G-25), the salicylate displacement spectrophotometric method (saturation index), the RBC uptake method, and the oxidation technique (peroxidase method) should all be capable of detecting small increases in plasma unbound bilirubin or “loosely bound” bilirubin, in theory, denoting increased risk for developing kernicterus.[6,7] However, current laboratory and clinical data are still insufficient to permit a recommendation for the use of either a single method or a combination of methods to guide the clinical management of infants with neonatal unconjugated hyperbilirubinemia. Furthermore, it may be falsely reassuring to assume that in vitro binding capacities will remain reliably static in an in vivo system that changes so dynamically during the first postnatal days.

The bilirubin-binding capacity of albumin is thought to be decreased in sick term and premature human neonates. In addition, the serum albumin concentration is often lower in these patients than in healthy, term counterparts. Theoretically, both of these factors may act to place the sick term or premature neonate at higher risk for kernicterus at lower TB levels than seen in the healthy term newborn.[223,246] There is still debate about whether the bilirubin-binding capacity of albumin decreases as pH drops below 7.4, despite the known solubility decrease of bilirubin with increasing acidity. Numerous agents compete with bilirubin for binding sites on albumin, acting to displace bilirubin and increase the ratio of free to bound bilirubin in the serum. Free fatty acids, which are elevated in sepsis and hypoxemia, are capable of displacing bilirubin. Similarly, intravenous lipid emulsions rarely can contribute to elevated free fatty acids and thus displacement of bilirubin. Sulfisoxazole and other sulfa drugs, indomethacin, and salicylates readily displace bilirubin. Even ampicillin, when injected rapidly, has the potential to act in a similar manner. Benzyl alcohol, once used as a preservative in various medications, has been shown to competitively inhibit bilirubin binding. Finally, certain substances used in the preparation of albumin solutions may act to decrease its bilirubin-binding capacity.[35,242]

Disruption of the blood-brain barrier allows the passage of molecules otherwise prevented from entering the CNS. Hypertonicity of the serum, meningitis, and hypoxemia all increase CNS permeability to bilirubin.[94] It has been reported that unconjugated bilirubin is a substrate for phosphorylated glycoprotein (P-GP)[106,247] and that P-GP in the blood-brain barrier may play a role in limiting the entry of bilirubin into the CNS. P-GP is an integral plasma membrane transport protein, dependent on ATP, which can transport a wide variety of substrates across biologic membranes.

Many other factors may play a role in regulating bilirubin entry into the brain. Kernicterus has been reported to occur in adults with Crigler-Najjar syndrome type I, but only when TB concentrations have reached 45 to 55 mg/dL (770 to 941 μmol/L). This contrasts with the situation in the full-term newborn in which kernicterus may be anticipated at somewhat lower concentrations, suggesting presence of a maturational process in the blood-brain barrier integrity.

In addition to bilirubin produced within the reticuloendothelial system, bilirubin may be produced within the brain. The mammalian brain has two isoforms of HO, HO-1 and HO-2, which convert heme to biliverdin.[69] HO-1 normally shows little baseline activity in the brain but is capable of being rapidly upregulated in response to stress. Most HO activity in the brain is the result of the constitutive enzyme HO-2. HO-1 and HO-2 are distributed in selected areas of the brain, many of which play roles in motor and auditory function. Biliverdin reductase is also found in the brain, catalyzing the conversion of biliverdin to bilirubin. Although bilirubin thus formed is normally rapidly cleared by bilirubin oxidase, it is possible that this fraction of the bilirubin pool does contribute to the development of kernicterus. These enzyme systems are developmentally regulated and may also be influenced by any of the disease states previously mentioned. Because the bilirubin produced and metabolized in situ must be transported out of the brain, interference with this transport mechanism may be another potential mechanism of contributing to kernicterus.

Once bilirubin has gained access to the CNS, there are several postulated mechanisms of neuronal injury: (1) passage through lipid moieties of cell membranes into the lipids of subcellular organelles such as mitochondria, interfering with critical steps in energy metabolism; (2) binding to specific membrane, organelle, or cytoplasmic proteins, and inhibiting their function; and (3) damage and direct interference with the function of DNA.[49]

The neurotoxicity of bilirubin is currently being debated. As described earlier, HO catalyzes the conversion of heme to biliverdin, releasing equimolar amounts of CO. Carbon monoxide may function as a neurotransmitter within the CNS and has been implicated as playing a role in memory. However, CO may also act as a neurotoxin and have deleterious effects, including neuronal necrosis. The deposition of bilirubin in the brain of patients with kernicterus may not be the primary insult, but rather may be a relatively innocuous marker of neuronal damage produced by other means. Bilirubin has antioxidant properties and may, at physiologic levels, provide protection from oxidative injury.[152,262] Whatever the mechanism of bilirubin neurotoxicity, clinical decisions regarding the management of hyperbilirubinemia and the institution of therapy are based on the TB concentration, and given its apparent effectiveness in reducing the incidence of kernicterus, it would be unwise to alter the current approach to therapy.

Diagnosis of Unconjugated Hyperbilirubinemia

About two thirds of the more than 4 million neonates born annually in the United States become clinically jaundiced. Clearly, the number of jaundiced neonates who will develop sequelae of hyperbilirubinemia is substantially less than this. The challenge to the pediatrician is to determine which newborns may become or are already abnormally jaundiced and therefore are at risk for severe sequelae.[137] The recommendations by the AAP for the laboratory evaluation of the jaundiced infant at 35 weeks' gestation or later are listed in Table 48-1.

TOTAL BILIRUBIN (TB) MEASUREMENTS

When the clinical screening examination detects a jaundiced newborn, the mainstay of clinical management includes determination of TB concentrations in the serum or plasma. Direct bilirubin measurements will not contribute much information in the early stages of jaundice but should be performed in cases of prolonged hyperbilirubinemia or of hyperbilirubinemia not responding to therapy, or if a disease process is suspected. In most patients, repeat determinations will be necessary in the acute stage of jaundice to determine the trajectory, the peak bilirubin concentration, and whether indications for instituting therapy have been reached. Following that, an at least daily determination should be performed until a clear pattern of decline is observed. Clinical judgment is necessary to determine whether TB concentrations may be monitored on an ambulatory basis, thereby eliminating the need for prolonged hospitalization, or whether the risk for severe hyperbilirubinemia warrants in-hospital observation. Thus, the clinician must determine whether any individual neonate is at high or low risk for developing severe hyperbilirubinemia or kernicterus. Neonates at high risk for kernicterus include those presenting with jaundice in the first 24 hours of life, pallor, or hepatosplenomegaly, and with documented immune or nonimmune hemolytic conditions.

Bhutani and colleagues, in a study performed in 1999 on a racially diverse population of term healthy newborns, established that a percentile-based bilirubin nomogram using age-in-hours-specific predischarge TB levels can accurately predict an infant's level of risk for developing hyperbilirubinemia (see Fig. 48-9).[27] Infants with a predischarge TB in the 95th percentile or higher (high-risk zone) had a 57% risk for developing severe hyperbilirubinemia (TB of 17 mg/dL [291 μmol/L] or greater). Risk was 13% for infants in the high-intermediate zone (TB between the 75th and 95th percentiles). Infants with TB levels between the 40th and 75th percentiles (low-intermediate risk) had a risk of 2.1%. Infants with TB in the 40th percentile or less had no risk. All TB measurements should be plotted on the Bhutani nomogram, which takes into account the rapidly occurring changes in TB concentrations. It will be clear from a study of the nomogram that an individual TB reading may have different connotations depending on the hour of life at which the blood was sampled. The closer the TB reading to the 95th percentile for hours-of-life, the greater becomes the risk for subsequent hyperbilirubinemia. Conversely, a TB reading below the 40th percentile is usually associated with a low risk for hyperbilirubinemia. A useful method of assessing whether the rate of rise of TB is greater than normal is to plot several TB points on the graph and determine whether the trajectory runs in parallel with the graph or at a more rapid rate or "jumping" to a higher percentile track (Fig. 48-15).

Classification of hyperbilirubinemia as conjugated or unconjugated requires fractionation of serum or plasma bilirubin into direct- and indirect-reacting pigments, respectively. Simple techniques that fail to distinguish direct- from

TABLE 48–1 Laboratory Evaluation of the Jaundiced Infant ≥35 Weeks of Gestation

Indications	Assessments
Jaundice in first 24 hr	TcB and/or TB
Jaundice appears excessive for age	TcB and/or TB
Infant receiving phototherapy or TB rising rapidly (i.e., crossing percentiles [see Fig. 48-15]) and unexplained by history and physical examination	Blood type and Coombs test, if not obtained with cord blood CBC and smear Direct or conjugated bilirubin Optional: reticulocyte count, G6PD, ETCOc, if available Repeat TB in 4 to 24 hr, depending on infant age and TB level
TB concentration approaching exchange levels or not responding to phototherapy	Reticulocyte count, G6PD, albumin, ETCOc (if available)
Elevated direct (or conjugated) bilirubin level	Urinalysis and urine culture Evaluate for sepsis indicated by history and physical examination
Jaundice present at or beyond age 3 weeks, or if the infant is sick	Total and direct (conjugated) bilirubin level If direct bilirubin elevated, evaluate for causes of cholestasis Check results of newborn thyroid and galactosemia screen; evaluate for signs and symptoms of hypothyroidism

CBC, complete blood count; ETCOc, end-tidal carbon monoxide, corrected for inhaled CO; G6PD, glucose-6-phosphate dehydrogenase; TcB, transcutaneous bilirubin; TB, total bilirubin.

From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297, 2004.

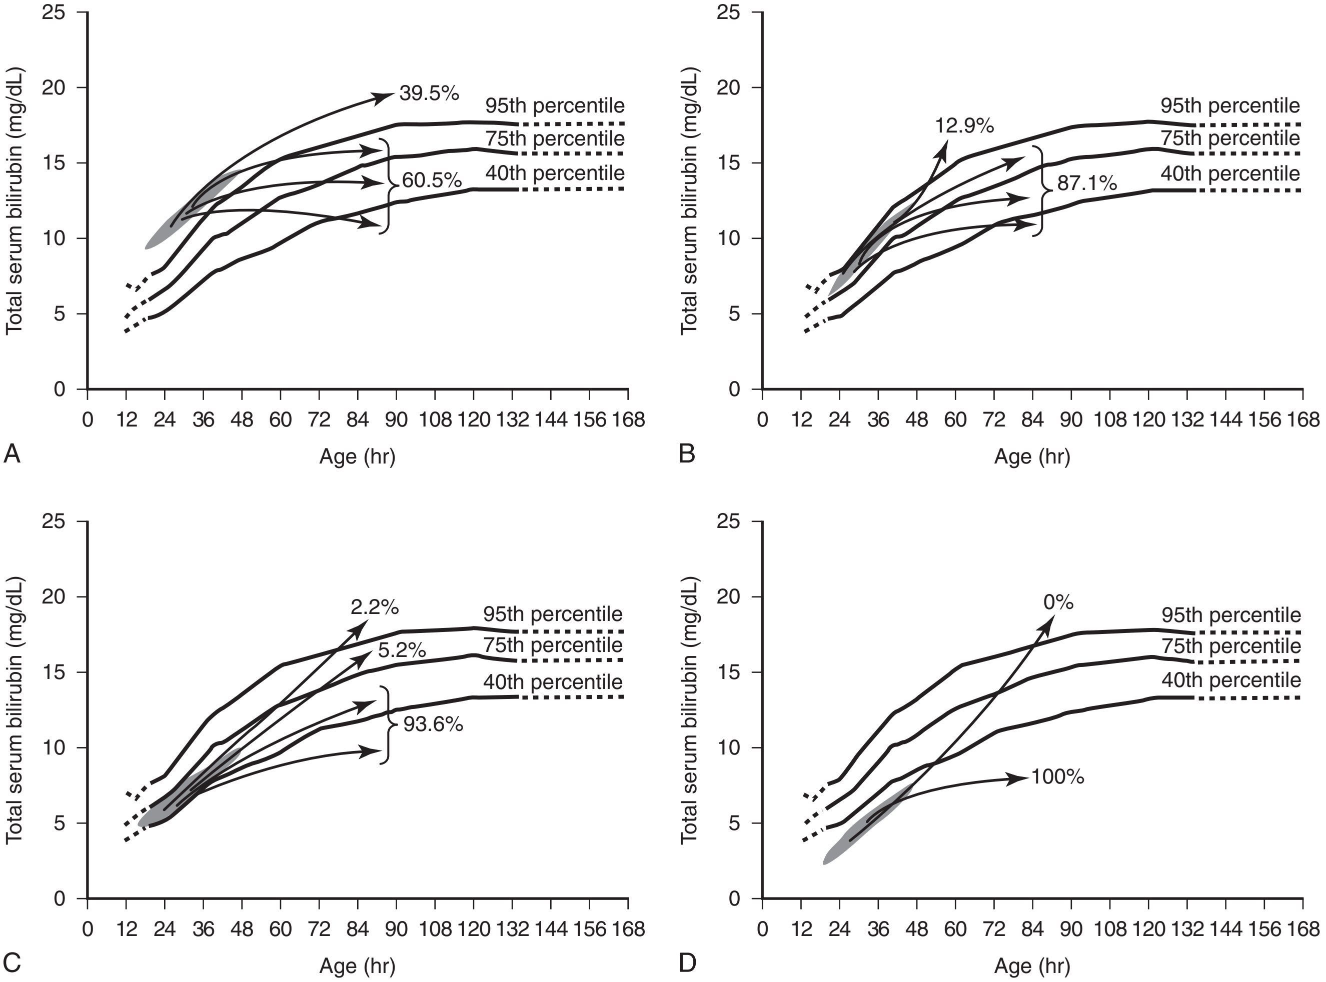

Figure 48–15. Outcome of newborns as defined by the percentage of newborns that remain or move up to the high-risk zone after their risk assessment with the predischarge bilirubin value (represented by the *shaded area*). **A**, Outcome for newborns designated in the high-risk zone ($n = 172$). **B**, outcome of newborns in upper-intermediate-risk zone ($n = 356$). **C**, Outcome of newborns in the lower-intermediate-risk zone ($n = 556$). **D**, Outcome of newborns in the low-risk zone ($n = 1756$). *(From Bhutani VK, et al: Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns,* Pediatrics *103:6, 1999.)*

indirect-reacting pigment are not recommended, but they may be useful as less expensive methods for screening and frequent repeat determinations, and in emergency situations. The prototype of colorimetric methods is the van den Bergh test, a modification of the Ehrlich diazo reaction. The Jendrassik-Grof method has also been used widely as an automated procedure in many hospital laboratories.

Newer automated methods, such as the Ektachem system, provide greater precision and the ability to measure the covalently bound δ-bilirubin. Compared with the values of direct bilirubin obtained by high-performance liquid chromatography, the Jendrassik-Grof and other diazo methods exaggerate this fraction to variable degrees. These older, nonspecific diazo reaction methods also fail to measure the δ-bilirubin fraction, underestimating total bilirubin by 0.2 to 0.3 mg/dL (3 to 5 μmol/L) in the normal adult. High-performance liquid chromatography probably provides the most accurate measurement of TB but is impractical for routine clinical laboratory use. The Ektachem method has gained wide acceptance. It uses a dry film system for measurement of TB and subfractions (indirect, direct, and δ) for general clinical laboratory use. The adult upper limit of normal for TB by this method is 1.3 mg/dL (22 μmol/L), and for the conjugated fraction, 0.3 mg/dL (5 μmol/L), of which two thirds is in the form of δ-bilirubin. For newborns younger than 2 weeks, a simpler and less expensive single-film method can be used, omitting measurement of δ-bilirubin, which is not found in this age group.

High levels of direct-reacting bilirubin reflect a different set of pathologic entities that do not respond to the usual interventions for unconjugated hyperbilirubinemia and will be considered later in this chapter. It is useful to consider four groups of newborns when making decisions regarding laboratory evaluation and therapy of unconjugated hyperbilirubinemia: (1) healthy term (more than 37 completed gestational weeks); (2) sick term; (3) healthy premature; and (4) sick premature neonates. Studies to date have dealt almost exclusively with the healthy term newborn. Although unconjugated hyperbilirubinemia is a disease of multiple causes, and neonates should be treated differently on the basis of gestational age and relative state of health, some general comments can be made.

Further laboratory investigation should be considered when TB concentrations are (1) 4 mg/dL (68 μmol/L) or greater in cord blood; (2) increasing at a rate of 0.5 mg/dL (9 μmol/L) or greater per hour over a 4- to 8-hour period; (3) increasing at a rate of 5 mg/dL (86 μmol/L) or greater per day; (4) 13 to 15 mg/dL (222 to 257 μmol/L) or greater in full-term infants at any time; (5) 10 mg/dL (171 μmol/L) or greater in premature neonates at any time; or (6) when clinical jaundice persists beyond 10 to 14 days of life.

Further diagnostic studies should be based on a thorough history and physical examination, which can narrow the differential diagnosis. A careful history from the parents may reveal familial patterns of neonatal hyperbilirubinemia or anemia or ethnic patterns associated with severe neonatal jaundice. Observation of the parents for jaundice and even determination of TB concentrations in them also may be useful in the diagnosis of familial types of hemolytic disease or inherited hepatic dysfunction. Patterns of feeding, the time of onset, and the frequency of breast feeding also may be important. A careful physical examination with special attention to liver and spleen size, skin appearance, and neurobehavioral status should be performed in the evaluation of a jaundiced neonate.

Initial studies that may be indicated include determination of maternal blood group and Rh type, a screen for antibodies directed against minor erythrocyte antigens, determination of neonatal blood group and Rh type, direct Coombs or antiglobulin test, hemoglobin or hematocrit, smear of peripheral blood for RBC morphology, and reticulocyte count. In the presence of significant jaundice with a potential ABO incompatibility (type O mother and type A or B infant), the direct Coombs test should be repeated at least once if originally negative because initial false-negative results have often been noted. It should be borne in mind that hematologic indexes indicative of hemolysis in older children and adults may not be useful in the diagnosis of increased hemolysis in neonates, because of overlap in these indexes between hemolytic and nonhemolytic conditions. An elevated ETCOc level may be indicative of ongoing hemolysis, but a suitable, noninvasive, point-of-care technology is not currently available (see "End-Tidal Carbon Monoxide Measurements," later). Determination of erythrocyte G6PD activity may be useful in cases of unexplained hyperbilirubinemia or hyperbilirubinemia not responding to intense phototherapy. Consideration of the family's ethnic group may be useful in deciding whether to perform a G6PD test. Cord blood should be saved in the event further testing is indicated.

More extensive studies for rarer forms of hemolytic disease and enzyme assays or genetic testing for UGT activity may be deferred until the chronicity of the disease has been established. Studies for hepatocellular disease (such as hepatitis and obstructive biliary disease), including serum glutamic-oxaloacetic transaminase and serum glutamic-pyruvic transaminase, alkaline phosphatase, and cholesterol, need to be performed only when there is a significant elevation of conjugated bilirubin or liver disease.

Until a laboratory method is proved to accurately assess the risk for developing BIND, the need for treatment, and the progression from phototherapy to exchange transfusion must be based on clinical judgment. Factors that will influence the use of therapeutic modalities available are based on the maturational state of the infant, the severity of the associated pathophysiologic process, and the presence of increased hemolysis, in conjunction with evaluation TB concentrations. The method of management chosen for an individual neonate is determined in part by the TB concentration at which therapy is instituted. The 2004 guideline of the AAP has formulated an established and uniform policy regarding the methods to be used and criteria for initiation of therapy.[13] The risk factors for the development of severe hyperbilirubinemia in infants of 35 weeks' gestation or more are listed in Box 48-2.

Another problem in the assessment of any particular TB concentration involves variation within and between laboratories. In a study by Vreman and colleagues, high interlaboratory and interinstrument variations in the measurements of

BOX 48–2 Risk Factors for Development of Severe Hyperbilirubinemia in Infants ≥35 Weeks of Gestation

MAJOR RISK FACTORS

- Predischarge TB or TcB level in the high-risk zone (see Fig. 48-9)
- Jaundice observed in the first 24 hours
- Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (e.g., G6PD deficiency)
- Gestational age 35 to 36 weeks
- Previous sibling received phototherapy
- Cephalohematoma or significant bruising
- Exclusive breast feeding, particularly if nursing poorly and weight loss is excessive
- East Asian race

MINOR RISK FACTORS

- Predischarge TB or TcB in the high intermediate-risk zone
- Gestational age 37 to 38 weeks
- Jaundice observed before discharge
- Previous sibling with jaundice
- Macrosomic infant of diabetic mother
- Maternal age ≥25 years
- Male sex

FACTORS ASSOCIATED WITH DECREASED RISK OF SIGNIFICANT JAUNDICE*

- TB or TcB in the low-risk zone (see Fig. 48-9)
- Gestational age ≥41 weeks
- Exclusive bottle feeding
- Black race
- Discharge from hospital after 72 hours

---

*Listed in order of decreasing importance.

G6PD, glucose-6-phosphate dehydrogenase; TcB, transcutaneous bilirubin; TB, total bilirubin.

From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297, 2004.

TB were reported.[233] They found that imprecision for a particular method or a given laboratory was acceptable, but inaccuracy was highly variable and should be taken into account in the interpretation of all TB measurements. Another factor contributing to these variations is the lack of appropriate bilirubin standards and consistent handling of clinical specimens. All these observations warrant the need for universal standardization of all bilirubin measurements. Lo and coworkers analyzed specimens of TB from the College of American Pathologists (CAP) Neonatal Bilirubin (NB) and Chemistry (C) surveys using the reference method.[133] They found that the use of different methods in the NB and C surveys, together with the presence of nonhuman protein base and ditaurobilirubin in the survey specimens, accounted for wide variations in accuracy and imprecision between instruments and laboratories. Furthermore, they recommend that survey samples should consist only of human serum enriched with unconjugated bilirubin.

The measurement of unbound or "free" bilirubin concentrations is another potential measure to assess the risk for developing bilirubin neuropathy or encephalopathy. Data are limited, but preliminary studies show that unbound bilirubin levels may be better correlated with BIND than the TB.[173,195,249]

TRANSCUTANEOUS BILIRUBINOMETRY

Visual inspection is the most commonly used means of screening newborns for hyperbilirubinemia. Jaundice progresses cephalocaudally. Digital pressure that blanches the skin diminishes the effects of pigmentation and local cutaneous perfusion and allows the detection of jaundice. Proper lighting is important in detecting subtle levels of jaundice. However, visual assessment is subjective, dependent on observer experience and is notoriously inaccurate.

Transcutaneous bilirubinometry (TcB) is a method using reflectance photometry or transcutaneous colorimetry[259,260] as a noninvasive estimate of TB levels.[147] The technique offers an objective measurement of skin color, from which a reading, reflecting the TB, is derived. Two devices, the BiliChek (Philips Childrens Medical Ventures, Monroeville, PA) and JM-103 Jaundice Meter (Konica Minolta/AirShields JM 103 Jaundice Meter, Draeger Medical AG and Co, Lubeck, Germany)[261] are currently commercially available. They differ in their ease of use and their propensity to be affected by variations in skin color. A number of studies have shown that these instruments provide fairly accurate estimates of TB in term and near-term newborn infants of varying races and ethnicities, generally providing values within 2 to 3 mg/dL (34 to 51 μmol/L) of the TB, if the TB is less than 15 mg/dL (257 μmol/L).[25,66,138,187] The technology tends to under-read the actual TB measurement and should be regarded as a screening mechanism rather than an accurate reflection of the TB. The devices have been evaluated as potential predischarge screening tools[138] to identify infants at risk (i.e., TB level at the 95th percentile or higher). As a result of these studies, an age-in-hours-specific nomogram based on TcB measurements has been established and shown to successfully predict the development of hyperbilirubinemia. However, additional studies are warranted to establish a strong and reliable correlation between TcB and TB at levels of 15 mg/dL (257 μmol/L) and higher, as well as during and after phototherapy and in premature or low-birthweight infants, before its routine use can be advocated.

END-TIDAL CARBON MONOXIDE MEASUREMENTS

Because the breakdown of heme by the rate-limiting enzyme HO produces equimolar quantities of CO and biliverdin, which is immediately reduced to bilirubin, the measurement of CO in the end-tidal breath, corrected for ambient CO (ETCOc), of the newborn can be used as an index of in vivo heme degradation and bilirubin production and, hence, hemolysis.[204] A portable device that allowed automatic sampling and bedside analysis of ETCOc yielded results comparable to gas chromatography and was used to accurately estimate COHb levels in neonates, children, and adults (see Chapter 31).[234] Unfortunately, this device is not currently available.

In a large multicenter study, Stevenson and colleagues found that a measurement of ETCOc at 30 ± 6 hours of age, alone or in combination with a TB measurement, did not improve the predictive ability of the age-in-hours-specific TB level, although it was as good as a measurement of TB alone for this purpose.[203] They did find, however, that the use of an ETCOc measurement in combination with the TB level aids in the following: (1) the discrimination between infants with increased bilirubin production rates and infants with decreased elimination; (2) the identification of infants with increased bilirubin production due to ABO incompatibility or other causes of hemolysis; and (3) the identification of infants with impaired conjugation defects, who have a normal ETCOc level with rising TB levels. In other words, high producers of CO and bilirubin are most likely undergoing a hemolytic process, whereas infants with high TB levels and normal bilirubin production rates most likely have a defect in bilirubin conjugation. The measurement of ETCOc could provide direct information of the rate of bilirubin production. Bhutani and coworkers, using data from this study, constructed an age-in-hours-specific ETCOc nomogram for measurements taken between 4 and 48 hours postnatal age, revealing that an ETCOc in the 75th percentile or less at 30 ± 6 hours of age is 1.7 ppm or less and is considered the threshold of increased bilirubin production.[26]

BILIRUBIN-TO-ALBUMIN MOLAR RATIO

The molar ratio of bilirubin (mg/dL) to albumin (g/dL) correlates with unconjugated bilirubin levels in newborns and, therefore, can be used as a surrogate for unbound bilirubin or residual binding capacity of albumin.[5] Sick infants have an impaired albumin binding of bilirubin and can have ratios of 0.7, and it is recommended that the ratio should not exceed 0.5. In addition, albumin levels and the ability of albumin to bind bilirubin vary significantly in sick infants. It has also been shown that binding increases with increasing gestational and postnatal age. The bilirubin-to-albumin molar ratio (BAMR) may be used as an adjunct to measurements of TB in determining the need for exchange transfusion (Table 48-2).

Therapy for Unconjugated Hyperbilirubinemia

After it has been determined that a patient is at risk for the sequelae of unconjugated hyperbilirubinemia, prompt therapy should be instituted. The current mainstay of treatment is phototherapy, which has been proved to be instrumental in containing the rate of rise of TB and lowering the TB. In cases of failure of phototherapy, or in newborns presenting with

TABLE 48–2 Bilirubin-to-Albumin Molar Ratio (BAMR) as a Determinant of the Need for Exchange Transfusion

	BAMR AT WHICH EXCHANGE TRANSFUSION SHOULD BE CONSIDERED	
Risk Category	*TB (mg/dL)/Albumin (g/dL)*	*TB (μmol/L)/Albumin (μmol/L)*
Infants ≥$38^0/_7$ wk	8.0	0.94
Infant $35^0/_7$ to $37^6/_7$ wk and well or ≥$38^0/_7$ wk if higher risk or isoimmune hemolytic disease or G6PD deficiency	7.2	0.84
Infant $35^0/_7$ to $37^6/_7$ wk if higher risk or isoimmune hemolytic disease or G6PD deficiency	6.8	0.80

If TB is at or is approaching the exchange level, send blood for immediate type and crossmatch. Blood for exchange transfusion is modified whole blood (red blood cells and plasma) crossmatched against the mother and compatible with the infant.

G6PD, glucose-6-phosphate dehydrogenase; TB, total bilirubin.

From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297, 2004.

extremely high TB concentrations, exchange transfusion will definitively lower the TB to a level that will no longer be of danger to the neonate. Intravenous immunoglobulin (IVIG) and phenobarbital therapy also have a role in the management of hyperbilirubinemia. The intensity and invasiveness of therapy are determined by the many factors discussed thus far, including the gestational age and relative health of the neonate, the current level of TB, and an estimation of the rate of rise in view of the dynamic nature of bilirubin metabolism in the newborn. An example of a clinical pathway for the management of the newborn infant readmitted for phototherapy or exchange transfusion is given in Box 48-3.

BOX 48–3 Examples of a Clinical Pathway for the Management of the Newborn Infant Readmitted for Phototherapy or Exchange Transfusion

TREATMENT

Use intensive phototherapy and/or exchange transfusion as indicated in Figs. 48-21 and 48-22.

LABORATORY TESTS

- TB and direct bilirubin level
- Blood type (ABO, Rh)
- Direct antibody test (Coombs test)
- Serum albumin
- CBC with differential and peripheral blood smear for RBC morphology
- Reticulocyte count
- ETCOc (if technology is available)
- G6PD screen, if indicated by ethnicity or geographic origin or if poor response to phototherapy
- Urinalysis for reducing substances
- If history or presentation suggests sepsis, perform blood culture, urine culture, and CSF examination for protein, glucose, cell count, and culture.

INTERVENTIONS

- If TB ≥25 mg/dL (428 μmol/L) or ≥20 mg/dL (342 μmol/L) in a sick infant or infant <38 weeks' gestation, obtain a type and crossmatch, and request blood in case exchange transfusion becomes necessary.
- In infants with isoimmune hemolytic disease and a TB rising despite intensive phototherapy or rising to within 2 to 3 mg/dL (34 to 51 μmol/dL) of exchange level (see Fig. 48-22), administer IVIG (500 to 1000 mg/kg) over 2 hours and repeat if necessary.
- If infant's weight loss from birth is greater than 12% or there is clinical or biochemical evidence of dehydration, recommend formula or expressed breast milk. If oral intake in question, give IV fluids.

FOR INFANTS RECEIVING INTENSIVE PHOTOTHERAPY

- Breastfeed or bottle-feed (formula or expressed breast milk) every 2 to 3 hours.
- If TB ≥25 mg/dL (428 μmol/L), repeat TB within 2 to 3 hours.
- If TB 20 to 25 mg/dL (342 to 428 μmol/L), repeat TB within 3 to 4 hours.
- If TB <20 mg/dL (342 μmol/L), repeat TB in 4 to 6 hours.
- If TB continues to fall, repeat TB in 8 to 12 hours.
- If TB is not decreasing, or is moving closer to level for exchange transfusion, or the TB-to-albumin ratio exceeds levels shown in Table 48-2, consider exchange transfusion.
- When TB is below 13 to 14 mg/dL (222 to 239 μmol/L), discontinue phototherapy.
- Depending on the cause of the hyperbilirubinemia, it is an option to measure TB **24 hours** after discharge to check for rebound hyperbilirubinemia (see text).

CBC, complete blood count; CSF, cerebral spinal fluid; ETCOc, end-tidal carbon monoxide, corrected for inhaled CO; G6PD, glucose-6-phosphate dehydrogenase; IV, intravenous; IVIG, intravenous immunoglobulin; RBC, red blood cell; TB, total bilirubin.

From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297, 2004.

PHOTOTHERAPY

Phototherapy is the most widely used form of therapy for the treatment and prophylaxis of neonatal unconjugated hyperbilirubinemia. In nearly all neonates, phototherapy reduces or blunts the rise of TB concentrations (regardless of maturity, the presence or absence of hemolysis, and the degree of skin pigmentation). Given the decades of experience with its use worldwide and the lack of reported serious long-term side effects thus far, short-term phototherapy appears to be safe. The initial report from the Collaborative Study on the Effectiveness and Safety of Phototherapy, undertaken under the auspices of the National Institute of Child Health and Human Development (NICHD), demonstrated that neonates receiving phototherapy require significantly fewer exchange transfusions. More important, these infants had an incidence of gross kernicterus and subsequent neurobehavioral performance that was lower than those who received only exchange transfusions to control hyperbilirubinemia. Furthermore, subsequent follow-up studies revealed no adverse outcome in the infants who received phototherapy in the neonatal period.[36,148,190]

Mechanism of Action

Three independent mechanisms have been proposed to explain the action of phototherapy in reducing TB concentrations in neonates (Fig. 48-16).[257] The first and most important pathway is geometric photoisomerization of the native unconjugated bilirubin IX-α (Fig. 48-17). Unconjugated bilirubin IX-α is normally in the 4Z,15Z configuration. In this form, the −COOH group of each carboxymethyl side chain interacts through three hydrogen bonds with the C=O and N-H group of the pyrrole rings in the opposite half-molecule. As a result, ionization of the two −COOH and two keto groups is inhibited, making the molecule nonpolar and water insoluble. When illuminated by wavelengths (peak, 460 ± 10 nm), light is absorbed by bilirubin and unconjugated bilirubin undergoes Z-to-E (configurational) isomerization at either one or both of the bridge double bonds to yield potentially three isomers: 4E,15Z; 4Z,15E; and 4E,15E. The E configuration spatially precludes hydrogen bonding of the molecule, which therefore remains open or unfolded and free to ionize. Thus, the E isomer is more polar and soluble than the Z isomer. Because the liver can transport only soluble bilirubin into bile, the E isomers can be excreted without the need for conjugation.

At least two pairs of geometric photoisomers have been identified in vivo. The first pair, photoisomers IA and IB, is presumably the two possible E,Z isomers. The second pair, photobilirubins IIA and IIB, is most likely two rotamers of the 4E,15E isomer. Both pairs are presumably formed rapidly in the skin, subcutaneous tissue, and capillaries. Being more polar, all these isomers partition into the plasma, continuously shifting the equilibrium to promote more isomer formation. These isomers are rapidly taken up by the liver and transported into bile. These photoisomers are destabilized by bile acids, rapidly reverting to native unconjugated bilirubin IX-α in the bile ducts and intestine. The rotameric isomers remain mostly intact and are the major polar photoproducts found in bile. This photoisomerization pathway may be responsible for more than 80% of the augmented bilirubin elimination during phototherapy. Geometric photoisomerization is not, however, the only isomerization pathway open to photoexcited bilirubin. The proximity of the side-chain double bond at C-3 to the adjacent pyrrole ring allows an intramolecular cyclization, again rendering the bilirubin molecule more polar (see Fig. 48-17B). This structural isomer of bilirubin is called *lumirubin*, and it is also excreted into bile without need for hepatic conjugation. Lumirubin, a soluble compound, is the major photoproduct excreted with the bile and urine, and its conversion is the rate-limiting step in the elimination of bilirubin by phototherapy.

The third pathway of phototherapy involves a variety of bilirubin oxidation reactions, resulting from an autosensitized reaction involving singlet oxygen. The products formed by these reactions are multiple but include biliverdin, dipyrroles, and monopyrroles. Many of these products are colorless, nonreactive in the van den Bergh test, and presumably excreted by the liver and kidney without need for conjugation. Compared with the photoisomerization pathway, the oxidation mechanism appears to play a very minor role in photocatabolism of unconjugated bilirubin in vivo (Fig. 48-18).[131,238]

Technique

Phototherapy is not a standardized practice in the United States at this time, and there exist many different devices capable of delivering phototherapy with varying efficacies. Any physician using one of these devices must be cognizant of the variables influencing the efficacy of phototherapy and ensure that the device is used appropriately.

The first variable to consider is the wavelength of light used to induce photoisomerization (Fig. 48-19). Bilirubin absorbs light maximally in the blue range (340 to 540 nm), with peak absorption for albumin-bound bilirubin at about 460 nm and for unbound bilirubin at about 440 nm. Daylight and cool white lamps have a spectral emission of 380 to 720 nm with a peak of 578 ± 10 nm and are less effective than blue lamps (F20 T12/B), which have a narrower spectral range and peak between 420 and 480 nm. Special blue lamps (F20 T12/BB and TL52 tubes [Philips, The Netherlands]) emit narrower spectra of light with greater irradiance at the main therapeutic spectrum and have been shown to be most effective. The blue hue that is produced by these lamps can interfere with skin color assessment in jaundiced neonates, and it has been reported to produce dizziness and nausea variably in those caring for these patients. These side effects may be readily tempered by the addition of daylight fluorescent lamps to the phototherapy unit.[54,68] However, incorporation of white fluorescence "dilutes" the blue intensity, thereby dramatically decreasing the effectiveness of phototherapy.[238]

Several studies showed that phototherapy with green light (peak at 525 nm) is as effective as that with blue light and better than white light in reducing bilirubin concentrations. Green light lacks the untoward side effects often

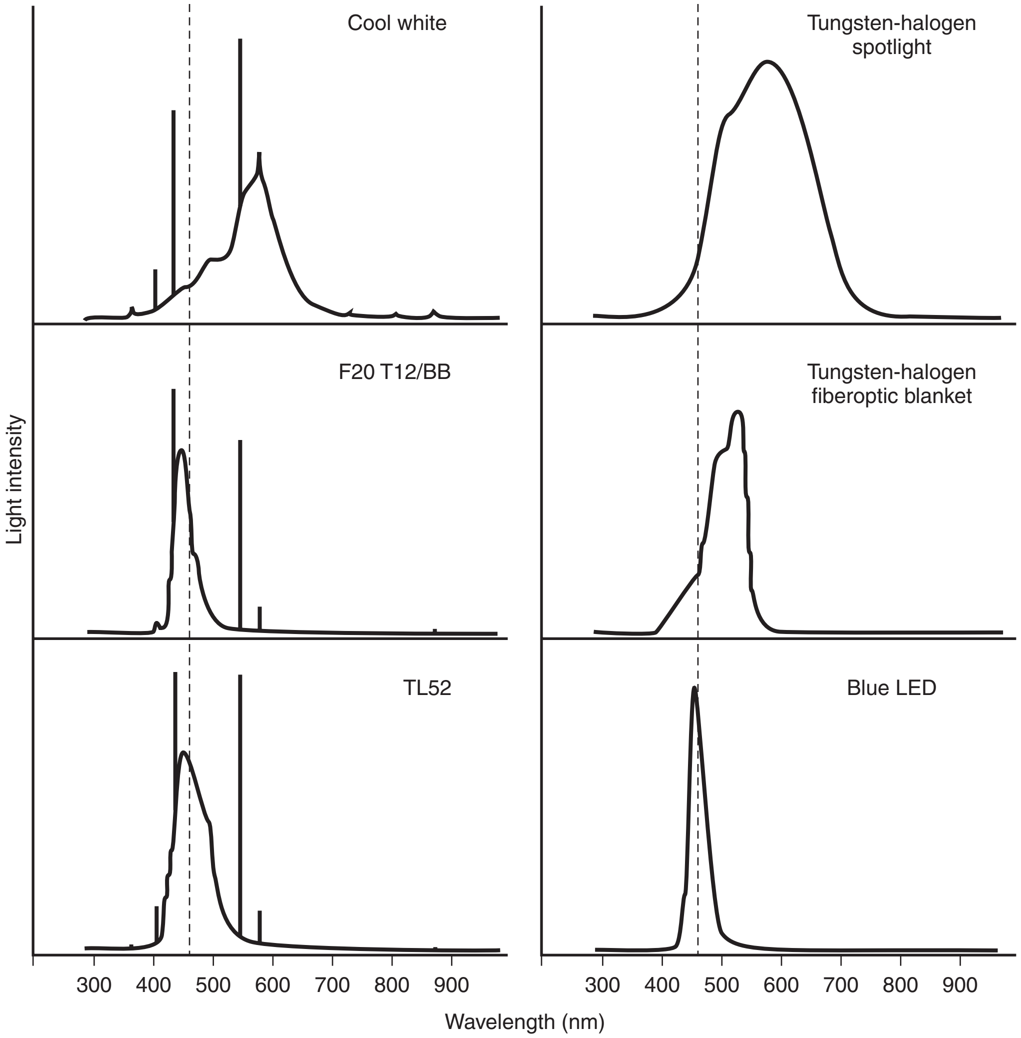

Figure 48–19. Emission spectra of phototherapy devices. The intensities are shown on a linear relative scale. The spectra of the three fluorescent lamps (cool white, and special blue [F20 T12/BB and TL52]), tungsten-halogen (spotlight [Olympic Medical Mini-Bililite, Seattle, WA] and fiberoptic blanket [Biliblanket, Ohmeda, Columbia, OH]), and blue light-emitting diodes (LEDs [neoBLUE, Natus Medical, Inc., San Carlos, CA]) were measured under identical conditions on an S-2000 spectrophotometer (Ocean Optics, Inc., Dunedin, FL). *Dotted line* represents the peak absorption of bilirubin at about 460 nm. *(From Vreman HJ, et al:* In vitro *efficacy of an LED-based phototherapy device [neoBLUE] compared to traditional light sources,* Pediatr Res *53:400A, 2003.)*

associated with intense blue light. However, further study is needed to definitively determine the clinical benefit of green light because green light phototherapy has not been widely adopted.[18,228]

The second variable that influences the efficacy of phototherapy is energy output or irradiance as measured in units of microwatts per square centimeter per nanometer (μW/cm^2/nm). Effective phototherapy must provide irradiance well above the levels that have been determined to be minimally effective in producing bilirubin degradation while not exceeding levels beyond which no significant increases in response are evident. This also helps avoid potential side effects such as elevation in body temperature. A standard phototherapy unit operating under optimal conditions would provide clinically significant, but minimally effective, levels of phototherapy (about 6 to 12 μW/cm^2/nm). In intensive phototherapy, irradiance is increased to 25 μW/cm^2/nm or greater. The BiliBed Phototherapy Unit (Medela, Inc., McHenry, IL) can deliver up to 60 μW/cm^2/nm.

Standard phototherapy lamps are normally positioned within 40 cm from the infant, but should more intensive phototherapy be required, the lamps may be placed within 15 to 20 cm of the patient, provided fluorescent lamps, and not heat-producing halogen lamps with a potential danger of causing thermal injury, are used. Conversely, increasing the distance from the lamp to the skin surface of the neonate results in a theoretical diminution of light energy by a factor equal to the square of the increase in the distance (Fig. 48-20).[139]

The greater the surface area of the newborn exposed, the greater will be the effectiveness of phototherapy. Skin

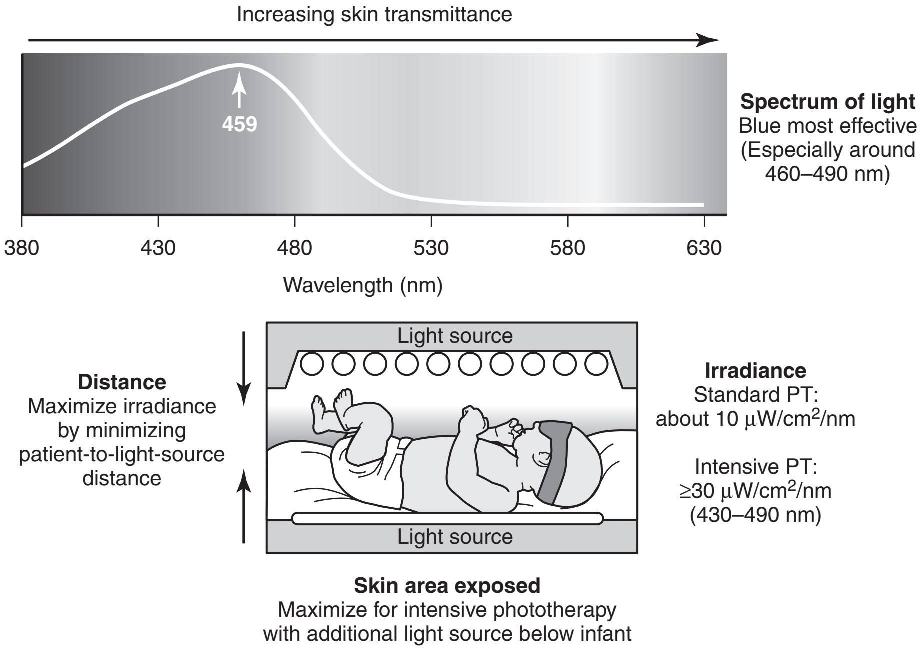

Figure 48–20. See color insert. Important factors in the efficacy of phototherapy (PT). The absorbance spectrum of bilirubin bound to human serum albumin (*white line*) is shown superimposed on the spectrum of visible light. Clearly, blue light is most effective for phototherapy, but because the transmittance of skin increases with increasing wavelength, the best wavelengths to use are probably in the range of 460 to 490 nm. Term and near-term infants should be treated in a bassinet, not an incubator, to allow the light source to be brought to within 10 to 15 cm of the infant (except when halogen or tungsten lights are used), increasing irradiance and efficacy. For intensive phototherapy, an auxiliary light source (fiberoptic pad, light-emitting diode [LED] mattress, or special blue fluorescent tubes) can be placed below the infant or bassinet. If the infant is in an incubator, the light rays should be perpendicular to the surface of the incubator in order to minimize loss of efficacy due to reflectance. *(From Maisels MJ, McDonagh AF: Phototherapy for neonatal jaundice,* N Engl J Med *358:920, 2008.)*

pigmentation does not reduce the effectiveness of phototherapy. With use, fluorescent lamp energy output declines to a degree that varies from one type of lamp to another. A meter for monitoring lamp energy output should be used routinely during treatment to ensure optimal treatment. Although commercially available photometers have been found to vary in their absolute measurement of irradiance because of differences in meter sensitivity (i.e., peak and range) and the emission characteristics of their light sources, they are still useful in determining relative lamp decay. Lamps that have lost more than 20% of the acceptable output should be replaced.

All lamps should be housed behind Plexiglas to reduce the danger to the patient should a lamp explode. Also, it has been shown that Plexiglas provides protection from any harmful ultraviolet irradiation arising from the available light sources. Patients may be cared for on an open warmer or in a crib. Use of a closed incubator may increase the distance of the light source from the infant, thereby attenuating the irradiance delivered to the patient.

The third variable affecting the efficacy of phototherapy is the body surface area of the neonate exposed to light. Ideally, neonates should be naked when under phototherapy; however, use of diapers, folded back to cover as little of the baby's surface as practically possible, may improve on the obvious disadvantages of leaving the infant unclothed. Positioning of several phototherapy units around the newborn, or placing the baby on a phototherapy mattress in addition to the overhead lights, may increase exposure. A white sheet draped around the periphery of the bed may also act to reflect light onto relatively underexposed areas, thereby increasing the overall light irradiance.

Other conventionally used devices incorporate tungsten-halogen lamps as their light source for use as spotlights. Another technique involves transmission of light through a fiberoptic bundle to a pad or blanket around the infant.[77] The advantage of the latter technology is that the source of light, and therefore heat, will be at a distance from the infant. In infants with severe hyperbilirubinemia, the previously mentioned techniques can be used in combination to increase light intensity (irradiance) and body surface area exposure.[3,67] Too frequently, currently used doses of phototherapy are well below the optimal therapeutic range.[210] The AAP recommends the use of intensive phototherapy, especially for infants readmitted for hyperbilirubinemia, or if the threshold for exchange transfusion is approaching. Intensive phototherapy implies the use of high levels of irradiance in the therapeutic range (usually ≥30 μW/cm^2/nm) delivered to as much of the infant's surface area as possible.

Another method of delivering light has been introduced. It involves the use of arrays of blue light-emitting diodes (LEDs), which can deliver high-intensity narrow band light in the absorption spectrum of bilirubin.[235,238] This technology has been incorporated into a new phototherapy device (neoBLUE, Natus Medical, Inc., San Carlos, CA) and shown to be an effective and safe alternative to other modes of phototherapy.[191,238] An LED light source is now also available as a mattress in addition to overhead lights. Advantages of the LED technology include the ability to increase the light intensity to a level higher than many conventional technologies without significantly warming the baby, and the long period during which the lamps remain effective without the need for replacement.

Clinical studies comparing intermittent to continuous phototherapy have yielded conflicting results. Several studies failed to show effectiveness of the intermittent therapy. These results may have resulted from prolonged light-on and light-off cycles—for example, 6- to 12-hour on-off schedules. Photoisomerization of bilirubin occurs primarily in skin layers, and the restoration of the bilirubin pool in the skin takes about 1 to 3 hours. Thus, a prolonged on-off schedule may not be as effective as continuous therapy, but an on-off cycle of less than 1 hour is apparently as effective as continuous treatment. Phototherapy lights should be shut off and eye patches removed during feeding and family visiting for up to 1 hour because this does not significantly reduce phototherapy effectiveness.

Some reports have demonstrated that home phototherapy may be an effective and safe alternative to prolonged hospitalization for healthy full-term neonates with jaundice. Clear advantages of home-centered phototherapy include (1) reduced cost; (2) avoidance of parent-infant separation; and (3) parental satisfaction.[95,183] However, complications of home phototherapy that might result from inadequate nursing supervision include corneal abrasion, eye patch misuse, excessive weight loss, temperature derangement, and ineffective bilirubin reduction. Whether there is any valid indication for phototherapy for those neonates who could be safely managed at home is questionable. Those with valid indications are generally too sick, too small, or too close to the exchange transfusion level to be safely treated at home. The Committee on the Fetus and Newborn (COFN)of the AAP has not endorsed home phototherapy, but it has issued a strict guideline for its use.[11] Because the devices available for home phototherapy may not provide the same degree of irradiance or surface-area exposure as those available in hospital, the Subcommittee on Hyperbilirubinemia of the AAP recommends that home phototherapy should be used only in infants whose bilirubin levels are in the "optional phototherapy" range (see "Indications," below).[13] It is not appropriate for infants with higher bilirubin concentrations or if the TB is approaching the exchange transfusion level. As with hospitalized infants, the TB must be monitored regularly.

Indications

Although not "evidence based," the AAP has issued a comprehensive guideline for the commencement of phototherapy in infants older than 35 weeks' gestation (Fig. 48-21). These guidelines take into account the presence of risk factors as well as prematurity, and also are adapted to the dynamic changes in TB concentrations during the first days of life. Thus, there is no single TB concentration at which phototherapy should be commenced, but each newborn must be assessed individually, taking into consideration postnatal age, gestational age, and other risk factors, enumerated in the legend of Figure 48-21. The TB level at which phototherapy may be discontinued must also be decided in view of these factors. It may be useful to continue plotting the TB concentrations of the hour-specific bilirubin nomogram during phototherapy, and discontinue phototherapy once the TB has decreased below the 75th percentile for hours-of-life, or even closer to the 40th percentile in infants with lower gestational age or in the presence of risk factors. Follow-up for rebound, not necessarily requiring continued hospitalization, should be performed in cases of newborns younger than 37 weeks' gestation, those with positive DAT, and those treated at or before 72 hours' postnatal age.[117]

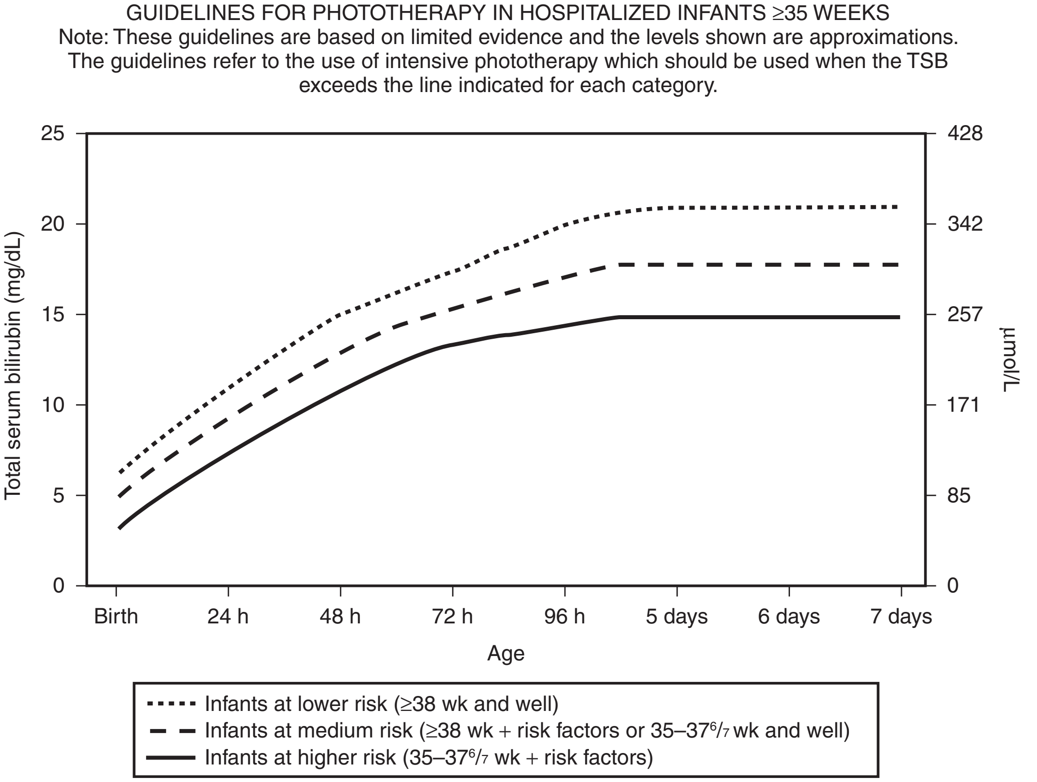
The AAP guideline does not extend to premature infants younger than 35 weeks' gestational age. However, Maisels and Watchko have suggested therapeutic guidelines for these newborns, both by gestational age and by birthweight (Tables 48-3 and 48-4).[141] Recently published NICE guidelines provide a graph incorporating indications for phototherapy and exchange transfusion for each week of gestational age. (Available at http://www.nice.org.uk/CG98.)

Complications

Several potential complications may occur with the use of phototherapy.[184] The effect of high-intensity light exposure on the eyes of human neonates is uncertain, but animal studies indicate that retinal degeneration may occur after several days of continuous exposure. It is essential therefore that the eyes of all newborns exposed to phototherapy be covered with sufficient layers of opaque material to guard against the possibility of damage. The use of fiberoptic phototherapy does not eliminate the need to cover the patient's eyes.

Phototherapy may produce an increase in body and environmental temperature. Fluid balance, especially in the premature neonate, is a key management issue in the patient being treated with phototherapy. There is increased insensible and intestinal water loss during phototherapy, which must be compensated for by an increase of about 25% above the estimated fluid need without phototherapy. In addition, stools may be slightly looser and more frequent.[21] Fiberoptic phototherapy appears to result in lower insensible water losses and therefore slightly less need for increased maintenance fluids (see Chapter 36). LED-based devices, however, do not release a significant amount of heat, and their use results in less insensible water loss. Term infants treated with LED light in open cribs should have their body temperatures monitored to detect excessive body cooling.

A well-recognized side effect of phototherapy is the *bronze baby syndrome*. In this disorder, the serum, urine, and skin become brown-black (bronze) several hours or more after a neonate is placed under the phototherapy lamps. All reported neonates with this syndrome have recovered without apparent sequelae, except one term neonate who died and was found to have kernicterus on autopsy. In nearly all patients, conjugated hyperbilirubinemia and retention of bile acids have been noted either before light exposure or



GUIDELINES FOR PHOTOTHERAPY IN HOSPITALIZED INFANTS ≥35 WEEKS
Note: These guidelines are based on limited evidence and the levels shown are approximations.
The guidelines refer to the use of intensive phototherapy which should be used when the TSB exceeds the line indicated for each category.

- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease. G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin <3.0 g/dL (if measured).
- For well infants 35–$37^{6}/_{7}$ wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wk and at higher TSB levels for those closer to $37^{6}/_{7}$ wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 μmol/L) below those shown but home phototherapy should not be used in any infant with risk factors.

Figure 48–21. Guidelines for phototherapy in hospitalized infants aged ≥35 weeks of gestation. Infants are designated as higher risk because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin. *(Adapted from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation,* Pediatrics *114:297, 2004. Used with permission of the American Academy of Pediatrics.)*

after the syndrome has developed. This syndrome has been reproduced in Gunn rats when their smaller bile ducts become obstructed by precipitated bile pigment during phototherapy. Photobilirubin II is shown to be degraded to brown pigments in vitro and when administered to Gunn rats in vivo. It seems likely that the bronze color of the plasma and urine in bronze baby syndrome results from retention of bile pigment photoproducts when their biliary excretion is impaired by concomitant cholestasis. A study in two infants with this syndrome showed an increase in coproporphyrin in the blood, and photoirradiation of this substance produced copper coproporphyrin degradation products similar to those found in neonates with this syndrome. It is generally recommended that phototherapy not be used in neonates with significant conjugated hyperbilirubinemia or other evidence of cholestasis. However, because there have been case reports of newborns who developed kernicterus in the presence of predominantly direct hyperbilirubinemia, the role of conjugated bilirubin in the pathophysiology of bilirubin encephalopathy is not clear, and affected infants should be assessed for the need for phototherapy on an individual basis.[89]

Congenital erythropoietic porphyria is another syndrome in which phototherapy is contraindicated because it may lead to death. This rare disorder is characterized by hemolysis, splenomegaly, and pink to red urine that fluoresces orange under ultraviolet light. Exposure to visible light of moderate to high intensity and of wavelengths between 400 and 500 nm (blue) produces severe bullous lesions on the exposed skin and accelerated hemolysis. Mixed hyperbilirubinemia with a significant direct-reacting fraction may also be seen in this disease.

Other theoretical dangers of phototherapy include electrical shock or fire from poorly grounded or defective equipment and unproven potential long-term effects on endocrine and sexual maturation and DNA repair mechanisms in skin

TABLE 48–3 Guidelines for the Use of Phototherapy and Exchange Transfusion in Low-Birthweight Infants Based on the Birthweight

	TOTAL BILIRUBIN LEVEL, mg/dL (μmol/L)*	
Birthweight	*Phototherapy*†	*Exchange Transfusion*‡
≤1500	5-8 (85 to 140)	13-16 (220-275)
1500-1999	8-12 (140 to 200)	16-18 (275-300)
2000-2499	11-14 (190 to 240)	18-20 (300-340)

Note that these guidelines reflect ranges used in neonatal intensive care units. They cannot take into account all possible situations. Lower bilirubin concentrations should be used for infants who are sick—for example, presence of sepsis, acidosis, hypoalbuminemia—or have hemolytic disease.

*Consider initiating treatment at these levels. Range allows discretion based on clinical conditions or other circumstances. Note that bilirubin levels refer to total serum/plasma bilirubin concentrations. Direct reacting or conjugated bilirubin levels should not be subtracted from the total.

†Used at these levels and in therapeutic doses, phototherapy should, with few exceptions, eliminate the need for exchange transfusions.

‡Levels for exchange transfusion assume that bilirubin continues to rise or remains at these levels despite intensive phototherapy.

epithelial cells. However, follow-up studies of phototherapy-treated premature and full-term neonates have failed to demonstrate any increase in morbidity or mortality ascribed to the appropriate use of phototherapy. A multicenter study to determine whether aggressive phototherapy to prevent neurotoxic effects of bilirubin benefits or harms extremely low-birthweight infants (≤1000 g) has recently been completed.[161] Aggressive phototherapy, compared with conservative phototherapy, significantly reduced the mean peak serum bilirubin level, but the primary outcome, a composite of death or neurodevelopmental impairment, was similar between groups. The rate of neurodevelopmental impairment alone was significantly reduced with aggressive phototherapy, but this reduction have been offset by an increase in mortality among infants weighing 501 to 750 g at birth.

No scientific evidence exists indicating that hydration directly lowers TB levels. On the other hand, dehydration is not known to be beneficial to patients in this context, and therefore all neonates should receive appropriate replacement and maintenance fluids. Conjugated bilirubin is water soluble and eliminated from the body in urine, bile, and stool. Inasmuch as appropriate hydration maintains adequate urine output, bile flow, and stool excretion, fluid administration indirectly assists in the removal of unconjugated bilirubin. Ideally, this fluid is given enterally to stimulate gastrointestinal tract motility. The use of a milk-protein formula may be considered to inhibit enterohepatic reabsorption of bilirubin, thereby lowering the TB.

PHARMACOLOGIC THERAPY

Phenobarbital

In experimental animals, UGT activity can be increased or induced with administration of phenobarbital, ethanol, chloroquine, antihistamines, heroin, and chlorophenothane (also known as DDT). These substances are not specific for any one enzyme but stimulate many hepatic membrane-bound enzyme systems and hepatic protein synthesis in general. Because of the known and potential toxicity of these agents, only phenobarbital has been used with regularity in humans.[220,243]

After the demonstration that phenobarbital administration to a child with Crigler-Najjar syndrome type II disease reduced TB concentrations, phenobarbital administration to pregnant mothers and their offspring was shown to reduce by about 50%, peak serum TB concentrations caused by physiologic jaundice. Studies in newborn rhesus monkeys have demonstrated that the major effect of this therapy is to increase hepatic UGT activity and the conjugation of bilirubin. It also may enhance hepatic uptake of bilirubin in the newborn. The administration of phenobarbital to newborns at the time jaundice is first observed or even immediately after delivery is much less effective than its administration to the mother during pregnancy for at least 2 weeks before delivery. The drug is much less effective in premature neonates. As a prophylactic measure, it would be necessary therefore to administer phenobarbital to large numbers of pregnant women for prolonged periods during pregnancy because the time of delivery could not be predicted with certainty. Even then, the premature neonates most susceptible to the toxic effects of hyperbilirubinemia would receive little or no beneficial effect.

Phenobarbital is potentially addictive, may lead to excessive sedation of the newborn, and has other potent metabolic effects in addition to those on bilirubin metabolism. For these reasons, its use has not achieved wide application but has been reserved largely for specific high-risk populations. For example, in the unexplained severe hyperbilirubinemia of newborns from the Greek coastal islands, the frequency of kernicterus has been significantly reduced by general administration of phenobarbital to pregnant women during the last trimester. A dosage of 60 mg/day is sufficient for maternal administration and 5 mg/kg per day for neonatal treatment. Similar effects have been observed in full-term Korean newborns. Phenobarbital is also useful in the differentiation of Crigler-Najjar syndromes type I and type II. Combining phenobarbital treatment with phototherapy has no advantage, the effect being no greater than that of phototherapy alone.

Metalloporphyrins

Metalloporphyrins, which are synthetic derivatives of heme, have been shown to be effective competitive inhibitors of HO, the rate-limiting enzyme for the degradation of heme to form bilirubin.[212] Originally proposed by Maines in 1981[135] for use in modulating bilirubin production, these compounds have been extensively studied. The first metalloporphyrin to be evaluated for use in preventing neonatal unconjugated hyperbilirubinemia was tin protoporphyrin (SnPP). Administration of this compound was shown to decrease bilirubin concentrations in newborn rats, rhesus monkeys, and adult rats with hemolytic anemia, and it was the first synthetic heme analogue used for the purpose of inhibiting HO in human neonates.[64] Although highly efficacious, the photoreactivity of this metalloporphyrin made it a less desirable drug.[230,237] Whitington and associates' studies demonstrate that SnPP reduces endogenous bilirubin formation without impairing hepatic uptake, excretion, or enteric resorption of bilirubin.[252] In newborn rhesus monkeys, administration of SnPP produced skin ulcerations, whereas in human neonates who also received phototherapy, some mild erythema of the skin was observed.[53,135,252] Human trials with tin mesoporphyrin (SnMP) in preterm neonates have shown a dose-dependent reduction in peak bilirubin levels irrespective of gestational age, and a reduction in the need for phototherapy compared with controls.[121,122,145,180,221] Mild transient erythema in patients requiring phototherapy was the only side effect noted.[221] In human studies, it has been shown that a single IM dose of 6 μM SnMP per kilogram body weight eliminates the need for phototherapy during the postnatal period.[145,221] The efficacy of SnMP has been well described by several investigators in patients with Crigler-Najjar syndrome,[76,186] but SnMP does contain a foreign metal, it induces the HO-1 promoter,[61,159,264] and it can inhibit other enzymes such as nitric oxide synthase and soluble guanylyl cyclase.[256] An alternative compound, zinc protoporphyrin (ZnPP), has been proposed, but it has a much lower inhibitory potency and is not well absorbed after oral administration. Nevertheless, it is a naturally occurring metalloporphyrin possessing both in vitro and in vivo inhibition of both HO-1 and HO-2 isozymes in studies using neonatal rodents and nonhuman primates.[230] Moreover, ZnPP is minimally photoreactive in vivo.[231,240] Other metalloporphyrins being evaluated for their safety and efficacy are chromium mesoporphyrin (CrMP) and zinc deuteroporphyrin bis glycol (ZnBG), compounds, which are orally absorbed and are potent heme oxygenase inhibitors.[230,237]

Other Nonmetalloporphyrin Inhibitors

Some nonmetalloporphyrin inhibitors of HO have been identified. Originally designed for use in transplantation survival studies, peptide inhibitors have been reported not only to be immunosuppressive in vitro and in vivo[103] but also to inhibit in vitro HO activity dose dependently. However, in mouse studies, it has been found that administration of peptides may upregulate HO-1 messenger RNA and protein in the liver, spleen, and kidney. These findings have precluded human studies investigating the efficacy of peptides for the treatment of hyperbilirubinemia.

Imidazole dioxolanes, inhibitors of cholesterol production,[41,209,241] have also been found to inhibit in vitro[60,126,229,239] and in vivo[160] HO activity, despite being structurally different from metalloporphyrins. It has been demonstrated that these compounds are highly selective for inhibiting the inducible HO-1, but like metalloporphyrins, some imidazole dioxolanes may affect other important enzymes, such as nitric oxide synthase (NOS) and soluble guanylyl cyclase.[126] One of these compounds, Azalanstat, has been reported to effectively inhibit in vivo HO activity, but does so only at a high dose and also can induce *HO-1* gene transcription,[160] thus limiting its clinical use.

Miscellaneous Agents

As already discussed, reabsorption of unconjugated bilirubin may contribute to a significant portion of hepatic bilirubin load in the newborn period. Frequent milk feeding (cow or human) may slow the rise of TB levels and enhance the bilirubin-reducing effect of phototherapy. Oral administration of nonabsorbable substances that bind bilirubin in the intestinal lumen and presumably reduce enteric absorption of bilirubin may reduce peak TB concentrations in physiologic jaundice. Orlistat has been used to increase fecal fat excretion, thereby enhancing bilirubin elimination and decreasing the serum unconjugated bilirubin concentrations in Crigler-Najjar syndrome.[92] Feeding breast-fed newborns β-glucuronidase inhibitors (L-aspartic acid or enzymatically hydrolyzed casein) during the first week reduced jaundice without affecting breast feeding deleteriously.[84] Activated charcoal has been used but is effective only when administered during the first

12 hours of life.[58] Agar has also been shown to be effective.[42,169] Further study of this type of therapy is needed before recommendations can be made regarding clinical applications. These pharmacologic agents may be no more effective than frequent milk feeding (every 2 hours).

Intravenous Immunoglobulin

High-dose IVIG (500 to 1000 mg/kg) administered over 2-4 hours has been shown in several small studies to reduce TB levels and the need for exchange transfusion in fetuses and neonates with Rh and ABO immune hemolytic disease.[128,188] Carboxyhemoglobin studies performed 24 hours after IVIG infusion in DAT-positive ABO-heterospecific neonates have demonstrated that, in those infants who responded to IVIG infusion with a decrease in TB, hemolysis was inhibited compared with the preadministration status. Exchange transfusion was avoided in responding newborns, but not in those in whom there was no response. Lack of response was attributed to higher rates of hemolysis, in which case use of a higher dose of IVIG was suggested.[93] The use of IVIG administration should be considered in neonates with DAT-positive immune hyperbilirubinemia who are not responding to intense phototherapy and whose TB concentration is approaching exchange transfusion indications. This dose can be repeated after 12 hours if necessary. Recommendations for IVIG have been included in the revised AAP Practice Parameter (see Box 48-3).

EXCHANGE TRANSFUSION

See Chapter 46, Part 2.

Exchange transfusion, first described by Diamond and associates,[62,63] is the standard mode of therapy for immediate treatment of hyperbilirubinemia to prevent kernicterus and for correction of anemia in erythroblastosis fetalis. Its use in the past decade has actually been reduced as a result of the use of RhoGAM to prevent Rh isoimmune disease, the application of phototherapy, and more recently, the administration of IVIG in cases of isoimmunity. In infants with severe hyperbilirubinemia due to isoimmunity or other hemolytic conditions, especially G6-PD deficiency, exchange transfusion may the only effective method of adequately reducing TB concentrations.

Objectives

With this technique, the equivalent of two neonatal blood volumes (160 mL/kg of body weight) is replaced in aliquots not to exceed 10% of the total blood volume. This results in the replacement of about 85% of the circulating RBCs.[227] Bilirubin concentrations are usually reduced by 50%. Although the procedure is relatively safe when performed by experienced practitioners in term neonates, it nevertheless carries a risk for both mortality (0.1% to 0.5% in term neonates) and morbidity as well as being time consuming and expensive. The procedure usually takes 1 to 2 hours. Slower exchanges should theoretically increase the quantity of bilirubin removed by permitting equilibration of pigment from tissue, but the differences are too small to justify the increased risk of prolonging the duration of the procedure. The indications for exchange transfusion need to be individualized, taking into account gestational age and severity of illness (Fig. 48-22). During acute hospitalization, exchange is recommended if TB rises to the indicated levels despite intensive phototherapy. For readmitted infants, if TB is above the exchange level, serial TBs should be performed every 2 to 3 hours, and if TB remains at or above levels indicated, exchange is recommended after 6 hours of intensive phototherapy.[13]

Indications

In the past, it was regularly recommended that TB, even in healthy term infants, be kept below 20 mg/dL (342 μmol/L) during the first 28 days of life. This has been questioned, and a growing consensus has developed that levels as high as 25 mg/dL (428 μmol/L) are acceptable for otherwise healthy, full-term, asymptomatic infants with no obvious hemolytic condition. When the exchange level is considered, conjugated bilirubin should not be subtracted from the total. Despite the inability of direct-reacting bilirubin to enter the CNS, it is possible that direct-reacting bilirubin can partially displace unconjugated bilirubin from albumin-binding sites to increase the risk for kernicterus.

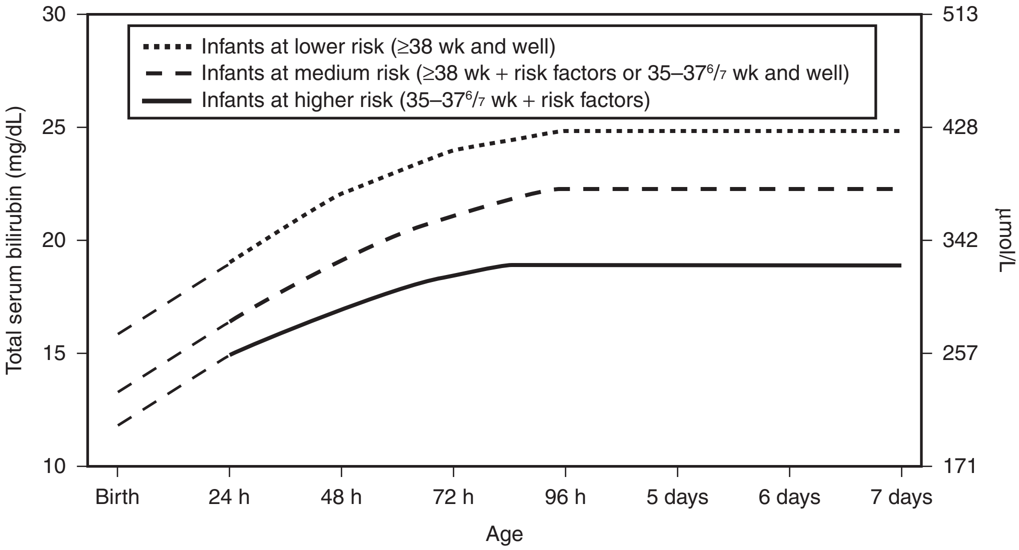
In the face of rapidly rising TB concentrations, as may be seen in Rh erythroblastosis or other types of hemolytic disease, the decision to perform the exchange transfusion should anticipate the rise (from previous TB concentrations, hemoglobin concentrations, and reticulocyte count), so that the exchange transfusion is underway by the time the critical level is reached.

The indications for exchange transfusion are based on the infant's TB concentrations in combination with postnatal age, gestational age, and other risk factors, such as isoimmune hemolytic disease, G6PD deficiency, asphyxia, lethargy, temperature instability, sepsis, acidosis, and bilirubin-to-albumin molar ratio (BAMR). In 2004, the AAP published a comprehensive guideline for initiating exchange transfusion for term and near-term neonates.[13] Indications for low-birthweight neonates or those with lower gestational ages than those specified in the AAP guideline have also been published.[141]

In the severely affected erythroblastotic neonate, clinical judgment rather than laboratory data should be used to decide whether the neonate requires immediate exchange transfusion after delivery. In this situation, a partial exchange transfusion using packed RBCs, coupled with reduction in blood volume if venous pressure is elevated, and with measures to ensure adequate ventilation and correction of acidosis and shock, will often be life saving. In most exchange transfusions, fresh whole or reconstituted citrate-phosphate-dextrose–anticoagulated blood should be used. If blood older than 5 days must be used, the pH should be checked and sodium bicarbonate added to correct the pH to 7.1. Full correction to pH 7.4 may result in later excessive rebound alkalosis as the citrate is metabolized. Use of heparinized blood avoids additional osmolar loads and may obviate the need to administer calcium or correct for acidosis but may result in hypoglycemia and markedly increased free fatty acid concentrations (see Chapter 49, Part 2).

Technique

Although there are numerous different combinations of blood components that can be used safely and effectively, there is no single combination or component that is superior.[211] RBCs reconstituted with 5% albumin or fresh frozen



GUIDELINES FOR EXCHANGE TRANSFUSION IN INFANTS ≥35 WEEKS

Note: These guidelines are based on limited evidence and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if TSB rises to these levels despite intensive phototherapy. For readmitted infants, if TSB is above exchange level, repeat TSB every 2–3 hours and consider exchange if TSB remains above levels indicated after intensive phototherapy for 6 hours.

- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high pitched cry) or if TSB is 25 mg/dL, (85 μmol/L) above these lines.
- Risk factors—isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate bilirubin/albumin (B/A) ratio (See legend).
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- If infant is well and 35–37 6/7 wk (median risk) can individualize TSB levels for exchange based on actual gestational age.

Figure 48–22. Guidelines for exchange transfusion in hospitalized infants aged ≥35 weeks of gestation. Note that these suggested levels represent a consensus of most of the committee but are based on limited evidence and the levels shown are approximations. *(Adapted from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation,* Pediatrics *114:297, 2004. Used with permission of the American Academy of Pediatrics.)*

plasma are most frequently used. Mixtures containing a citrate anticoagulant may cause hypocalcemia, but the administration of calcium during the exchange is seldom practiced. Transfused blood should not contain RBC antigens to which the mother has antibodies. Irradiation of blood is recommended for all exchange transfusions, especially if the infant had undergone an intrauterine transfusion, but may be omitted in clinical emergencies.[80] Because the transfused blood is frequently deficient in platelets, the platelet count should be monitored after exchange transfusion, and platelet transfusion should be considered in infants who are severely thrombocytopenic or who have a bleeding tendency.

The administration of salt-poor albumin (1 g/kg) to neonates 1 to 2 hours before exchange transfusion to increase the efficiency of bilirubin removal by shifting more tissue-bound bilirubin into the circulation has been advocated and shown to increase the bilirubin removed by 40%. As the total amount of bilirubin removed during an exchange transfusion is only a small portion of the total-body pool of bilirubin, this increase may not significantly alter subsequent bilirubin concentrations or the need for additional exchange transfusions. In addition, theoretically, the transient increase in TB concentration after albumin administration could increase, rather than reduce, the risk for kernicterus if there are local phenomena at the brain level that enhance entry of bilirubin into neurons. Finally, constituents of some albumin solutions may act to displace bilirubin from its binding sites, potentially increasing the percentage of free bilirubin present in the plasma. Thus, pretreatment with albumin before exchange transfusion is not routinely recommended.

Complications

The AAP[13] recommends that exchange transfusions be performed only by trained personnel in a neonatal intensive care unit with full monitoring and resuscitation capabilities. Exchange transfusion is an invasive procedure, and complications may be related to the blood transfusion itself, catheter-related complications, and those related to the procedure.[244] The potential complications of exchange transfusion are listed in Box 48-4. Severe hemolysis due to the use of incompatible RBCs may be life-threatening. With modern-day screening for infection, there is only a slight chance of transmission of viral or bacterial infection. Hyperkalemia may result if the transfused blood has been stored for a long period. Rebound hypoglycemia may occur if the glucose load during exchange transfusion is large. Graft-versus-host disease is rare but may occur in premature infants or those who have had in utero transfusions. Umbilical venous catheterization may result in air embolism, hemorrhage, or infection.

Presently, serious complications of exchange transfusion are uncommon. Mortality rates are very low in healthy, term neonates, but are increased for sick or extremely premature infants. In a study of 106 neonates who underwent 140 exchange transfusions between 1980 and 1995, the overall mortality was 2%, but increased to 8% in the subset of infants who were ill.[104] In a smaller series, no serious adverse effects or death occurred among 22 term neonates who had 26 exchange transfusions between 1990 and 1998.[46] In another review of 55 neonates who underwent 66 exchange transfusions between 1992 and 2002,[176] 74% had some form of adverse event, with the most common being thrombocytopenia, hypocalcemia, and metabolic acidosis.

If performed under intensive care facilities and with appropriate expertise, the advantages of performing an exchange transfusion clearly outweigh the potential risk, albeit small, of serious complications. Preparations for emergency situations should be made before initiation of the procedure.

Individualization of Therapeutic Guidelines

The TB level is one of the major criteria to be evaluated when considering the initiation or escalation of treatment for unconjugated hyperbilirubinemia. Although it is believed that it is the unconjugated fraction that presents the danger of kernicterus, the exact ratio of unconjugated and conjugated bilirubin is difficult to assess because its quantitation exhibits great variability among laboratories. In view of this, the conjugated bilirubin level should not be subtracted from the TB level unless it constitutes more than 50% of the total. As was stated previously, many variables other than the TB level influence the susceptibility of a particular patient to the sequelae of unconjugated hyperbilirubinemia; these include genotype, gestational age, chronologic age, and the presence of hemolytic or other disease states. Therefore, it is useful to consider four groups of patients at risk for kernicterus and modify treatment on the basis of the category: the healthy term (>37 weeks' estimated gestational age), the sick term, the healthy premature, and the sick premature neonate.

BOX 48–4 Potential Complications of Exchange Transfusion

- Thrombocytopenia, particularly with repeat transfusions
- Portal vein thrombosis or other thromboembolic complications
- Umbilical or portal vein perforation
- Acute necrotizing enterocolitis
- Arrhythmia, cardiac arrest
- Hypocalcemia, hypomagnesemia, hypoglycemia
- Respiratory and metabolic acidosis, rebound metabolic alkalosis
- Graft-versus-host disease
- Human immunodeficiency virus, hepatitis B and C infection
- All other potential complications of blood transfusions

In 1994, the Provisional Committee for Quality Improvement and Subcommittee on Hyperbilirubinemia of the AAP published recommendations for the management of unconjugated hyperbilirubinemia in healthy term neonates.[12] The recommendations were revised in 2004[13] and are detailed in Figures 48-15, 48-21, and 48-22. Whereas the 1994 guidelines did not offer suggestions for the management of newborns with hemolytic conditions, the 2004 guidelines take into account both term and late preterm infants, with and without risk factors. Risk factors to be taken into account for the purpose of deciding whether to institute phototherapy or exchange transfusion include isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, and acidosis. Jaundice manifesting in the first 24 hours of life is emphasized as an important risk factor, and recommendations for infants with early jaundice are included in the therapeutic guidelines. Therefore, a more conservative approach should be taken to initiating therapy for hyperbilirubinemia (Table 48-5). Similarly, TB levels rising at a rate greater than 0.5 mg/dL per hour (9 μmol/L) or "jumping tracks" on the bilirubin nomogram indicate a state of active hemolysis; such patients should be considered as falling into the "sick," or risk factor, category. It is exceedingly important in these cases to institute and revise therapies on the basis not only of the current level of bilirubin but also of an estimate of the anticipated peak. Thus, early in the patient's course, phototherapy or exchange transfusion may be performed at a relatively lower bilirubin level than for a similar bilirubin level occurring at a later time (see Box 48-3).

Prediction of Hyperbilirubinemia and Postdischarge Follow-up

An examination of the hours-of-life specific bilirubin nomogram will reveal that the TB continues to rise in a steady fashion throughout the first days of life, arriving at its peak at about 4 to 5 days. An infant who is discharged home at or around 48 hours of age will only have started to increase the TB and will reach the peak TB at home. Great responsibility is, therefore, placed on the parents to detect deepening jaundice and to approach the appropriate facilities should hyperbilirubinemia develop. Many cases of kernicterus have developed at home in newborns previously thought to be well and discharged from the newborn nursery as healthy.[28] To assist in discharge planning and in an attempt to detect at least some of the infants with developing hyperbilirubinemia, the AAP[13] has issued guidelines for postdischarge follow-up (Box 48-5). It is recommended that every newborn be seen by a pediatrician within 2 to 3 days of discharge, even those

BOX 48–5 Postdischarge Follow-up

INFANT DISCHARGED	SHOULD BE SEEN BY:
Before age 24 hr	72 hr
Between age 24 and 47.9 hr	96 hr
Between age 48 and 72 hr	120 hr

From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297, 2004.

who were not jaundiced at the time of discharge. Clinical judgment should be used when scheduling follow-up, and infants with risk factors for hyperbilirubinemia may be seen earlier than recommended in Box 48-5, as judged clinically necessary.

In a recent update[137a] to the 2004 AAP guidelines, a predischarge measurement of TB or transcutaneous bilirubin is recommended and the risk for hyperbilirubinemia detected on the basis of the infant's age in hours and the bilirubin measurement, which may require readmission to the hospital for treatment. Moreover, all infants should be screened for risk factors when planning for the postdischarge visit.

CONJUGATED HYPERBILIRUBINEMIA

Neonatal jaundice associated with a rise in conjugated bilirubin is indicative of a defect or insufficiency in bile secretion, biliary flow, or both and is always pathologic. It is commonly accompanied by a rise in serum levels of other constituents of bile, such as bile salts and phospholipids. The designation *cholestasis*, meaning reduction in bile flow, is used to describe this group of disorders. The rise of conjugated serum bilirubin may be the result of primary defects in the hepatocellular transport or excretion of bile, or secondary to abnormalities in bile duct function or structure.[17] Sequelae are specific to the many diverse diseases producing this clinical entity, and therefore treatment, when possible, is directed at the underlying disease.

The hepatocellular phase of bile secretion involves the transport of conjugated bilirubin across the hepatic cell membrane at the biliary pole. The lateral cell membrane at this site is folded to form microvilli and becomes part of the canalicular space, surrounded by two or more adjacent hepatocytes. Microvilli and the underlying cytoplasm contain microfilaments visible by electron microscopy. These structures consist of the contractile protein actin, which is necessary for normal canalicular contraction and microvillous motility, important elements in the generation of intrahepatic bile flow. At the border of the bile canaliculus, hepatocytes are joined in a "tight junction," which under normal circumstances forms an efficient barrier, preventing the contents of the bile canaliculus from entering the perisinusoidal space of Disse or the vascular compartments (Fig. 48-23). The bile

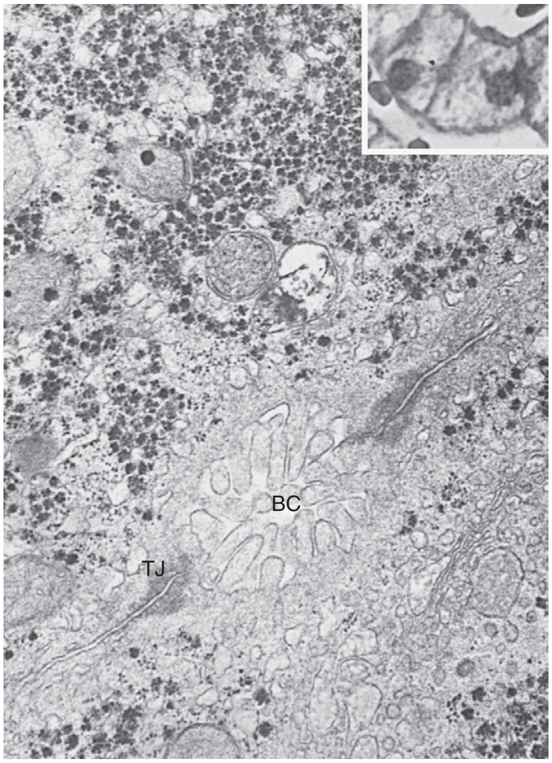

Figure 48–23. Electron micrograph of two adjacent normal hepatocytes. Note the microvillar surface of the bile canaliculus (BC). Tight junctions (TJ) border the canaliculus. *Insert:* A high-power view of two adjacent hepatocytes as seen in the light microscope. In such preparations, bile canaliculi appear as poorly defined condensations of the cell membrane. Epon-embedded; ×6000. (*Courtesy of Dr. L. Biempica, Albert Einstein College of Medicine, Bronx, NY.)*

canaliculus is an integral part of hepatocytes. It follows that any hepatocellular injury may result in impairment of the cellular phase of bile excretion and breakdown of the tight junctions, leading to the clinical and laboratory findings of cholestasis.

Hyperbilirubinemia resulting from hepatocellular injury may be associated with other abnormalities that reflect impairment of other hepatocellular functions. These abnormalities include hypoglycemia, fluid retention, and bleeding. On the other hand, injury may selectively impair bile secretion at the biliary pole of hepatocytes, resulting in an isolated laboratory finding of conjugated hyperbilirubinemia. A liver biopsy taken in the early stages of one of the diseases caused by a hepatocellular defect in bile secretion would characteristically show bile pigment granules in hepatocytes and canaliculi, referred to as *intracellular* and *intracanalicular cholestasis*. Bile pigment granules are not seen in either hepatocytes or canaliculi of normal liver parenchyma. In fact, the canalicular lumen is not visualized in routine sections of normal liver parenchyma because it is partially obliterated by microvilli identifiable only by electron microscopy. In cholestasis, there is usually blistering, blunting, or destruction of these microvilli, transforming the bile canaliculus into a widened, round space containing bile (the bile plug). On rare occasions, liver biopsies from patients with conjugated hyperbilirubinemia fail to show any abnormalities when examined with the light microscope.

The ductal phase of bile excretion includes those events that take place in the biliary system distal to the bile canaliculus (Fig. 48-24). The intrahepatic biliary system comprises the bile ductules (the initial portion of which is frequently referred to as the *canals of Hering*); the interlobular (portal) bile ducts, recognized by their constant association with a vein and an arteriole; and the right and left hepatic ducts, which in some individuals may partially extend beyond the liver capsule at the liver hilum. The extrahepatic component includes the common hepatic duct, the cystic duct, the gallbladder, and the common bile duct (choledochus). The extrahepatic biliary system and the major right and left hepatic ducts contain intramural and periductal glandular structures. Although the role of these structures in humans is not clearly understood, information derived from animal experiments suggests they may play an important role in bile duct regeneration or failure to regenerate. This is suggested by the presence of glands or ductules in duct remnants resected during portoenterostomy for biliary atresia (see under specific disorders in the following paragraphs). Most diseases affecting the extrahepatic bile ducts, and occasionally the left and right hepatic ducts, are associated with segmental or diffuse luminal obliteration and are primarily expressions of mechanical disturbance in bile flow.

Diseases involving the intrahepatic ducts, in the absence of concomitant extrahepatic disease, are complex and probably result from a combination of mechanical obstruction to the flow of bile, abnormalities of the biochemical pathways involved in the process of bile secretion, and, in some cases, persistence of infectious agents or viral antigens. In rapidly occurring duct obstruction, dilation of proximal branches is noted. This change may not be present when luminal obliteration is incomplete or when it develops slowly because these cases are frequently complicated by reduction in intrahepatic bile secretion and flow. A constant and characteristic tissue response to complete mechanical obstruction of a major bile duct is dilation and proliferation of proximal portions of the intrahepatic biliary system, including the ductules and canals of Hering, structures that are outside the confines of the portal tracts. A constant accompaniment to bile duct proliferation is an increase in surrounding connective tissue, which eventually leads to fibrous bridging between adjacent portal tracts, causing biliary cirrhosis. Although bile secretory

defects may initially be purely hepatocellular or ductal, any long-standing abnormality in the flow of bile leads to some degree of hepatocellular damage.

Box 48-6 lists diseases that may manifest as conjugated hyperbilirubinemia in the neonatal period. This list is divided into those disorders caused by a primary defect in the hepatocellular phase of bile secretion and those caused by ductal disturbances. In most of these disorders, direct-reacting bilirubin accounts for 50% to 90% of the TB level. A small amount of indirect-reacting bilirubin is always present, reflecting mild hemolysis, defective uptake and excretion, or hydrolysis of conjugated bilirubin. Early in the onset of conjugated hyperbilirubinemia in the neonate, the direct-reacting portion may account for only 10% to 25% of TB. As hepatic conjugation and uptake of bilirubin mature, the indirect-reacting portion decreases, whereas the direct portion increases.[55,98,179]

Causes of Conjugated Hyperbilirubinemia

Conjugated hyperbilirubinemia results from interference with the hepatic excretion of conjugated bilirubin into bile. Idiopathic neonatal hepatitis and biliary atresia together account for about 60% to 80% of all cases of conjugated hyperbilirubinemia. It is possible that similar pathogenetic mechanisms produce a spectrum of disease, with biliary atresia being the final possible, but not the inevitable, outcome. Because of this, it is useful to discuss these two entities simultaneously.[19]

Idiopathic neonatal hepatitis is defined as prolonged conjugated hyperbilirubinemia without the apparent stigmata of a generalized viral illness, the evidence of identifiable infectious agents, or an etiologically specific metabolic abnormality. On liver biopsy, this group is characterized by extensive transformation of hepatocytes into multinucleated giant cells, and it is therefore sometimes referred to as *neonatal giant cell hepatitis*. Giant cell transformation of hepatocytes does not reflect any specific etiology. It is caused by rupture of lateral cell membranes of adjacent hepatocytes, with consequent reduction in the number of bile canaliculi and retention of conjugated bilirubin. It is seen in various inherited metabolic disorders and some infections. Necrosis of hepatocytes and inflammation are usually present, although special stains (e.g., silver impregnation) may be necessary to demonstrate loss of hepatocytes. Necrosis and inflammation may be transient, with giant hepatocytes persisting for many months or even years.[51]

Extrahepatic biliary atresia is defined as a condition in which there is luminal obliteration or apparent absence of all or segments of the extrahepatic biliary system.

BOX 48–6 Diseases That May Manifest as Conjugated Hyperbilirubinemia in the Neonatal Period

HEPATOCELLULAR DISTURBANCES IN BILIRUBIN EXCRETION

Primary Hepatitis

Neonatal idiopathic hepatitis (giant cell hepatitis)

Hepatitis caused by identified infectious agents

- Hepatitis B
- Rubella
- Cytomegalovirus
- *Toxoplasma* organisms
- Coxsackie virus
- Echoviruses 14 and 19
- Herpes simplex and varicella-zoster viruses
- Syphilis
- *Listeria* organisms
- Tubercle bacillus

“Toxic Hepatitis”

Systemic infectious diseases

- *Escherichia coli* (sepsis or urinary tract)
- *Pneumococcus* organisms
- *Proteus* organisms
- *Salmonella* organisms
- Idiopathic diarrhea

Intestinal obstruction
Parenteral alimentation
Ischemic necrosis

Hematologic Disorders

Erythroblastosis fetalis (severe forms)
Congenital erythropoietic porphyria

Metabolic Disorders

α_1-Antitrypsin deficiency
Galactosemia
Tyrosinemia
Fructosemia
Glycogen storage disease type IV
Lipid storage diseases

- Niemann-Pick disease
- Gaucher disease
- Wolman disease

Cerebrohepatorenal syndrome (Zellweger syndrome)
Trisomy 18
Cystic fibrosis
Familial intrahepatic cholestasis: Byler disease
Hemochromatosis
Idiopathic hypopituitarism

DUCTAL DISTURBANCES IN BILIRUBIN EXCRETION

Extrahepatic Biliary Atresia

Isolated
Trisomy 18
Polysplenia-heterotaxia syndrome

Intrahepatic Biliary Atresia (nonsyndromatic paucity of bile ducts)

Alagille Syndrome (arteriohepatic dysplasia)

Intrahepatic Atresia Associated with Lymphedema

Extrahepatic Stenosis and Choledochal Cyst

Bile Plug Syndrome

Cystic Disease

Tumors of the Liver and Biliary Tract

Periductal Lymphadenopathy

Differentiation between these two groups of diseases may be difficult in the early stages; however, an early accurate diagnosis is essential for the choice of proper clinical management.[161b] Extrahepatic biliary atresia requires early surgical intervention. Unrelieved by surgery, the defect inevitably leads to death from biliary cirrhosis in the first 3 years of life. The prognosis in idiopathic neonatal hepatitis is uncertain and cannot be predicted on the basis of clinical or laboratory findings. Familial cases have a poor prognosis, with recovery rates of less than 30%. Sporadic cases have a recovery rate of 65% to 83% in various series. The poor prognosis in familial cases may be indicative of a metabolic defect.

The causes of idiopathic neonatal hepatitis and biliary atresia remain undetermined. The long-held view that biliary atresia represents a simple congenital developmental anomaly with failure of canalization is now thought untenable. In most cases, biliary atresia and neonatal hepatitis occur as isolated abnormalities, and both are considered to represent acquired conditions that may be initiated by the same or similar noxious factors. In support of the acquired nature of most cases of biliary atresia is the absence of reported cases in stillborn fetuses and the relatively rare association with other malformations. Similarly, clinical evidence of total obstruction to the flow of bile (such as acholic stools or colorless meconium) is not detected in the early stages of jaundice. The onset of acholic stools and conjugated hyperbilirubinemia is frequently delayed until 2 weeks of life or later. Microscopic changes observed in the extrahepatic biliary system or its fibrous remnant removed during the Kasai procedure (see under "Treatment of Extrahepatic Biliary Atresia," later), strongly suggest a sequence of changes that include acute cholangitis, necrosis, inflammation, attempted regeneration, and obliterative fibrosis (Fig. 48-25).

Clinical and pathologic observations over a long period indicate that some patients fulfill all known criteria for neonatal hepatitis, including surgical demonstration of patent biliary ducts in the early stages of jaundice, and then go on to develop extrahepatic biliary atresia.

Injury to the structures involved in bile secretion (hepatocytes and biliary epithelium) may occur either in utero or in the perinatal period, but the consequences of such injury, and therefore clinically manifested disease, are delayed until some time after birth. Clinical manifestations and eventual outcome may depend on the severity and persistence of lesions in a specific location. Thus, primary injury to hepatocytes may result in clinical manifestations of neonatal hepatitis, whereas injury to major bile ducts and gallbladder may result in biliary atresia. Reovirus type 3 has been implicated as an etiologic factor in extrahepatic biliary atresia as well as in neonatal hepatitis. These studies include an experimental model in which a hepatobiliary disease bearing a strong resemblance to human biliary atresia can be induced in very young mice by infection with reovirus type 3. No studies, however, have definitively proved a role for any of the known hepatotrophic viruses including reovirus type 3 in the etiology of biliary atresia in humans.[81,158]

Other viruses such as cytomegalovirus and rubella virus have been implicated in intrahepatic bile duct destruction and paucity.[73] Patients currently classified as having idiopathic neonatal hepatitis constitute a heterogeneous group that undoubtedly includes various, as yet undefined, metabolic disorders. A metabolic disorder may explain the recurrent incidence of this disease in some families.

Most patients with idiopathic neonatal hepatitis or biliary atresia represent isolated cases without familial incidence or associated anomalies. Neonatal hepatitis has a familial incidence of 10% to 15%, whereas no familial cases of histologically proven extrahepatic biliary atresia have been observed.[77a,130a] Rare occurrences of neonatal hepatitis and biliary atresia in two siblings have been reported. Both neonatal hepatitis and biliary atresia occur more frequently in patients with trisomy 18 than in the general population. Biliary atresia has been observed in

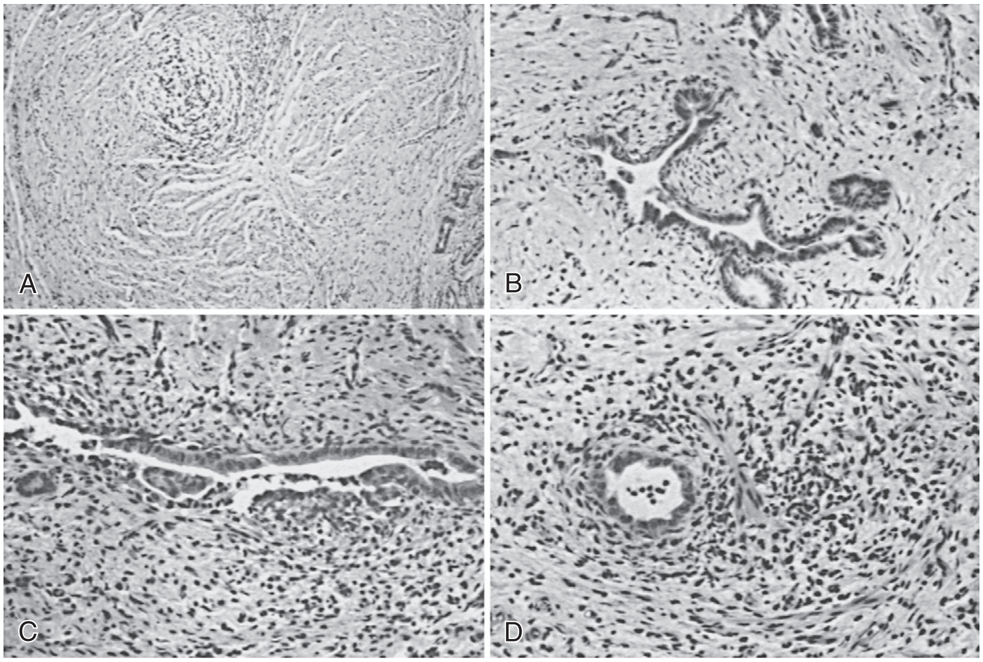

Figure 48–25. Microscopic preparations of fibrous remnant of extrahepatic biliary system resected during Kasai procedure for biliary atresia. **A**, Most distal portion of specimen, showing complete obliteration of lumen by fibrous tissue. **B** to **D**, More proximal segments, illustrating a spectrum of changes that includes necrosis of lining epithelium, acute and chronic inflammation, mural fibrosis with distortion of lumen, and great variation in size of ductlike structures. All micrographs ×60.

association with the polysplenia-heterotaxia syndrome in 10% to 15% of cases. This syndrome is characterized by situs inversus of abdominal organs, intestinal malrotation, multiple spleens, centrally placed liver, and a variety of cardiac, pulmonary, and vascular malformations. The inferior vena cava is frequently absent.

Early clinical manifestations of both idiopathic neonatal hepatitis and biliary atresia may be limited to jaundice. In a small proportion of patients, especially among those who later develop neonatal hepatitis, jaundice may be apparent at birth, documented by increased concentrations of conjugated bilirubin in cord blood. No case of extrahepatic biliary atresia has ever been described in which elevation of direct-reacting bilirubin was found in the cord blood. Jaundice usually becomes apparent between the second and sixth weeks of life. The dark yellow staining of diapers from the presence of bilirubin in the urine often prompts the parents to seek medical advice. Jaundice is frequently first noted by the physician during a well-baby visit. Hepatomegaly may be present in both neonatal hepatitis and biliary atresia. Splenomegaly is more frequently present in neonatal hepatitis, but this is not a constant finding. Its presence in biliary atresia usually signifies cirrhosis. Obstruction to the flow of bile is reflected by acholic stools and may be observed in both neonatal hepatitis and biliary atresia. It is always transient and incomplete in neonatal hepatitis, but its duration is variable and may extend beyond the crucial period during which an accurate diagnosis must be established if surgical correction is needed. Routine clinical and laboratory findings usually do not distinguish between extrahepatic biliary atresia and neonatal hepatitis. A routine series of diagnostic laboratory tests is suggested, however, to establish the severity of hepatic involvement and to screen for possible causes (Box 48-7). The failure of routine tests to distinguish between neonatal hepatitis and biliary atresia has led to a continued search for other distinguishing biochemical characteristics. α-Fetoproteins are frequently present in the sera of patients with neonatal hepatitis but may be absent in patients with biliary atresia.

A reliable method for the evaluation of patency of extrahepatic bile ducts is the use of technetium-99m acetanilidoiminodiacetic acid (IDA) or IDA derivatives such as paraisopropyl iminodiacetic acid or di-isopropyl iminodiacetic acid.[200] These compounds are efficiently extracted by hepatocytes and are excreted with bile into the intestines. When complete obstruction exists, no activity is detected in the intestines. Pretreatment with phenobarbital for 7 days before testing promotes excretion of isotope in neonates with severe intrahepatic cholestasis and thus reduces the chance for a mistaken diagnosis of extrahepatic obstruction. Phenobarbital is given orally at the dose of 5 mg/kg daily. Patients are given nothing by mouth for 1 hour before and 2 hours after injection of the radiotracer to avoid gallbladder contraction and dilution of radiotracer excreted into the intestines. Combining cholescintigraphy with a string test (determination of color and radioactivity count in duodenal fluid) increases the sensitivity and specificity of the diagnosis. Infants with biliary atresia will have a negative hepatobiliary scan at 24 hours or a string radioactive count of less than 197,007 counts per minute.[161a]

BOX 48–7 Laboratory Tests Recommended for Evaluation of Neonatal Conjugated Hyperbilirubinemia

LIVER FUNCTION TESTS

- TB and direct-reacting bilirubin, total serum protein, and serum protein electrophoresis
- SGOT (AST), SGPT (ALT), alkaline phosphatase (and 5′-nucleotidase if alkaline phosphatase elevated), and γ-glutamyl transpeptidase
- Cholesterol
- Serum and urine bile acid concentrations, if available
- α_1-Antitrypsin
- Technetium-99m iminodiacetic acid scan
- α-Fetoprotein

HEMATOLOGIC TESTS

- Complete blood count, smear, and reticulocyte count
- Direct Coombs test and erythrocyte G6PD
- Platelet count
- Prothrombin time and partial thromboplastin time

TESTS FOR INFECTIOUS DISEASE

- Cord blood IgM
- VDRL; FTA-ABS; complement fixation titers for rubella, cytomegalovirus, and herpesvirus; and Sabin-Feldman dye test titer for toxoplasmosis
- HB$_s$Ag in both infant and mother
- Viral cultures from nose, pharynx, blood, stool, urine, and cerebrospinal fluid

URINE TESTS

- Routine urinalysis, including protein and reducing substances
- Urine culture
- Bilirubin and urobilinogen
- Amino acid screening

LIVER BIOPSY

- Light microscopy
- Specific enzyme assay (if indicated)

RADIOLOGIC AND ULTRASOUND STUDIES (IF INDICATED)

ADDITIONAL DIAGNOSTIC STUDIES FOR METABOLIC DISORDERS (IF INDICATED)

ALT, alanine transferase; AST, aspartate aminotransferase; FTA-ABS, fluorescent treponemal antibody absorption (test); G6PD, glucose-6-phosphate dehydrogenase; HB$_s$Ag, hepatitis B surface antigen; SGOT, serum glutamic-oxaloacetic transaminase; SGPT, serum glutamic-pyruvic transferase; TB, total bilirubin; VDRL, Venereal Disease Research Laboratory.

Ultrasonography has also been applied in the evaluation of neonatal cholestasis. Although the demonstration of a normal gallbladder is usually indicative of an intrahepatic cause for cholestasis, it may be seen in extrahepatic biliary atresia and is, therefore, not a reliable sign. As intrahepatic bile ducts are usually not dilated in extrahepatic biliary atresia, their presence should suggest another cause.

Histopathologic examination of the liver is an integral part of the evaluation of any patient with persistent conjugated hyperbilirubinemia. It is best performed and analyzed after all other pertinent laboratory data have been gathered. A percutaneous liver biopsy usually yields adequate tissue for microscopic and, if desired, electron microscopic and virologic studies. If a metabolic disorder is suspected, as for example in familial cases, a liver core should be frozen and saved at −70°C for possible subsequent biochemical analysis. In most patients (90% to 95%), liver biopsy establishes or confirms the correct diagnosis, sparing the neonate with neonatal hepatitis an unnecessary surgical procedure. Before the biopsy, the prothrombin time and platelet count must be ascertained and assessed to determine the safety of performing the procedure and the need for correction. A prolonged prothrombin time may be corrected in some patients by administration of vitamin K. In some situations in which a biopsy is urgently required, fresh frozen plasma may be administered before and 6 hours after percutaneous biopsy. Postoperatively, neonates must be observed closely for vital signs or clinical changes that indicate significant bleeding, bile peritonitis, or pneumothorax, the rare but significant complications of the procedure. In the final analysis, the isotope scan and a percutaneous liver biopsy are the only reliable means available without surgical exploration to distinguish between neonatal hepatitis and extrahepatic biliary obstruction.

The liver biopsy in neonatal hepatitis is characterized by marked irregularity in the size of hepatocytes and, in some cases, by numerous giant hepatocytes (Figs. 48-26 and 48-27). Giant cells may contain from 4 to 100 nuclei. The cytoplasm of these giant cells is usually foamy and contains bile pigment. Bile canaliculi appear to be reduced in number and proportion to the number of giant hepatocytes. Necrosis and inflammation are frequently detected. Kupffer cells are swollen and contain bile pigment, lipofuscin, iron, and phagocytosed debris of destroyed hepatocytes. Extramedullary hematopoiesis is almost always present. Although these findings may also be present in biliary atresia, it is the relative absence of bile duct proliferation that distinguishes neonatal hepatitis from biliary atresia. In some cases of neonatal hepatitis, there is evidence of inflammatory injury to portal bile ducts, with epithelial reduplication interpreted as regenerative activity. The aforementioned changes are usually seen in early stages, soon after onset of jaundice. Biopsies taken after 3 months of age may show little necrosis and inflammation and, instead, demonstrate fibrosis or cirrhosis. Giant cell transformation of hepatocytes may persist for months or years.

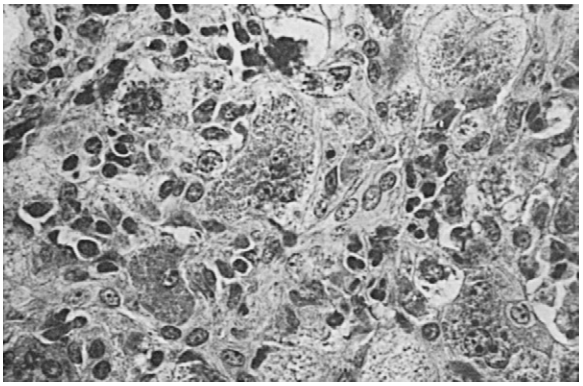

Figure 48–26. Neonatal hepatitis. Note the marked cellular irregularity obliterating the normal orderly plate arrangement. Intracanalicular bile is present. Small cells in sinusoids are Kupffer cells and elements of extramedullary hematopoiesis. Paraffin embedding and hematoxylin-eosin staining; ×60.

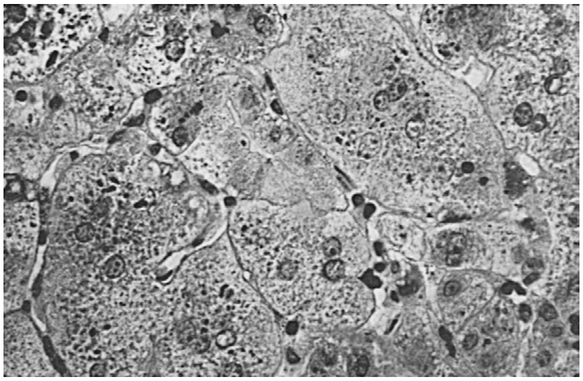

Figure 48–27. High-power view of transformed giant hepatocytes. Most of the intracytoplasmic granules represent bile pigment. Paraffin embedding and hematoxylin-eosin staining; ×200.

It has been shown in patients and in animal experiments that soon after obstruction of the common bile duct, ducts and ductules in portal tracts and in periportal zones begin to proliferate. This phenomenon involves most, if not all, portal tracts and is present even at the periphery of the liver, far removed from the site of obstruction. Therefore, in biliary atresia, changes suggesting blockage in the major (mostly extrahepatic) bile ducts are seen. At least three portal tracts should be available for examination. In biliary atresia, all tracts will show some degree of proliferation. In early stages, ductular proliferation may be present without increased fibrosis. The ducts have a varicose appearance and contain focal bile plugs. Later, ducts and ductules frequently appear distorted (Fig. 48-28) because of a discrepancy between the rate of proliferation of biliary epithelium and that of the surrounding fibrous tissue. An associated inflammatory exudate is occasionally seen around proliferated ductules, but a true cholangitis with epithelial necrosis and intramural inflammation is rarely encountered except in association with surgical complications. Other changes within portal tracts include dilated lymphatics and, occasionally, tortuous and thick-walled arterioles. In later stages of extrahepatic biliary atresia, ductular epithelium may disappear, having been replaced by collagen fibers, and this may lead to a secondary paucity of portal bile ducts.

Extensive paucity of bile ducts, whether primary or secondary, is associated with a clinical syndrome resembling that observed in primary biliary cirrhosis, or sclerosing cholangitis, with hypercholesterolemia, xanthomas, and pruritus. Hepatocytes in biliary atresia show intracellular and canalicular cholestasis, with the canalicular component predominating (Fig. 48-29). In about one third of all patients with biliary atresia, there is giant cell transformation of hepatocytes. In most cases, this transformation is primarily centrolobular (around terminal branches of the hepatic vein) and is not associated with necrosis and inflammation. Extramedullary hematopoiesis may also be present.

Treatment of Neonatal Hepatitis

Clinical management of neonatal hepatitis consists of supportive measures because no specific therapy is known. Many neonates have a transient but significant reduction in bile flow, often requiring replacement of fat-soluble

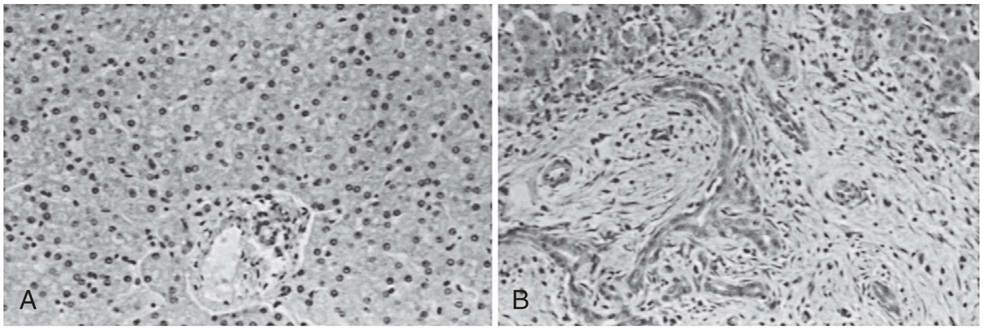

Figure 48–28. **A**, Portal tract of normal neonate, containing a large, thin-walled vein and single cross section of a bile duct. **B**, Portal tract from neonate with biliary atresia. Note marked enlargement of tract from fibrosis that surrounds multiple elongated bile ducts. Both micrographs, ×60.

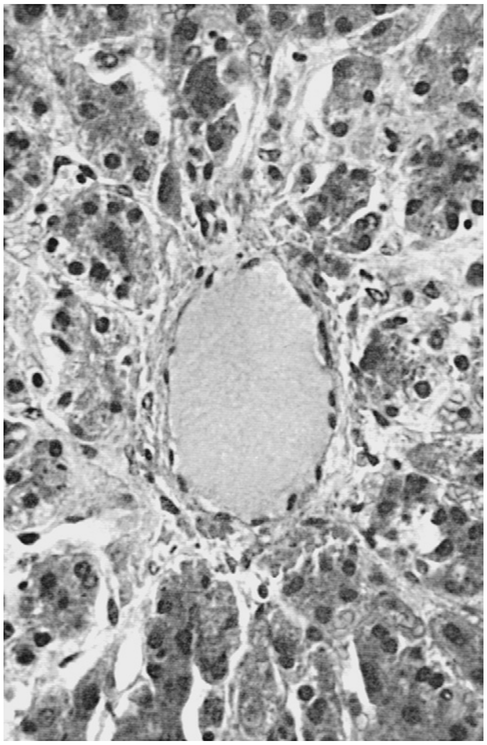

Figure 48–29. Extrahepatic biliary atresia. Central vein surrounded by hepatocytes. Intracanalicular bile plugs are present. In addition, hepatocytes contain intracytoplasmic bile pigment granules. Paraffin embedding and hematoxylin-eosin staining.

vitamins, particularly vitamins D and K. Subclinical rickets is common in these neonates and may contribute to the increase in serum concentrations of alkaline phosphatase. Persistence of acholic or very pale stools without significant lowering of direct-reacting serum bilirubin concentrations after 1 month should be viewed as an indication for repeat clinical study, including liver biopsy. This practice permits detection of patients whose extrahepatic bile ducts sclerose after an initial phase of hepatitis and who are, therefore, suitable candidates for exploratory laparotomy and corrective surgery. On rare occasions, patients with neonatal hepatitis and complete obstruction, as evidenced by acholic stools, may recover rapidly after operative cholangiography that shows normal extrahepatic ducts. This phenomenon is probably the result of flushing out of inspissated bile in the extrahepatic biliary system, with consequent relief of obstruction. This situation may be seen in cystic fibrosis or severe dehydration. Fluctuations in stool color should alert the clinician to the possible existence of a choledochal cyst, which can usually be diagnosed with ultrasound and treated surgically. There are no early reliable criteria on which the prognosis of a particular patient can be based.

Treatment of Extrahepatic Biliary Atresia

When the clinical evaluation indicates complete biliary obstruction or proves inconclusive, the patient should undergo an exploratory laparotomy. On entry of the abdomen and after initial scrutiny of the biliary system, an operative cholangiogram should be performed to confirm and characterize the extrahepatic lesion and define its extent. The classification proposed by the Japanese Society of Pediatric Surgeons divides extrahepatic biliary atresia into three types, based on gross observations during laparotomy:

Type I: Atresia of the common bile duct with patent proximal ducts
Type II: Atresia of the common hepatic duct with patent proximal ducts
Type III: Atresia of the right and left hepatic ducts at the porta hepatis

Operative examination of these neonates should be performed only by surgeons prepared to proceed with corrective procedures if necessary. Reoperation after exploratory laparotomy increases the technical difficulties and delays the institution of corrective measures. Reconstitution of normal biliary drainage by direct anastomosis of grossly identifiable segments of patent bile ducts to the gastrointestinal tract is possible in only a very small proportion of patients with biliary atresia (estimated at 5% to 10%). These include the rare cases of choledochal cyst and occlusion of a short segment of the common bile duct by a valve, a membrane, or fibrosis. In most patients with biliary atresia, there are no grossly visible ducts proximal to the atretic segment. In the past, all these patients were considered inoperable. Untreated patients, although jaundiced, often appear clinically well in the first few months of life, but they deteriorate rapidly after cirrhosis develops, with clinical manifestations of portal hypertension, ascites, hypersplenism, infection, and hemorrhage.[100a,190a]

In 1968, Kasai and associates[122a] described for the first time in the American literature an operative procedure in which the periphery of the transected fibrous tissue of the porta hepatis, devoid of grossly identifiable ducts, was anastomosed to a Roux-en-Y loop of small intestine (portoenterostomy). Kasai's portoenterostomy or variations of this procedure are currently performed in most medical centers.

The immediate goal for surgical correction is the reestablishment of bile drainage, which is now achieved in most neonates when operated on before 3 months of age. Cure rate, however, is still poor. In most operated patients, fibrosis increases with time and eventually progresses to cirrhosis despite adequate bile drainage. It is currently unclear whether progressive liver fibrosis represents continuation of the same type of injury responsible for the initial obliterative process in extrahepatic ducts or if it is the result of ascending cholangitis complicating surgery. In addition to the age at the time of surgery, other factors that influence the outcome include the size and patency of microscopic ducts in the transected porta hepatis and the preservation of intact epithelial lining.[123]

Orthotopic liver transplantation is the definitive therapy for biliary atresia. Survival statistics have steadily improved since 1981, when cyclosporin A and steroid therapy were introduced. Other drugs that produce effective immunosuppression and fewer side effects, such as FK 506, lessen the mortality and morbidity of transplantation, resulting in longer and more productive lives for graft recipients.[190a,218,258]

KNOWN INFECTIOUS CAUSES

In a small proportion of neonates with neonatal hepatitis, a specific infectious agent may be identified either by direct isolation and culture or by serologic tests that detect specific antibodies. In addition, microbial antigens may be identified in liver biopsy using monoclonal antibodies and immunocytochemical staining methods. Among infectious agents reported in association with neonatal hepatitis are organisms such as *Treponema pallidum* and *Listeria* species, and viruses such as rubella and Coxsackie virus, the herpes group of viruses (herpes simplex, varicella-zoster, cytomegalovirus), and adenovirus. The protozoan *Toxoplasma gondii* also has been implicated. Fetal infection may take place in utero either by transplacental spread or by an ascending infection of the amniotic fluid, usually after rupture of membranes. In some cases, infection may occur during delivery by aspiration or swallowing of vaginal contents. Clinically, patients in this group may appear sick and fail to thrive and also may have evidence of CNS and other organ involvement. In many patients, there are stigmata of generalized infection. Laboratory findings are similar to those seen in idiopathic neonatal hepatitis, but stools are not acholic, and therefore biliary atresia usually is not suspected. Although congenital infection with human immunodeficiency virus (HIV) is diagnosed with increasing frequency, cholestasis is rare in the neonatal period.

Liver biopsy may be helpful in the diagnosis of infectious agents, especially in infections with the herpesviruses. These DNA viruses replicate in the nucleus, resulting in intranuclear inclusion bodies that can be seen with the light microscope. Cytomegalic inclusion disease is characterized by marked enlargement of hepatocytes, biliary epithelium, and Kupffer cells caused by intranuclear as well as intracytoplasmic inclusions. In some cases, however, the virus has been isolated from patients in whom liver biopsy showed giant cell transformation of hepatocytes with no evidence of inclusions.[155]

Hepatitis B surface antigen (HBsAg) may be transmitted from mother to infant, probably by aspiration of vaginal contents, including blood, during delivery. With few exceptions, infants born to HBsAg-positive mothers show no antigenemia in cord blood or in the first month of life. Repeated serologic tests indicate that HBsAg appears in the serum of these infants between 5 and 7 weeks of life and reaches a peak at 10 weeks. Antigenemia in the newborn may be associated with liver injury, and both may persist for many months or possibly years. It is necessary, therefore, to closely observe all infants of HBsAg-positive mothers for many years for clinical and laboratory evidence of chronic liver disease. Severe and even fulminant neonatal hepatitis associated with HBsAg has been described in infants of chronic carriers and after neonatal transfusions. Prophylaxis with concurrent administration of hepatitis B immune globulin (HBIG) and hepatitis B vaccine is effective in preventing neonatal infection in more than 90% of exposed newborns. HBIG (0.5 mL IM) should be given within 12 hours of birth. In addition, hepatitis B vaccine should be given IM concurrently within 12 hours of birth at a different anatomic site and repeated at 1 to 2 and 6 months of age (for preterm infants who weigh less than 2000 g at birth, a total of four doses of vaccine should be given according to the immunization schedule for preterm infants, see also appendix C). Concurrent use of HBIG and vaccine does not appear to interfere with vaccine efficacy (see Chapters 23 and 39).[45,201]

Hepatitis C virus (HCV), a single-stranded RNA virus in the flavivirus family, has been found to be the etiologic agent in most cases previously referred to as non-A, non-B hepatitis. Transmission occurs through both the percutaneous and the nonpercutaneous route. The incubation period varies from 2 weeks to 6 months. The signs of acute disease include malaise, fever, elevation in hepatic transaminases, and jaundice. Fulminant hepatitis and acute hepatic failure are rare. Although about three fourths of acute infections are asymptomatic, about one half of affected patients will develop chronic hepatitis, with 20% of these patients progressing to cirrhosis. Progression of the disease is slow, with an average of 10 years to chronic hepatitis, 20 years to cirrhosis, and 30 years to hepatocellular carcinoma. Although infected infants manifest biochemical features of hepatocellular injury, other manifestations of the disease are relatively mild throughout childhood.[30]

The overall risk for vertical transmission of HCV has been shown to be as high as 10% in several studies. Women who are infected with both HCV and HIV and those with HCV viremia are at the greatest risk for transmitting HCV to their offspring.[86,170] The persistence of maternal antibody in the infant is variable but may be as long as 8 to 12 months. Diagnosis in the neonate and infant is made by measuring serial anti-HCV (IgG) titers (using enzyme immunoassays followed by recombinant immunoblot assays detecting antibody against HCV core antigen or other nonstructural proteins) or by directly detecting the presence of HCV ribonucleic acid through the reverse-transcriptase polymerase chain reaction. No proven therapy is currently available to neonates infected with HCV. Combination therapy with peginterferon and ribavirin is recommended for chronic HCV in adults.[206] The safety and efficacy of HCV therapies are currently being investigated in children. HCV has been detected in the breast milk of HCV-infected mothers.

Although theoretically possible, transmission of HCV through breast feeding has not been documented in HCV-positive, HIV-negative mothers. Thus, according to most authorities, breast feeding is not currently contraindicated in HCV-positive, HIV-negative women.[132]

SEPSIS

Microorganisms and their biologic products may have direct toxic effects on the cells and structures responsible for the hepatocellular and ductal phases of conjugated bilirubin excretion. This may be complicated by sepsis-induced hemolysis, further adding to the bilirubin load. Postmortem examination of neonates with severe sepsis has shown centrilobular cholestasis, focal hepatocellular necrosis, and giant cell transformation in some patients. In others, no hepatic lesions can be demonstrated by light microscopy. Severe urinary tract infection, particularly with coliform bacilli, is associated with this syndrome. In this case, generalized septicemia is not an essential feature, and cholestasis may be caused by massive endotoxin release. Antibiotic treatment is followed by prompt relief of hyperbilirubinemia.

HEPATIC METABOLIC DISEASE

Several metabolic disorders result in hepatocellular injury in the neonatal period and give rise to a clinical pathologic syndrome that may resemble neonatal hepatitis or biliary atresia. α_1-Antitrypsin deficiency in the homozygous state (PiZZ) may be manifested by neonatal liver injury. It is estimated that only 10% to 20% of all individuals with this abnormality will have liver disease. Most PiZZ individuals never develop clinical evidence of liver disease, but they may develop pulmonary emphysema as adults. Patients with α_1-antitrypsin deficiency may show all the signs and symptoms of neonatal hepatitis or biliary atresia, including acholic stools. Liver biopsy also may show changes consistent with either one of the aforementioned conditions. Bile duct proliferation may be so pronounced that exploratory laparotomy is performed. Although in older children, periportal hepatocytes frequently contain intracytoplasmic inclusions that give a positive reaction with periodic acid–Schiff stain and resist diastase digestion, these are rarely seen in the neonatal period. Immunocytochemical staining may be helpful in demonstrating granules of α_1-antitrypsin, present in hepatocytes of patients with deficient states, but not in normal phenotypes. Phenotyping of the Pi system should be carried out in all suspected cases. In many infants, neonatal cholestasis may regress before the age of 6 months and reappear later in childhood or adolescence when the patient becomes cirrhotic. The pathogenesis of liver disease associated with this anomaly is not fully understood.[2,167] Recent studies suggest that the liver disease is a result of toxic gain-of-function mutations that cause the α_1-antitrypsin protein to fold aberrantly and be retained in the endoplasmic reticulum of hepatocytes rather than be secreted into the blood.[87,178]

Several defects in carbohydrate, protein, and lipid metabolism occur with conjugated hyperbilirubinemia. Deficient activity of galactose-1-phosphate uridyltransferase is inherited as an autosomal recessive disease with an incidence of about 1 in 50,000. It results in the accumulation of galactose-1-phosphate in the liver, producing hepatomegaly and conjugated hyperbilirubinemia. Other associated findings in galactosemia include hypoglycemia, emesis, failure to thrive, cataracts, and ascites. Mental retardation and cirrhosis occur if dietary treatment is not instituted early. The acute form of tyrosinemia is also an autosomal recessive disease and is characterized by elevations in plasma tyrosine and methionine accompanied by hepatic and renal dysfunction, emesis, and failure to thrive. Dietary tyrosine restriction prevents cirrhosis and early death. Niemann-Pick disease (deposition of sphingomyelin and cholesterol) and Gaucher disease (deposition of glucosylceramide), both autosomal recessive diseases, have also been reported to be associated with conjugated hyperbilirubinemia (see Chapter 50).[88]

TOTAL PARENTERAL NUTRITION–INDUCED HEPATIC INJURY

Prolonged use (≥2 weeks) of total parenteral nutrition may produce conjugated hyperbilirubinemia which may persist for some time after cessation of this mode of nutrition. Liver biopsy shows evidence of hepatocellular injury with swelling of hepatocytes, necrosis, cholestasis, and occasional giant cell transformation. Trace elements (specifically manganese and copper) should be removed from the total parenteral nutrition solution if conjugated hyperbilirubinemia occurs.[38,251] Baseline copper levels and monthly monitoring are recommended to avoid copper deficiency.[101]

MECHANICAL OBSTRUCTION

Inspissated Bile (Bile Plug) Syndrome

Obstruction of a major bile duct by thick bile or mucus is known as the *bile plug syndrome* or the *inspissated* (Latin *inspissatus*, thickened) *bile syndrome*. Although it may be seen in cases of cystic fibrosis, most often the cause is obscure. The obstruction usually resolves gradually, with or without phenobarbital therapy. Severe cases may require irrigation of the biliary tree or direct surgical extraction of the plug.

Choledocholithiasis

Choledocholithiasis is most commonly seen in neonates with a history of severe intrauterine hemolysis. The excessive bilirubin load results in the formation of gallstones, which have the potential to block the secretion of conjugated bilirubin. Gallstones may also be seen in patients receiving total parenteral nutrition. The diagnosis is suspected because of the presence of conjugated hyperbilirubinemia, bilirubinuria, acholic stools, and a palpable gallbladder. It is confirmed with ultrasound or radiotracer imaging of the hepatobiliary system. Spontaneous resolution is common, but cholecystectomy may be necessary in cases of cholangitis or progressive elevation of conjugated bilirubin levels.

Cystic Diseases

Cyst formation in the biliary system may result in obstruction of bile flow and produce conjugated hyperbilirubinemia. Congenital hepatic fibrosis is an autosomal recessive disease marked by hamartomatous and fibrotic changes of the interlobular bile ducts. Most cases are associated with cysts of the renal collecting tubules, and the prognosis depends greatly on the degree of renal impairment. *Caroli disease* is the name given to cystic dilation of the major intrahepatic ducts. Cholangitis is a chronic problem, and the outcome is variable. Cysts found along the extrahepatic biliary tree (common hepatic duct, common bile duct, gallbladder) are known as *choledochal cysts*. These are more commonly seen in females and may lead to portal hypertension, cirrhosis, and carcinoma. Complete surgical excision is the definitive treatment. It is believed that these three disease entities may have a common etiology that differentially manifests itself depending on the timing, duration, and location of the insult. Taken together, they are rare causes of conjugated hyperbilirubinemia presenting in the neonatal period.

Masses

Obstruction of the extrahepatic biliary ducts may also rarely occur with tumors such as primary hepatoblastoma and metastatic neuroblastoma, enlarged periductal lymph nodes, and distended loops of bowel. Treatment is directed at the underlying disorder.

MISCELLANEOUS CAUSES OF CONJUGATED HYPERBILIRUBINEMIA

Alagille syndrome (arteriohepatic dysplasia) is an autosomal dominant disease with clinical variability characterized by a paucity of intrahepatic bile ducts in the presence of patent extrahepatic ducts. Other findings include unusual facies, vertebral anomalies, peripheral pulmonary stenosis, posterior embryotoxon (incomplete iridocorneal separation), and retarded mental, physical, and sexual development.[9,255] Mutations in Jagged1 (chromosome 20p12) have been identified in about 70% of patients studied with Alagille syndrome.[56,127,168] Jagged1 is a cell surface ligand for the Notch receptor. The interaction between Jagged1 and Notch is critical for proper cell differentiation during early development. The Alagille syndrome appears to result from haploinsufficiency of Jagged1. Inability to identify a Jagged1 mutation in nearly 30% of patients indicates that additional causal defects are likely.

Early clinical manifestations and laboratory findings are identical to those observed in patients with extrahepatic biliary atresia. Later in the first year of life, however, serum cholesterol concentrations rise well beyond those observed in other forms of infantile liver disease. Levels higher than 1000 mg/dL may be seen in as early as the third month of life. Cutaneous xanthomas are prominent in the later stages of untreated disease, usually after 1 year of age. It is important to recognize this condition before exploratory surgery because the patency of the very narrow and collapsed extrahepatic ducts may be extremely difficult to demonstrate. Not only is portoenterostomy unsuccessful in establishing bile flow in this condition, but also it actually accelerates the progression of liver disease.

A nonsyndromic form of intrahepatic bile duct paucity has also been described. A familial form of cholestasis and paucity of intrahepatic bile ducts is associated with development of lymphedema of the lower extremities around the time of puberty. Although initially described cases in this group were from families of Norwegian extraction, similar cases have been reported from England, France, and Sweden.[1]

Zellweger (cerebrohepatorenal) syndrome is a rare autosomal recessive disease marked by the absence of hepatic and renal peroxisomes. Because peroxisomes have many vital anabolic and catabolic functions within the cell, their absence results in profound cellular dysfunction. In addition to conjugated hyperbilirubinemia, affected patients manifest characteristic facies (high forehead, flat occiput, large fontanelle, shallow orbital ridges, micrognathia), feeding difficulties, hypotonia, seizures, and mental retardation. Death usually occurs early in infancy.

Isolated cases of conjugated hyperbilirubinemia have been described in association with hypoplastic left heart syndrome, severe internal hemorrhage, familial lethal hemochromatosis, and rarely in association with umbilical vein catheterization.

CHAPTER 49

Metabolic and Endocrine Disorders

PART 1

Disorders of Carbohydrate Metabolism

Satish C. Kalhan and Sherin U. Devaskar

The fetus depends entirely on the mother for its nutrient needs, including glucose. At birth, when the maternal supply is discontinued, the neonate must adjust to an independent existence. This transition to the extrauterine environment is often perturbed by alterations in the mother's metabolism or by intrinsic fetal and placental problems that result in changes in the neonate's glucose homeostasis. An understanding of the normal physiologic adaptation of the maternal-fetal nutritional relationship during pregnancy and of fetal glucose homeostasis and glucose metabolism during the transition to extrauterine life serves as a framework for evaluating disordered glucose metabolism in the neonate.

PLACENTAL TRANSPORT OF NUTRIENTS: MATERNAL-FETAL RELATIONSHIP

Although the fetus is entirely dependent on the mother for nutrients, it is hormonally independent of the mother (Fig. 49-1). Because no maternal peptide hormones are transported to the fetus in any significant amount, fetal endocrine and paracrine responses are mediated by the transport of nutrients such as glucose and amino acids to the fetus.

Glucose

Maternal glucose is the major substrate delivered to the human fetus for energy metabolism.[47] Glucose is transported to the fetus along a downward concentration gradient by carrier-mediated transport. In normal pregnancies, the plasma glucose concentration of the fetus is about 70% to 80% of that for the mother. Because maternal-fetal glucose transfer is not saturated by the range of glucose concentrations observed in human pregnancy, even when complicated by diabetes, fetal glucose uptake becomes excessive as the maternal glucose concentration increases. When fetal glucose uptake exceeds the requirements of energy production and growth, the excess glucose is stored as glycogen and triglycerides.

Fatty Acids

The transfer of fatty acids from the mother to the fetus appears to occur only in the free form (i.e., free fatty acids [FFAs]) and to depend on chain length, lipid solubility, and protein binding. A progressive shortening of chain length from C16 to C8 is associated with an increased transfer rate. Protein binding appears to slow the rate of transfer. Contrary to a previously held belief, data suggest that fatty acids are transported in significant amounts from the mother to the fetus.[78] A number of proteins involved in the sequestration and transport of fatty acids have been identified in the human placenta.[25] In addition, a significant amount of nonessential fatty acid appears to be synthesized de novo by the fetus in utero.

Amino Acids

Amino acids are transported to the fetus against a concentration gradient by a carrier-mediated transport process. Amino acids may be transported through the placenta either unchanged or after placental metabolism and processing—for example, leucine can be transferred intact or as its keto analogue α-ketoisocaproic acid. The syncytiotrophoblast is usually considered the main transport epithelium of the term placenta. Amino acids are transported by means of energy-dependent processes through selective amino acid transport systems.

Other Fetal Substrates

β-Hydroxybutyrate and possibly acetoacetate, the major ketone bodies, are transported along a concentration gradient.[3] The concentration of β-hydroxybutyrate in fetal blood is significantly less than that in maternal plasma ($<50\%$);

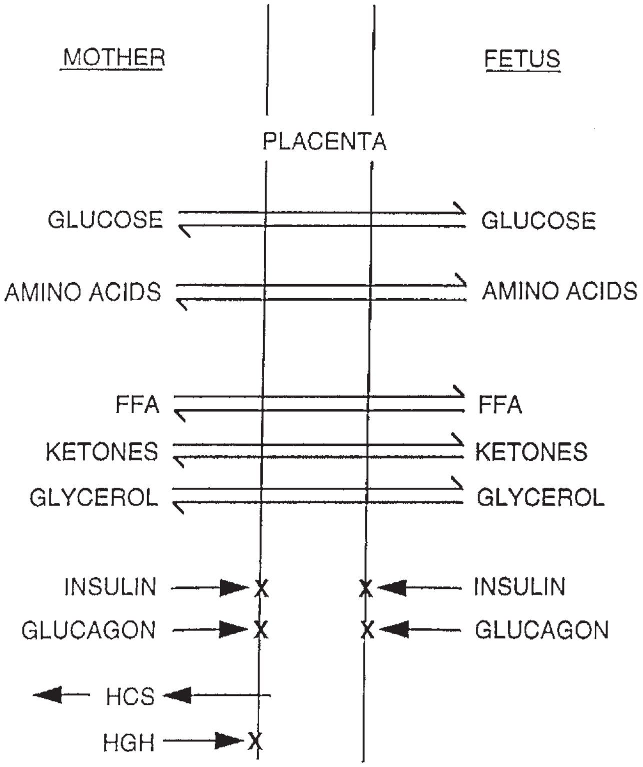

Figure 49–1. Maternal-fetal substrate hormone relationship. FFA, free fatty acids; HCS, human chorionic somatomammotropin; HGH, human growth hormone.

however, a linear correlation between the maternal and fetal concentrations has been reported.

Glycerol

There is a linear correlation between maternal and fetal glycerol levels, in most instances with the fetal level being somewhat lower than the simultaneously determined maternal plasma level.[3]

Lactate

The data on the maternal-fetal lactate relationship in human studies are conflicting. Two studies in sheep clearly demonstrated placental production and fetal utilization of lactate,[11] but the data in human studies showed higher levels of lactate in fetal than in maternal blood. In the few studies in which umbilical artery and vein samples were obtained simultaneously, the data could be interpreted as net fetal production and placental clearance of lactate.

FETAL HORMONES MEDIATING GROWTH

Immunoreactive insulin has been demonstrated in both plasma and pancreatic tissue at as early as 8 weeks of gestation; the source appears to be the fetal pancreas because the placenta is impermeable to insulin. At 13 to 18 weeks of gestation, the fetal insulin response to sustained maternal hyperglycemia is negligible. However, at term, the fetus is capable of a significant response to prolonged hyperglycemia, although to a lesser degree than adults. When the fetus receives appropriate glucose from the mother, the requirement for an insulin response is minimal. With repeated episodes of hyperglycemia, as in maternal diabetes, a greater insulin response is seen, indicating that B-cell sensitivity is being induced or enhanced. That insulin may modify the growth rate in utero has been shown by the positive correlation between the fetal plasma insulin concentration and fetal weight. Human growth hormone (GH) has been measured at as early as 9 weeks of gestation and increases rapidly between the 11th and 16th weeks. Because the transplacental transfer of GH is negligible, the fetal pituitary appears to be its source in the fetus. At term, fetal plasma GH levels are higher than those of maternal plasma. Unlike those of adults, fetal GH levels are not suppressed during hyperglycemia and actually show a paradoxical rise. Several studies have demonstrated the role of insulin as the growth-promoting hormone of the fetus and that the fetus can sustain normal growth in the absence of GH.

FETAL GLUCOSE METABOLISM

Under normal circumstances (i.e., in an uncomplicated, normal pregnancy), the fetus is entirely dependent on the mother for a continuous supply of glucose for both energy metabolism and the synthesis of other metabolic substrates.[47] The fetal liver contains the full complement of enzymes required for the synthesis and breakdown of glycogen. Hepatic glycogen content is low early in gestation; a slow, continuous increase occurs between 15 and 20 weeks; and a rapid accumulation of glycogen in the liver is observed late. The fetus also has all the key hepatic enzymes involved in gluconeogenesis, although their levels are lower than those in adults.[45] The only exception is cytosolic phosphoenolpyruvate carboxykinase, which, at least in the rat, is not expressed in utero and appears immediately after birth (Fig. 49-2).[34] Data in humans in vivo are not available; however, there is a consensus that in the mammalian species studied, the gluconeogenic capacity is not expressed in utero under unperturbed circumstances and the contribution of gluconeogenesis from lactate, pyruvate, or alanine to glucose is quantitatively negligible.[58] Studies in humans and animals have consistently demonstrated that the fetus does not produce glucose and that maternal glucose is the only source of fetal glucose. Fluctuations in maternal blood glucose are rapidly reflected in parallel changes in fetal glucose concentration. These variations occur even in response to acute hypoglycemia induced by insulin infusion in the mother during sheep pregnancy. However, if maternal hypoglycemia is prolonged, the fetus begins glucose production.[23] Whether such a response can occur in human pregnancy has not been examined and cannot be pursued without violating ethical standards. Glucose is the primary fuel for the fetus, accounting for about 80% of fetal energy consumption. The remaining 20% of fetal energy needs is provided by lactate, amino acids, and other means.

GLUCOSE METABOLISM AFTER BIRTH

At birth, as a result of cutting the umbilical cord, the supply of glucose and other nutrients abruptly ceases, and the newborn infant has to mobilize its depots to meet energy requirements.

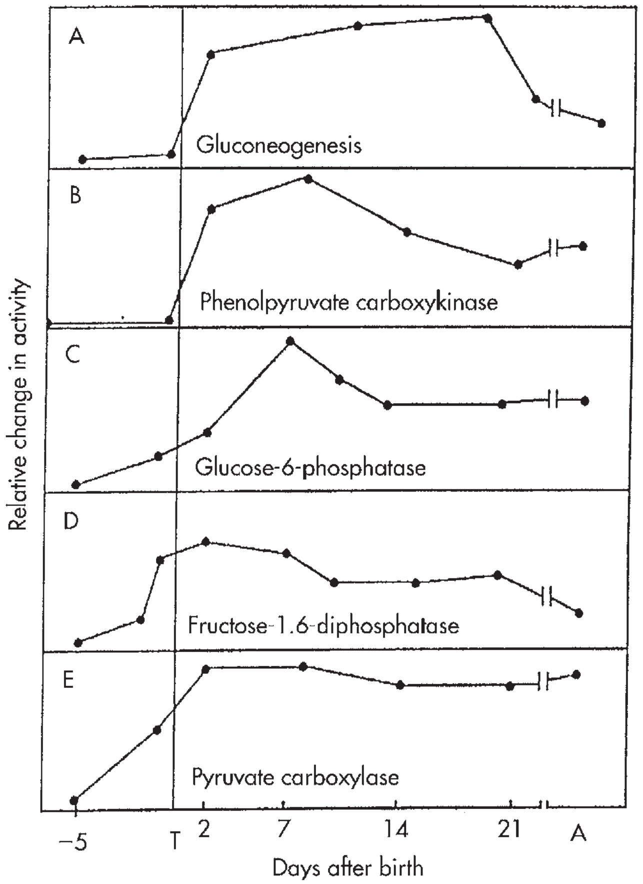

Figure 49–2. Changes in the relative activity of gluconeogenic enzymes in the rat liver during development. *(From Hanson RW, et al:* Gluconeogenesis: its regulation in mammalian species, *New York, 1976, John Wiley & Sons.)*

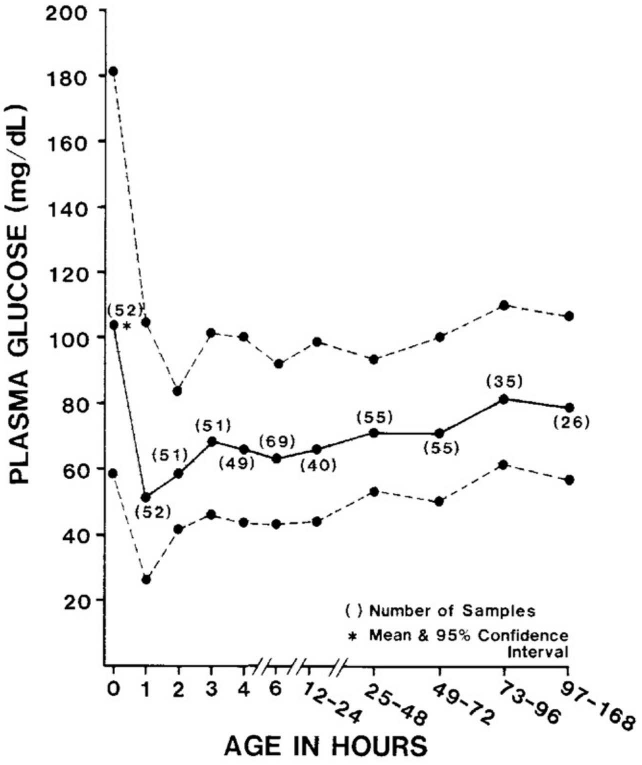

Figure 49–3. Plasma glucose levels in healthy term neonates delivered vaginally with birthweight between 2.5 and 4 kg. *(From Srinivasan G, et al: Plasma glucose values in normal neonates: a new look,* J Pediatr *109:114, 1986.)*

Coincident with clamping of the umbilical cord are an acute surge in the levels of circulating epinephrine, norepinephrine, and glucagon and a fall in the levels of insulin. These hormones concomitantly mobilize hepatic glycogen and stimulate gluconeogenesis, resulting in a steady rate of glucose production and maintenance of the plasma glucose concentration.

The plasma glucose concentration in umbilical vein blood is about 80% of the prevailing maternal blood glucose concentration. After birth, the plasma glucose concentration falls in all infants, reaching its lowest value between 30 and 90 minutes after birth. Thereafter, in full-term healthy neonates, the plasma glucose concentration rises and is maintained at a steady level of 40 to 80 mg/dL. Full-term newborn infants can tolerate fasting without a significant change in the blood glucose concentration. Fasting up to 9 hours after a meal did not cause a decrease in the plasma glucose concentration.[21] In full-term infants, the plasma glucose levels obtained at random intervals during the first week after birth have ranged from 40 to 100 mg/dL, with a mean of 80 mg/dL (Fig. 49-3).[83] These levels are higher than those previously reported in fasting infants and reflect changes in feeding practices and the random nature of measurements. The plasma glucose concentration in healthy, asymptomatic, breast-fed babies has been reported to be lower than that in formula-fed infants[86] during the first 24 hours of life—an average of 2.1 ± 0.07 mmol/L, or 37 mg/dL (range, 1.2 to 3.4 mmol/L, or 21 to 61 mg/dL). The plasma glucose values in infants who are small for gestational age (SGA) and in premature infants are somewhat lower.[37,45] Although no clear definition of hypoglycemia can be described, most investigators consider a plasma glucose level lower than 35 mg/dL to be abnormal, regardless of gestational age (see Chapter 14).

The rates of glucose production and utilization have been measured by a number of investigators with isotopic tracer dilution methods.[21] All these studies demonstrated the ability of newborn infants, both full-term and preterm, to produce glucose at rates significantly higher than those in adults. On average, the neonate produces glucose at rates between 4 and 6 mg/kg per minute. The higher rates of glucose production in the neonate reflect the higher ratio of brain to body weight, the brain being the major glucose-using organ. In the first few days after birth, the rate of glucose production during fasting in full-term infants has been reported to decrease slightly. As the infant grows, the rate of glucose production expressed per unit of body weight decreases, so by adolescence, it approaches the rate of adults.

Hepatic glucose output depends on (1) adequate glycogen stores, (2) sufficient supplies of endogenous gluconeogenetic precursors, (3) a normally functioning hepatic gluconeogenetic and glycogenolytic system, and (4) a normal endocrine system for modulating these processes. At birth, the neonate has glycogen stores that are greater than those in the adult.

However, because of twofold greater basal glucose utilization, the stores begin to decline within 2 to 3 hours after birth. Muscle and cardiac carbohydrate levels fall more slowly. During asphyxia, the energy requirements are met by anaerobic glycolysis, an inefficient mechanism that results in a limited amount of energy and a decrease in glycogen stores. In premature infants, both total carbohydrate and fat content are reduced, and depletion of liver carbohydrates occurs. Endogenous *gluconeogenetic* substrate availability is probably not a limiting factor because the concentration of plasma amino acids is high at birth as a consequence of active placental transport. Similarly, other *gluconeogenetic* precursors, such as lactate, pyruvate, and glycerol, are also increased. Nevertheless, active gluconeogenesis from alanine and lactate has been demonstrated in the human newborn soon after birth.[48,49] Finally, hepatic glucose production is normally regulated; that is, it decreases in response to glucose as well as insulin infusion in both full-term and preterm healthy neonates.[42] However, in sick or stressed neonates, exogenous glucose infusion may not completely suppress endogenous glucose production.

The fall in blood glucose that normally occurs after birth is accompanied by an increased level of GH, a relatively low concentration of immunoreactive insulin, and an increase in plasma glucagon. The neonate shows an attenuated but significant insulin response to a variety of stimuli. After the oral administration of glucose, the insulin response in the normal neonate is similar to that in adults with chemical diabetes, that is, a lag in insulin response and a delayed peak. The premature infant has a minimal and variable insulin response, but the values are markedly increased by the intravenous administration of glucose plus amino acids. The physiologic role of increased GH levels has not been defined; GH values are high during the first 48 to 72 hours and gradually decline but are still elevated at 8 weeks of age. In addition, the newborn shows a paradoxical rise in GH after glucose infusion. Plasma glucagon values at birth are similar to or slightly higher than maternal levels. Glucagon and GH are not suppressed during hyperglycemia. In healthy newborns, intravenous and oral alanine feedings raise plasma glucagon and glucose levels.

Adaptation to prolonged starvation in adult humans is facilitated by the ability of the brain to derive much of its energy from the oxidation of ketone bodies, which decreases the need for gluconeogenesis and spares muscle protein. The enzymes involved in ketone body utilization pathways are present in the brain tissue of human fetuses and newborns. That ketone bodies can be used by the brain of infants and children has been shown by measurements of arteriovenous differences across the brain.

The transition from an intrauterine environment to independent extrauterine life is also characterized by intense lipid mobilization, as shown by a rapid increase in plasma glycerol and FFAs. In addition, there is a shift in the sources of energy for oxidative metabolism, as evidenced by a decline in the respiratory quotient. An increased contribution of fat to oxidative metabolism is reflected in a drop in the respiratory quotient from near 1.0 at birth to a level between 0.8 and 0.85 within a few hours after birth. Evidence of significant lipolysis in the neonate has been obtained by using isotopic tracers to measure glycerol kinetics.[10,68] These studies showed that lipolysis in the neonate occurs at rates almost threefold greater than those in adults, and that the major metabolic fate of glycerol released as a result of lipolysis is conversion to glucose.

Measurement of Glucose

Factors frequently overlooked in the interpretation of glucose concentration are the type of sample and the method of analysis. Whole blood includes red blood cells, which have a glucose concentration lower than that of plasma. Plasma glucose values are higher than those of whole blood by about 14%; the difference may be greater at very low glucose values (<30 mg/dL). Whole-blood glucose content also varies in accordance with the hematocrit. Neonatal red blood cells contain high concentrations of glycolytic intermediates; therefore, whole blood must be deproteinized with zinc hydroxide before analysis. Capillary blood samples should be collected from a warm heel and kept on ice because the rate of in vitro glycolysis is increased in red blood cells at room temperature; whole-blood glucose values may drop 15 to 20 mg/dL per hour if the sample is allowed to stand at room temperature. The most frequently used method for glucose determination in the laboratory is an automatic analysis technique with glucose oxidase or a commercial glucose oxidase immobilized electrode. Plasma or serum glucose concentrations are determined, and the results are very accurate.

In many nurseries, the rapid assessment of whole-blood glucose concentrations is accomplished by a glucose oxidase and peroxidase chromogen test strip method, either alone or with a reflectance colorimeter. However, all test strip methods show significant variations in glucose concentrations compared with laboratory methods, particularly in the low glucose range (<45 mg/dL). Devices and operator techniques vary, with confounding influences of incubation time and the hematocrit. It remains to be determined whether laboratory instrumentation can be moved to the bedside and used effectively, safely, and legally by nursery personnel. There should not be sole reliance on test strip devices, and tests resulting in borderline values (<40 to 45 mg/dL) should be repeated by using standard laboratory methods. Test strips are more reliable at high glucose concentrations and may be useful for screening or identifying a trend when hyperglycemia is suspected.

Continuous glucose monitoring, using a subcutaneously placed microdialysis sensor, has been validated in adults and children with diabetes. The feasibility, safety, and usefulness of these techniques have been examined in babies with low birthweight.[6,8] These data show that such devices can be useful for monitoring asymptomatic hypoglycemia, which may be missed by the current practice of intermittent testing. However, these methods cannot measure glucose levels below 45 mg/dL with confidence, and the variance is large at the high glucose concentrations. Thus far, these techniques have been used only for research studies, and their associated potential risks require further evaluation.

HYPOGLYCEMIA

Perturbations in glucose metabolism after birth caused by failure to adapt to the extrauterine environment, as a result of either alterations in maternal metabolism or intrinsic metabolic problems in the neonate, often result in hypoglycemia. Lengthy debate has occurred among investigators regarding the definition of hypoglycemia.[16] The controversy arises partly because of the spontaneous decrease followed by recovery of the blood glucose concentration after birth and partly because many neonates have very low blood glucose concentrations without any clinical signs or symptoms (i.e., asymptomatic hypoglycemia). Finally, a convincing relationship between asymptomatic hypoglycemia in the neonate and long-term neurologic sequelae has not been demonstrated (see later section, "Prognosis of Neonatal Hypoglycemia"). Attempts have been made to define hypoglycemia by either a statistical approach or correlation of blood glucose concentration with clinical signs and symptoms. Because the clinical signs of hypoglycemia in the neonate are not specific to alterations in glucose concentration, the latter approach has not been successful. The statistical definition of hypoglycemia is based on surveys of large numbers of infants. *Abnormality* is defined as a blood glucose concentration that falls outside a prescribed limit, for example, outside 2 standard deviations from the norm.[16,54] Based on studies of preterm and term neonates conducted in the 1960s, abnormal blood glucose levels were defined as those less than 30 mg/dL in full-term infants during the first 72 hours after birth and less than 20 mg/dL in preterm infants (i.e., infants weighing <2500 g). However, since that time, the intrapartum clinical care of the mother and nutritional clinical management of the neonate have changed markedly, so the glucose concentrations observed several years ago are no longer seen in current clinical practice. In addition, the routine use of intravenous dextrose-containing fluids in preterm infants has confounded the ability to study glucose concentration in these small babies. Using 95% confidence intervals of the mean, Srinivasan and colleagues[83] showed that normal, healthy, full-term infants who were fed early achieved plasma glucose values of higher than 40 mg/dL within 4 hours after birth and higher than 45 mg/dL within 24 hours after birth. In their study, 10% of the neonates had at least one value of less than 35 mg/dL in the first 3 hours (see Fig. 49-3). Others have recommended that serum concentrations of lower than 30 mg/dL in the first 24 hours and lower than 40 mg/dL after 24 hours be considered hypoglycemic. Based on their study of preterm infants, Lucas and coworkers[55] suggested that plasma glucose values of less than 47 mg/dL be considered hypoglycemic.

Although a consensus regarding cutoff values for hypoglycemia has not been reached, most investigators would consider a plasma glucose concentration of lower than 36 mg/dL to be low (hypoglycemia requiring intervention) in a full-term neonate 2 to 3 hours after birth. Care should be taken in interpreting glucose values during the transition period (i.e., the first 2 to 3 hours after birth), when the plasma glucose concentration may drop to low levels followed by spontaneous improvement. If low glucose levels are observed during this time, frequent glucose determinations should be obtained to demonstrate recovery. The definition of hypoglycemia for preterm infants should not be any different from that for full-term infants. Finally, hypoglycemia in the neonate should be described as transient or persistent, and in either or both of these cases, as symptomatic or asymptomatic. Such a description has implications for both clinical management and long-term consequences.

Transient hypoglycemia implies low glucose values that last only a short time if not corrected and that it is confined to the newborn period. In contrast, persistent and recurrent hypoglycemia implies a form that requires prolonged management (glucose infusions for several days at high rates of infusion) and perhaps pharmacologic intervention. Several of these hypoglycemia syndromes may continue throughout infancy and childhood.

The clinical manifestations of hypoglycemia are nonspecific and similar to those of many disorders in newborn infants (Box 49-1). The clinical signs and symptoms of hypoglycemia should improve with correction of the low glucose concentration. In addition, careful attention should be given to ensure that other associated disorders (e.g., sepsis, asphyxia) are not missed.

Because of its implications for both long-term prognosis and clinical management, it is worthwhile to consider two types of neonatal hypoglycemia: those cases limited to the newborn period (transient hypoglycemia) and those cases continuing over an extended period of time or occurring more than once (persistent or recurrent hypoglycemia) (Box 49-2). Transient hypoglycemia is often a consequence of changes in the metabolic environment in utero or ex utero, whereas persistent or recurrent hypoglycemia arises from intrinsic metabolic problems in the infant. Either type of hypoglycemia may manifest asymptomatically or symptomatically.

Transient Hypoglycemia Caused by Changes in Maternal Metabolism

INTRAPARTUM GLUCOSE ADMINISTRATION

As already discussed, the fetus is entirely dependent on the mother for the supply of glucose, and fetal glucose concentration closely mimics that of the mother.[3] An increase in maternal glucose concentration as a result of exogenous glucose infusion causes an increase in fetal glucose concentration, which in turn causes an increase in fetal insulin levels.

BOX 49–1 Clinical Symptoms and Signs of Hypoglycemia*

- Abnormal crying
- Irritability
- Apnea, cyanotic spells
- Jitteriness, tremors
- Feeding difficulty
- Lethargy or stupor
- Grunting, tachypnea
- Seizures
- Hypothermia
- Sweating
- Hypotonia, limpness
- Tachycardia

---

*Clinical signs should be alleviated with concomitant correction of plasma glucose levels.

BOX 49–2 Causes of the Two Types of Neonatal Hypoglycemia

- **I.** Transient hypoglycemia
  - **A.** Associated with changes in maternal metabolism
    - **1.** Intrapartum administration of glucose
    - **2.** Drug treatment
      - **a.** Terbutaline, ritodrine, propranolol
      - **b.** Oral hypoglycemic agents
    - **3.** Diabetes in pregnancy: infant of diabetic mother
  - **B.** Associated with neonatal problems
    - **1.** Idiopathic condition or failure to adapt
    - **2.** Intrauterine growth restriction
    - **3.** Birth asphyxia
    - **4.** Infection
    - **5.** Hypothermia
    - **6.** Hyperviscosity
    - **7.** Erythroblastosis fetalis
    - **8.** Other
      - **a.** Iatrogenic causes
      - **b.** Congenital cardiac malformations
- **II.** Persistent or recurrent hypoglycemia
  - **A.** Hyperinsulinism
    - **1.** β-cell hyperplasia, nesidioblastosis-adenoma spectrum, sulfonylurea receptor defect
    - **2.** Beckwith-Wiedemann syndrome
  - **B.** Endocrine disorders
    - **1.** Pituitary insufficiency
    - **2.** Cortisol deficiency
    - **3.** Congenital glucagon deficiency
    - **4.** Epinephrine deficiency
  - **C.** Inborn errors of metabolism
    - **1.** Carbohydrate metabolism
      - **a.** Galactosemia
      - **b.** Hepatic glycogen storage diseases
      - **c.** Fructose intolerance
    - **2.** Amino acid metabolism
      - **a.** Maple syrup urine disease
      - **b.** Propionic acidemia
      - **c.** Methylmalonic acidemia
      - **d.** Hereditary tyrosinemia
      - **e.** 3-hydroxy, 3-methyl glutaric acidemia
      - **f.** Ethylmalonic-adipic aciduria
      - **g.** Glutaric acidemia type II
    - **3.** Fatty acid metabolism
      - **a.** Defects in carnitine metabolism
      - **b.** Acyl-coenzyme dehydrogenase defects
  - **D.** Neurohypoglycemia (hypoglycorrhachia) due to defective glucose transport

Studies in animals have shown that fetal hyperinsulinism, caused by either direct infusion of insulin to the fetus or fetal hyperglycemia, results in an increased metabolic rate in the fetus, fetal hypoxemia, and metabolic acidosis. Similar patterns of change have been demonstrated in human pregnancy.[72] The acute administration of glucose during the intrapartum period—for example, to prevent hypotension during the conduction of anesthesia—has been shown to result in increased glucose, insulin, and lactate levels in the cord blood obtained at delivery.[49,72] Fetal hyperinsulinism leads to hyperinsulinemia and hypoglycemia in the neonate. Similar observations have been reported in diabetic pregnancy. Therefore, caution should be exercised in the administration of glucose to the mother during labor and delivery (see Chapter 25). Blood glucose concentrations in the mother should not be allowed to exceed those observed in the normal physiologic range.

MATERNAL TREATMENT

The antidiabetic drugs tolbutamide and chlorpropamide cross the placenta and produce pancreatic β-cell hyperplasia and increased insulin release. Tolbutamide has a markedly prolonged half-life in the neonate and has been found in higher concentrations in the newborn after delivery than those found in maternal blood. Although they are not used extensively in the United States, these drugs are used in other countries to treat gestational diabetes. Protracted hypoglycemia may occur after birth. Exchange transfusion was required in one infant whose mother received chlorpropamide and in whom hypoglycemia was not responsive to any conventional method of management. Newer formulations of these drugs have been shown to be safer because they do not cross the placenta as readily as the previous products.

Benzothiadiazide diuretics may cause neonatal hypoglycemia by stimulation of fetal β cells or secondary to an elevation in maternal glucose levels. Salicylates may cause hypoglycemia by uncoupling mitochondrial oxidative phosphorylation.

Oral β-sympathomimetic tocolytic drugs such as terbutaline and ritodrine have caused sustained hypoglycemia and elevated cord blood insulin levels in infants delivered within 2 days after termination of tocolytic therapy (see Chapter 16). These agents may cause neonatal hypoglycemia through maternal hyperglycemia and fetal hyperglycemia and hyperinsulinemia.

β-Adrenergic blocking agents such as propranolol cross the mammalian placenta, and their effects on the fetus are easily demonstrated. These drugs are used during pregnancy for the treatment of hypertension, hyperthyroidism, cardiac arrhythmia, and other conditions. They may interfere with the effects of the normal surge in catecholamine levels at birth. In animal studies, propranolol has been shown to impair fetal growth and may cause neonatal hypoglycemia and impair the thermogenic response to cold exposure.

DIABETES IN PREGNANCY: THE INFANT OF A DIABETIC MOTHER

Although perturbations in glucose metabolism in the mother and their consequences to the fetus and neonate constitute the major metabolic disturbances of diabetes in pregnancy, neonatal morbidity involves a number of organ systems. The major neonatal morbidities in infants of diabetic mothers (IDMs) whose maternal diabetes was not rigorously managed are displayed in Box 49-3.

The pathogenesis of the spectrum of fetal and neonatal morbidities in the IDM has now been described by a number of careful studies in human and animal models. Intermittent hyperglycemia in the mother results in hyperglycemia in the fetus, which in turn causes hypertrophy of the fetal pancreatic islets and β cells and increased secretion of insulin. Because

BOX 49–3 Morbidity in Infants of Diabetic Mothers

- Congenital anomalies
- Heart failure and septal hypertrophy of heart
- Hyperbilirubinemia
- Hypocalcemia
- Hypoglycemia
- Macrosomia
- Renal vein thrombosis
- Small left colon
- Unexplained intrauterine demise
- Polycythemia
- Visceromegaly

of the lack of significant transfer of insulin from the mother to the fetus in humans, the circulating insulin in the fetal compartment is mostly of fetal origin. However, two studies have demonstrated that in insulin-dependent diabetes, in the presence of antibodies to insulin, a small amount of insulin exogenously administered to the mother may be transported to the fetus.[5,59] Nevertheless, the newborn IDM has been shown to be hyperinsulinemic, as evidenced by increased levels of insulin and C peptide in the umbilical blood. The consequences of fetal hyperinsulinemia have been documented in experimental animal models. By infusing insulin directly into the normal rhesus monkey fetus through an osmotic pump, Susa and associates[85] showed that fetal hyperinsulinemia resulted in macrosomia, cardiomegaly, and an increase in adipose tissue. In addition, the activity of hepatic enzymes affecting lipid synthesis increased. Chronic fetal hyperinsulinemia also results in an increase in the metabolic rate and oxygen consumption, leading to relative hypoxemia, which in turn results in an increase in the synthesis of erythropoietin and an increase in red blood cell mass and polycythemia.[12] In addition, hyperinsulinemia has been shown to suppress the production of surfactant in the lung and thus predispose to respiratory distress syndrome after birth (see Chapter 44). An excessive accumulation of glycogen in the liver, adipose tissue, and other tissues has also been observed in IDMs. The sequence of these metabolic events is outlined in Figure 49-4.

Although the excessive transport of glucose from the mother to the fetus has been said to be primarily responsible for fetal metabolic and physiologic perturbations in the IDM, this hypothesis may also include the excessive transport of other nutrients (i.e., amino acids and lipids). An absolute or relative lack of insulin in the mother leads to the increased transport of mixed nutrients to the fetus as a consequence of increased levels of these nutrients in the maternal compartment. The increased concentration of these nutrients in the fetal circulation stimulates fetal insulin secretion, which in turn stimulates excessive fetal growth.

After birth, the newborn IDM whose mother's disease has not received rigorous antepartum management appears to be unable to produce sufficient circulating glucose and alternative fuels. Even the infants of mothers with rigorous management (i.e., those who have maintained normoglycemia throughout gestation) develop significantly lower blood glucose concentrations than those of normal infants. In addition, they do not mobilize fatty acids from adipose tissue; as a result, their circulating levels of FFAs remain low, although a normal increase in plasma glycerol has been observed. Such a metabolic picture

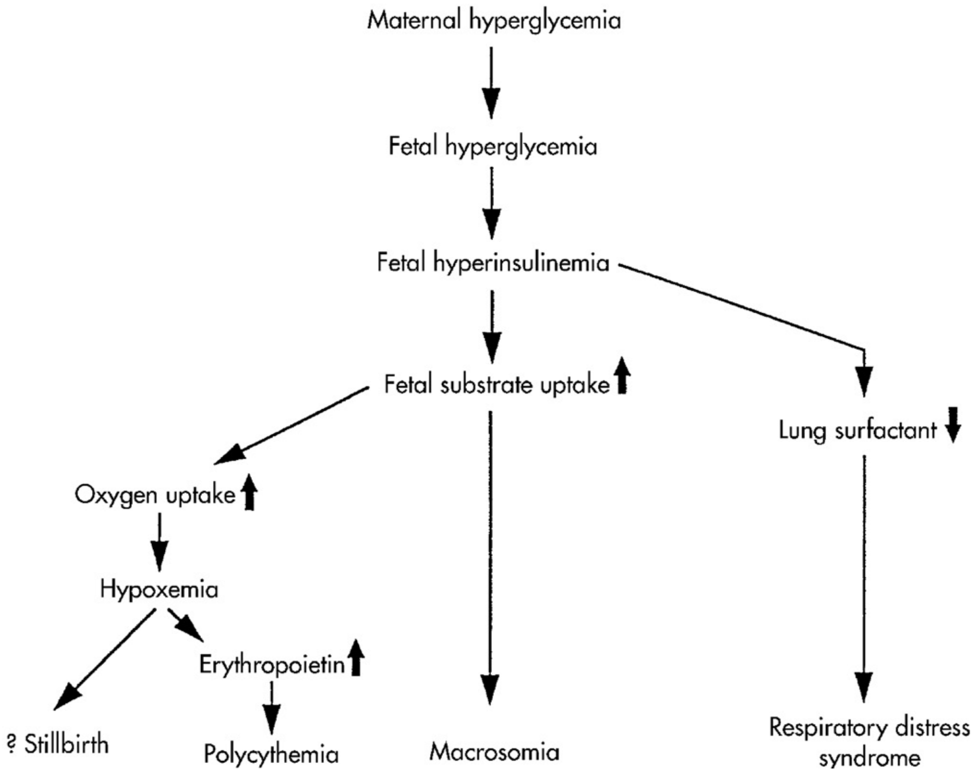

Figure 49–4. Flow diagram of pathogenic events that result in fetal and neonatal morbidity in infants of diabetic mothers. *(From Schwartz R, et al: Infant of the diabetic mother,* J Pediatr Endocrinol *5:197, 1992.)*

suggests a persistent insulin action and the lack of a counter-regulatory hormonal response. The latter is confirmed by the lack of an increase in circulating glucagon and catecholamine levels in IDMs during hypoglycemia. The combination of hyperinsulinism and insufficient counter-regulation results in decreased hepatic glucose production, increased peripheral glucose uptake, and impaired lipolysis. When measured by the isotope tracer dilution method, IDMs produce glucose at significantly lower rates than normal infants.[46] In addition, their basal metabolic rates, or rates of oxygen consumption, have been reported to be lower than those of normal infants.

Several of these metabolic and morphologic abnormalities can be reversed with fastidious management of diabetes in the mother. Data from several studies showed that with rigorous management throughout pregnancy, IDMs do not become hypoglycemic and maintain normal rates of glucose production and basal metabolism.

Clinical Manifestations

It should be recognized that the clinical manifestations described here relate to diabetic mothers whose metabolism has not been well controlled. Data from a study[4] in which maternal diabetes was rigorously managed by either an insulin infusion pump or split-dose insulin therapy are shown in Table 49-1. Despite rigorous management and reduced maternal hyperglycemia, significant morbidity may persist.

MACROSOMIA

At birth, these infants are obese, plethoric, and large for gestational age (LGA) and show evidence of excessive fat as well as visceromegaly in the form of a large liver, spleen, and heart (Fig. 49-5). Because the growth of the brain and possibly the kidney is not dependent on insulin, these two organs are normal in size. Careful management of maternal metabolism tends to reduce the incidence of macrosomia but does not prevent it.

CONGENITAL ANOMALIES

The incidence of congenital malformations is increased twofold to threefold in the infants of insulin-dependent diabetic mothers compared with the normal population. The frequency of congenital anomalies is not increased in the infants of gestationally diabetic mothers or in those of diabetic fathers. A developmental morphologic approach, as applied by Mills and colleagues, suggests that congenital malformations in IDMs occur before the seventh week of development.[62] A number of congenital anomalies, including those of the heart, musculoskeletal system, and genitourinary system, have been reported. Caudal agenesis or dysplasia syndrome (Fig. 49-6) is seen with markedly increased frequency, especially in IDMs. This syndrome consists of agenesis or hypoplasia of the femora in conjunction with agenesis of the lower vertebrae and sacrum. Data from animal models show that certain genes belonging to the *PAX* family are involved in enhancing apoptosis, which then results in structural defects, for example, neural tube defects. The frequency of congenital anomalies is significantly increased in mothers with poor metabolic control, as evidenced by increased hemoglobin A_{1c} levels early in gestation,[61] and a significant decrease in congenital malformations has been reported with rigorous metabolic regulation in the periconceptional period (see Chapter 16).[30]

HYPOGLYCEMIA

The pathogenesis of hypoglycemia has been described already. Immediately after birth, there is a significant decrease in plasma glucose concentration, reaching a nadir between 30 and 90 minutes and followed by a spontaneous recovery in most infants. However, in some infants, the plasma glucose level remains persistently low (i.e., <36 mg/dL, often <20 mg/dL), necessitating intervention. Most of these infants are asymptomatic. Irrespective of symptoms, the current recommendation is to correct the hypoglycemia with an appropriate glucose infusion. It should be underscored that hypoglycemia in the newborn does not necessarily reflect the

TABLE 49–1 Neonatal Outcome in Infants of Rigorously Managed Diabetic Mothers

Parameter	Infants of Diabetic Mother ($N = 78$)	Controls ($N = 78$)	P
Birthweight (g)	3454 ± 817	3271 ± 621	—
Gestational age (wk)	37.9 ± 0.95	39.3 ± 1.7	.0001
K score*	0.77 ± 0.95	0.18 ± 0.91	.0001
Macrosomia (>4 kg)	19 (24%)	8 (10%)	.03
Large for gestational age	32 (41%)	12 (15%)	.0002
Hypoglycemia	11 (14%)	1 (1%)	.0025
Hyperbilirubinemia	36 (46%)	18 (23%)	.002
Respiratory distress syndrome	9 (12%)	1 (1%)	.008
Admission to neonatal intensive care unit	21 (27%)	9 (12%)	.01

*The K score is a method of adjusting the birthweight in grams for the infant's gestational age. A K score of 1 represents the 90th percentile for weight; scores of 0 and −1 represent the 50th and 10th percentiles, respectively.

Adapted from Aucott SW, et al: Rigorous management of insulin-dependent diabetes mellitus during pregnancy, *Acta Diabetol* 31:126, 1994.

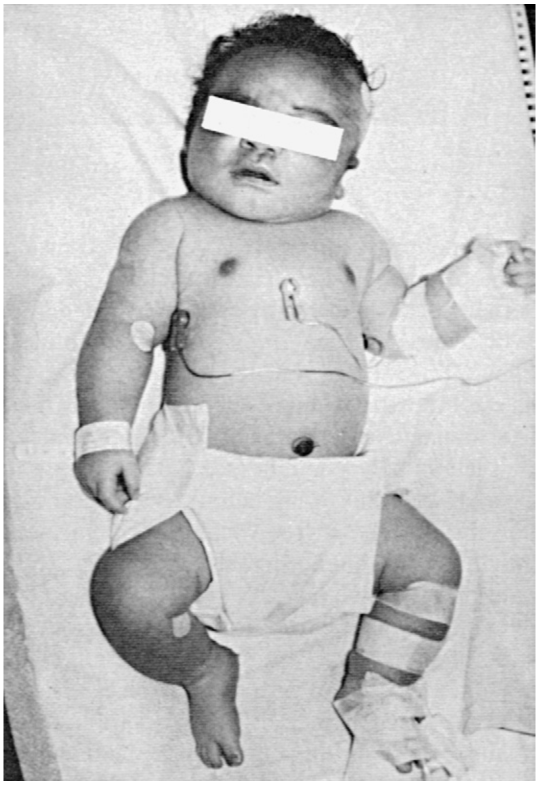

Figure 49–5. Infant of mother with gestational diabetes; the baby was born at 40 weeks of gestation with a birthweight of 4.6 kg. The infant developed hypoglycemia and was treated with intravenous glucose.

magnitude of antepartum metabolic control of the mother and may simply be the consequence of hyperglycemia during labor and delivery.

HYPOCALCEMIA AND HYPOMAGNESEMIA

See Chapter 49, Part 2.

Alterations in calcium and magnesium homeostasis occur in about 50% of infants born to insulin-dependent diabetic mothers. Unlike hypoglycemia, hypocalcemia becomes apparent between 48 and 72 hours after birth. Plasma calcium concentrations of lower than 7 mg/dL are frequently observed. Hypocalcemia has been related to the severity and duration of maternal diabetes. In addition, it may be potentiated by prematurity and asphyxia. The mechanisms of hypocalcemia are probably failure of the IDM to mount an appropriate parathyroid hormone (PTH) response, persistently high levels of calcitonin, and possibly alterations in vitamin D metabolism. Hypomagnesemia (<1.5 mg/dL) has also been frequently observed. It is usually transient, and its pathophysiologic significance remains uncertain.

Both hypocalcemia and hypomagnesemia may be manifested with jitteriness and may require supplemental calcium therapy. However, in most infants, they are transient events that improve spontaneously.

The management strategies for other clinical problems, such as polycythemia (see Chapter 46, Parts 1 and 2), hyperbilirubinemia (see Chapter 48), and renal vein thrombosis (see Chapter 51), that occur with slightly higher frequency in IDMs are similar to those in otherwise normal infants.

SEPTAL HYPERTROPHY OF THE HEART

Septal hypertrophy and cardiomegaly are specific phenotypic consequences of diabetes in pregnancy and may be manifested with heart failure in the neonate (Fig. 49-7) (see Chapter 45). In addition, data in the asymptomatic infants of gestationally diabetic mothers have shown alterations in diastolic function and decreased passive compliance of the ventricular myocardium. By serially evaluating cardiac growth in utero in the fetuses of diabetic mothers, it has been shown that despite good metabolic control, cardiac hypertrophy developed in late gestation (34 to 40 weeks). Although IDMs with septal hypertrophy may present with obstructive left heart failure, they may also be asymptomatic. Follow-up data show that cardiomyopathy in an IDM is a transient disease and usually disappears spontaneously within 6 months after birth. Otherwise minor functional changes, such as impaired diastolic filling, have been reported in infants of gestational diabetic mothers and are usually not clinically significant.

Management of the Diabetic Mother

See Chapter 16.

Strict metabolic control, improved fetal surveillance, early delivery, and neonatal intensive care have led to improved survival among IDMs. Preconceptional and early postconceptional metabolic control may decrease the incidence of congenital malformations. Improving maternal compliance, preventing ketoacidosis, and recognizing and treating pregnancy-induced hypertension and pyelonephritis are particularly important. Attempts should be made to maintain maternal fasting plasma glucose values at less than 80 mg/dL and 2-hour postprandial plasma glucose values at less than 120 mg/dL.

With appropriate ambulatory support, hospitalization is not required in most mothers. Indications for hospitalization include pregnancy-induced hypertension, acute or chronic polyhydramnios, infections, and poor metabolic control. Early screening for congenital malformations includes a determination of the maternal serum α-fetoprotein level for open neural tube defects and a level II ultrasound at 18 to 20 weeks of gestation (see Chapters 8 and 9). Follow-up ultrasonography is useful in the evaluation of amniotic fluid volume, fetal growth, and placental grading. Tests of fetal well-being begin in the second trimester (28 to 32 weeks of gestation). These tests usually include daily fetal movement counts and biweekly biophysical testing (nonstress testing, biophysical profile, or both) or nonstress testing combined with an amniotic fluid index (see Chapter 10).

Delivery in insulin-dependent women is indicated after documentation of fetal lung maturity by amniocentesis (see Chapter 44, Part 1). With appropriate care and fetal surveillance, most patients are now monitored expectantly for the spontaneous onset of labor at term. Vaginal delivery is preferred, but obstetric factors may justify cesarean delivery. Caution should be exercised in the delivery of a macrosomic fetus at risk for traumatic complications. During labor, glucose and insulin therapy should be adjusted to maintain normoglycemia in the mother.

Delivery should take place in a hospital, where the newborn can be carefully monitored. Glucose values are checked

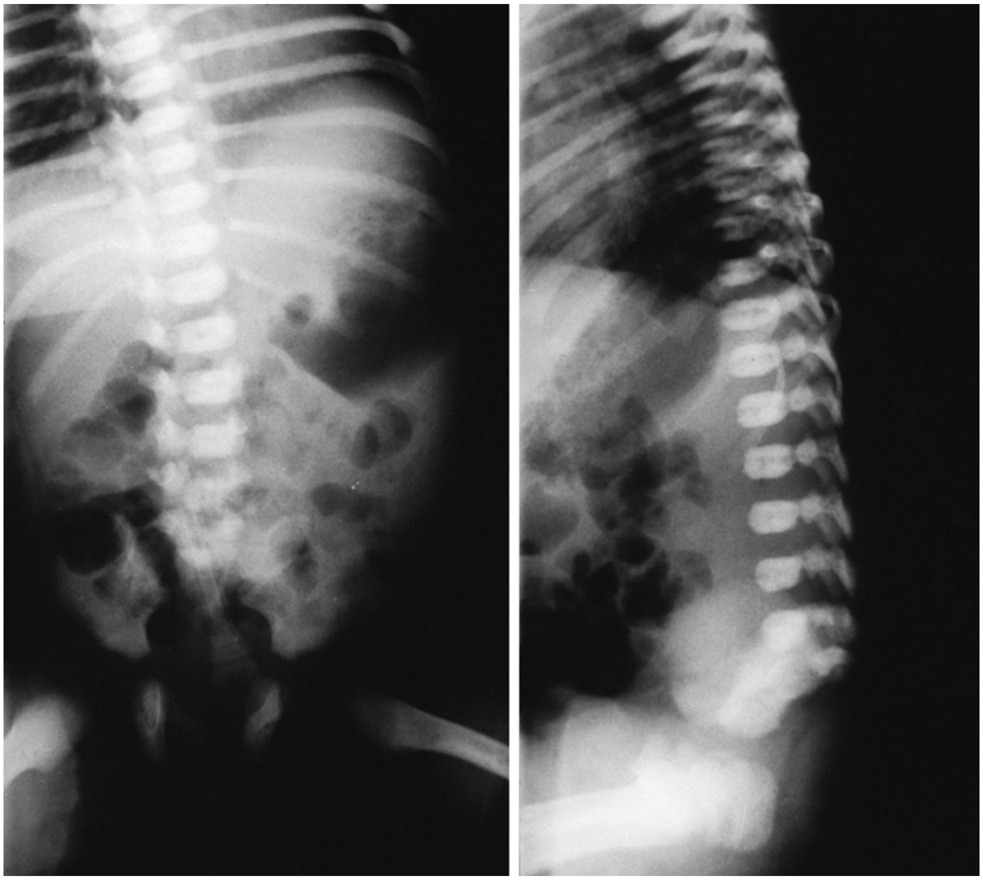

Figure 49–6. Anteroposterior (*left*) and lateral (*right*) radiographs of sacral agenesis in an infant of a diabetic mother.

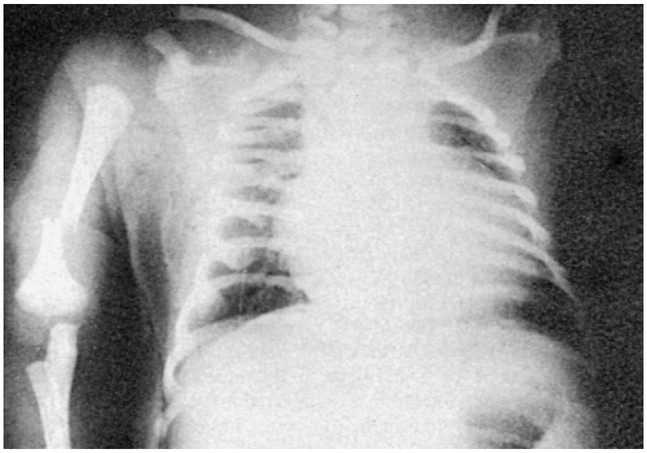

Figure 49–7. Chest radiograph of a vaginally delivered, full-term infant (4.7 kg) of a diabetic mother. The infant had cardiomegaly, hepatomegaly, congested lung fields, and fractures of the right humerus and left clavicle.

during the first 3 hours after birth (typically between 30 and 60 minutes), sporadically before feedings, and any time symptoms are suspected. Feedings may be started as soon as the infant is stable, usually within 2 to 4 hours after birth, and continued at 3- to 4-hour intervals.

Even though physiologic and clinical data clearly demonstrate a marked reduction in fetal and neonatal morbidity and mortality in pregnancy with diabetes, two studies from the United Kingdom failed to show that such a goal was achieved in clinical practice.[13,41,82] Continuous rigorous surveillance of diabetes throughout the pregnancy and fastidious management of altered metabolism are required.

Prognosis

Improvements in antepartum care, fetal monitoring, rigorous control of maternal metabolism, and maternal education have all resulted in reduced perinatal mortality and morbidity. In addition, control of maternal metabolism during the periconceptional period has resulted in a decreased incidence of congenital malformations in IDMs. However, certain morbidities, such as hypoglycemia, macrosomia, and polycythemia, persist. The long-term consequences of an abnormal intrauterine metabolic environment remain a subject of continued interest. In the rat fetus, intrauterine hyperinsulinism induced by injection of insulin resulted in fetal and neonatal macrosomia. Significantly, this macrosomia persisted for up to 12 weeks after birth—the final time point of the study. In addition, mild hyperglycemia induced by glucose infusion during pregnancy in the rat resulted in glucose intolerance and impaired insulin secretion. Limited data in humans have examined the long-term consequences of an altered intrauterine metabolic environment in the infant and young adult.[70] Even though the IDM may be born macrosomic and obese, most of these changes in body composition tend to reverse during infancy. Long-term follow-up studies have not shown an increased risk for obesity or diabetes in this population.[70] Exceptions were a study by Vohr and colleagues,[90] which demonstrated a correlation between being LGA at birth and having a higher weight-to-height ratio at 7 years of age, and a study of the Pima Indians by Pettitt and coworkers, which demonstrated a high incidence of obesity and diabetes in the children of diabetic mothers. However, the impact of the intrauterine environment could not be separated from genetic predisposition in the latter study.

The risk for the subsequent development of insulin-dependent diabetes in IDMs has been carefully examined in a series of studies from the Joslin Diabetes Center. The cumulative risk for the development of insulin-dependent diabetes mellitus before 20 years of age was 2.1% (20 of 739 mothers) when the mother had diabetes and 5.1% (28 of 840 fathers) when the father had insulin-dependent diabetes.[27,92] The slightly increased risk for diabetes mellitus in IDMs was shown to be independent of risk factors for perinatal morbidity. Diabetes in the father did not influence morbidity in the infant except for the genetic predisposition for diabetes.

Another study revealed that the children of diabetic mothers, with and without macrosomia in the newborn period, had higher body mass indexes, higher blood pressures, and higher glucose and insulin levels on glucose tolerance testing when evaluated at age 18 to 26 years.[75] Other studies have shown impaired insulin signaling and glucose transport and altered mitochondrial number and function in the skeletal muscle of the adult offsprings of diabetic mothers. These data need to be confirmed and their health consequences determined in a large cohort of carefully monitored children.

The evaluation of the neurodevelopmental outcome of IDMs is confounded by the contribution of perinatal events such as birth asphyxia and metabolic acidosis. Recent data from animal models suggest relative iron deficiency in the brain that has been related to functional impairment. Nonetheless, several investigators have examined the impact of alterations in maternal metabolism, specifically changes in blood glucose and ketones, on neurodevelopment in the newborn period and early childhood. In 1969, Churchill and colleagues[14] first reported that diabetic mothers with acetonuria had offspring with lower intelligence quotients (IQs) than controls (mean IQ, 93 versus 102). These subjects were part of the large Perinatal Study, and the infants were given either Bayley mental and motor examinations at 8 months or the Stanford-Binet IQ test at 4 years. In this study, the mean IQ of the offspring of diabetic mothers without acetonuria was equal to that of controls (101). In addition, this association between acetonuria and the IQ of the children was present in both gestational diabetes and insulin-dependent diabetes. Intellectual delay at ages 3 and 5 years in infants born to acetonuric women has been observed. It should be emphasized that acetonuria is also a marker of poor metabolic control. Since these early studies, much improvement in the antepartum management of maternal diabetes has occurred, so the neuropsychological outcome for the IDM should be examined in relation to maternal blood glucose control, alterations in lipid metabolism (e.g., FFAs, ketones), and perinatal events such as neonatal asphyxia and hypoglycemia. Available data[81] show that, when examined as a group, IDMs have mental development indexes and Stanford-Binet test scores that are not significantly different from those of infants of normal mothers. However, when correlation analyses were performed, a negative correlation was observed by Rizzo and colleagues[76] between second- and third-trimester glycemic regulation (hemoglobin A_{1c} and fasting plasma glucose levels) and the newborn behavior dimensions of the Brazelton Neonatal Behavioral Assessment and between third-trimester ketonuria and mental developmental index scores at 2 years of age and Stanford-Binet scores at 3 to 5 years of age. Finally, it was demonstrated in other studies that IDMs who were born with malformations or who were shown to have early growth delay in utero tended to present with developmental impairments.[70]

The impact of neonatal hypoglycemia on later developmental outcome was examined by Haworth and coworkers[39] in a prospective follow-up study of 36 IDMs. They did not find any correlation between neonatal blood glucose levels or the duration of hypoglycemia and neurologic abnormalities.

Transient Hypoglycemia Associated with Neonatal Problems

IDIOPATHIC CONDITION OR FAILURE TO ADAPT

For apparently unknown reasons, a number of infants develop hypoglycemia, and the cases have been designated as idiopathic hypoglycemia or failure to adapt to the extrauterine environment. As maternal obstetric care continues to improve and more contributory factors are identified, the number of cases of idiopathic hypoglycemia continues to decrease. A careful maternal history should be obtained whenever an infant develops hypoglycemia for reasons that are not easily evident. Contributory factors may include maternal obesity and mild glucose intolerance in the mother.

Maternal Obesity

Many infants born to obese mothers without evidence of impaired glucose tolerance develop low blood glucose concentrations in the immediate newborn period. With the increasing incidence of obesity in the general population, the number of such babies continues to increase. The exact mechanism of impaired glucose homeostasis in these infants has not been examined. It is likely to be related to obesity-related insulin resistance of the mother, which also has been correlated with the higher frequency of macrosomia in these infants.

INTRAUTERINE GROWTH RESTRICTION AND INFANTS WHO ARE SMALL FOR GESTATIONAL AGE

See Chapter 14.

Hypoglycemia has been frequently reported in infants who are SGA (<10th percentile in weight for gestational age). However, the reported incidence has been quite variable. Lubchenco and coworkers[54] reported the following frequencies of hypoglycemia (defined as plasma glucose levels lower than 30 mg/dL before the first feeding) in infants who are SGA: 18% in infants born between 42 and 46 weeks of gestation, 25% between 38 and 42 weeks of gestation, and 67% at less than 38 weeks of gestation. Most of the hypoglycemic infants also had a history of fetal distress and birth hypoxia. Other investigators have reported a much lower rate of hypoglycemia. The variation in incidence may reflect different causes of intrauterine growth restriction, such as maternal nutrition, uteroplacental insufficiency, fetal infection, or maternal metabolic perturbations. In addition, because polycythemia and fetal and neonatal hypoxemia are frequently seen in infants who are SGA, polycythemia and hypoxemia by themselves could contribute to the incidence of hypoglycemia. The data from the previous studies are probably overestimated and not applicable to the present-day population. Studies suggest that the incidence of hypoglycemia (blood glucose <30 mg/dL) in infants born SGA to an otherwise healthy population of mothers is much less than previously reported and ranges from 6% to 14%.[77] The age at which hypoglycemia occurred was examined by Holtrop.[44] In that study, 27 (90%) of 30 infants who were SGA developed hypoglycemia during the first 12 hours after birth.

Therefore, the infant who is SGA is at a high risk for neonatal hypoglycemia, particularly when born prematurely, that is, at less than 38 weeks of gestation. Hypoglycemia, which may be either symptomatic or asymptomatic, is usually seen within the first 24 hours after birth. Associated findings include evidence of asphyxia or hypoxia, polycythemia, and hypocalcemia. The incidence of these findings is probably related to the cause of growth restriction.

The relation between neonatal hypoglycemia and so-called symmetric and asymmetric growth restriction has not been specifically addressed. In general, the consensus among investigators is that hypoglycemia is more common among infants with asymmetric growth restriction because that group represents true intrauterine nutrient deprivation.

The pathogenesis of hypoglycemia has been the subject of numerous investigations and speculation in both humans and animal models. Clinical observations in infants who were SGA showed an early recruitment of fat for oxidative metabolism, as evidenced by a lower respiratory quotient and a higher rate of lipolysis, compared with infants who were appropriate sizes for gestational age.[68] This finding led to the speculation of decreased glycogen stores and their early depletion in infants who are SGA. Early depletion of glycogen stores was also postulated based on the higher brain-to-body ratio of infants who are SGA and the dependence of the brain on glucose for oxidative metabolism. The data of Hawdon and colleagues[36-38] contrast with those of these older studies; however, most of the infants they studied were in the fed state or were receiving intravenous glucose. A decreased rate of gluconeogenesis has been proposed as a contributor to hypoglycemia in infants who are SGA based on high levels of *gluconeogenetic* substrates and a lower glucose response to the administration of alanine, a key *gluconeogenetic* amino acid. However, Frazer and coworkers,[29] using isotopic tracer methods, were able to demonstrate the incorporation of alanine carbon into glucose in such infants soon after birth. Other investigators have reported high insulin levels[15] and higher fractional rates of the disappearance of glucose in infants who were SGA, but again these infants were in the fed state or were receiving parenteral nutrients when they were examined. The role of glucagon in the development of hypoglycemia remains unclear. Infants who are SGA have been observed to mount a significant glucagon response to hypoglycemia. However, the response to exogenous glucagon administration has been variable, particularly in relation to plasma amino acids. Hypoglycemic infants who are SGA appear not to show a normal decrease in plasma amino acids in response to intravenous infusion of glucagon. The GH response to hypoglycemia and glucose infusion is reported to be normal.

Studies of the fetal metabolic state by cordocentesis in pregnancies complicated by intrauterine growth restriction have shown a high incidence of hypoxemia, high blood lactate concentrations, and metabolic acidosis.[26,58,64]

A number of approaches have been applied to study intrauterine growth restriction in animal models. They include uterine artery ligation, maternal starvation, maternal hypoxemia, and maternal hypoglycemia. The neonatal metabolic responses varied with the type of experimental model, but all of the models showed growth restriction, hypoglycemia, and depletion of hepatic glycogen stores. The mechanism of hypoglycemia remains unclear. Newborn dogs that had growth restriction as a result of maternal starvation showed lower glucose levels but unchanged glycogenolysis, lower plasma fatty acids, and ketone levels but also lower rates of gluconeogenesis from alanine, and unchanged rates of lipolysis, suggesting that reduced gluconeogenesis and ketogenesis contributed to hypoglycemia. In comparison, growth restriction by ligation of the uterine artery in the rat resulted in lower plasma glucose concentrations and inappropriate hyperinsulinemia as well as lower hepatic glycogen levels. The delayed induction of liver phosphoenolpyruvate carboxykinase in this model suggests delayed appearance of gluconeogenesis. On follow-up, the intrauterine growth-restricted pups in this rat model remained smaller than those of the controls in both weight and length; that is, they showed no evidence of catch-up growth,[66] suggesting that the intrauterine insult had a permanent impact on growth. Maternal treatment with glucocorticoids attenuated neonatal hypoglycemia in the rat model, possibly by stimulating gluconeogenesis. Finally, studies of the adrenergic system and cerebral oxidative metabolism have not demonstrated any significant change, and studies of somatostatin C (insulin-like growth factor-1) have shown decreased levels in the growth-restricted rat fetus.

The management of these infants involves treatment of the associated clinical problems—hypoxia, hyperviscosity, careful monitoring for hypoglycemia, and the early establishment of adequate nutrition. The treatment of hypoglycemia is similar to the one outlined later.

HEPATIC GLUCOSE-6-PHOSPHATASE AND PREMATURITY

Glucose-6-phosphatase is a membrane-bound enzyme associated with the endoplasmic reticulum in the liver and the kidney—the two important glucogenic organs. It catalyzes the breakdown of glucose-6-phosphate into free glucose, the terminal step in both glycogenolysis and gluconeogenesis. Hume and colleagues[44a] have measured the activity and protein content of glucose-6-phosphatase in the liver of newborn infants soon after their deaths and observed that the enzyme activity is low before birth and increases to about 10% of adult values by term gestation. In a series of studies, they have suggested that the low activity of glucose-6-phosphatase, partly influenced by hormonal, nutrient, and other factors, including stress, may contribute to hypoglycemia in premature infants. However, the direct cause-and-effect relationship is difficult to discern from their studies. A severe deficiency of glucose-6-phosphatase certainly can lead to profound hypoglycemia, as in glycogen storage disease type I. Whether a relatively lower activity, as measured by Hume and colleagues[44a] in autopsy samples, can cause hypoglycemia remains to be confirmed.

BIRTH ASPHYXIA

The mechanism of low glucose after birth asphyxia remains unknown. Affected infants often require high rates of glucose infusion to maintain a normal glucose concentration, suggesting either an increased insulin concentration or increased sensitivity to insulin. An inappropriately high insulin concentration relative to prevailing glucose concentration has been reported in a number of case reports and in a prospective study by Davis and associates.[18] Interestingly, high plasma insulin levels in their study were associated with a poor neurodevelopmental outcome. The mechanism of the resulting hyperinsulinemia remains unclear. Because asphyxia also results in an increase in plasma glucagon, interleukin-6, hydrocortisone, and other counter-regulatory hormones, with associated changes in insulin receptor binding, it can also induce an insulin-resistant state. From a clinical perspective, it is important to carefully monitor the plasma glucose concentration in asphyxiated newborn babies and adjust the parenteral glucose infusions accordingly.

INFECTION

See Chapter 39.

Hypoglycemia in association with overwhelming sepsis has rarely been reported in newborn infants. Hyperglycemia is more common than hypoglycemia. The mechanism of hypoglycemia with sepsis is not well defined. Depleted glycogen stores, impaired gluconeogenesis, and increased peripheral glucose utilization may all be contributing factors. The usual response to sepsis in most animal models has been an increase in the rates of glucose production and gluconeogenesis as a result of counter-regulatory hormonal responses. A decrease in these processes is seen only during an agonal stage; therefore, hypoglycemia with sepsis should be considered an indicator of a fulminating infection.

HYPOTHERMIA

See Chapter 30.

The occurrence of hypothermia secondary to hypoglycemia has been well documented and is a useful clinical sign. Studies in which 2-deoxy-D-glucose was used in adults suggest that hypoglycemia, directly or secondarily, may affect a central thermoregulatory center in the hypothalamus that is sensitive to glucose. Hypoglycemia may also be secondary to hypothermia. The normal core temperature in the neonate is between 36.5° and 37.5°C (97.7° to 99.5°F). If the body temperature falls, the heat production increases several times above that of the basal level, resulting in a more rapid depletion of energy stores. Hypoglycemia is also seen in neonates with severe cold injury after prolonged exposure to cold who had rectal temperatures lower than 32°C (89.6°F).

HYPERVISCOSITY

See Chapter 46.

A negative correlation between plasma hematocrit and glucose concentration was reported by Haworth and colleagues[40] in full-term infants with growth restriction. The mechanism for the lower glucose concentration observed with increased viscosity was examined by Creswell and associates[17] in newborn lambs. Their data showed that newborn lambs made polycythemic by exchange transfusion had lower plasma glucose concentrations; however, there was no change in the rates of glucose production and utilization. The authors suggested that hyperviscosity acts as an independent variable to depress plasma glucose concentration.

ERYTHROBLASTOSIS FETALIS

See Chapter 21 and Chapter 46, Parts 1 and 2.

Previous studies reported an association between erythroblastosis fetalis due to Rh incompatibility and neonatal hypoglycemia. Hypoglycemia was particularly prominent in severely anemic infants and was seen more frequently after exchange transfusion. Because the exchange transfusions were performed with blood containing acid citrate dextrose, the hypoglycemia occurring after exchange transfusion could be the result of glucose-induced hyperglycemia and hyperinsulinemia. Intravenous glucose tolerance tests performed in infants affected by erythroblastosis fetalis who were not anemic showed their blood glucose and insulin levels before and during the test to be similar to those in normal infants. With the use of cordocentesis and the ability to obtain fetal blood samples in an undisturbed state, attempts have been made to examine the effects of fetal anemia and associated hypoxemia on fetal growth and biochemical parameters. The data revealed that only the severely anemic fetuses (i.e., those with hemoglobin concentrations of less than 30% of the normal value) showed decreased growth rates[65] and changes in umbilical venous blood pH. More importantly, no correlations between the severity of anemia and hypoxemia and levels of plasma insulin and C peptide were observed. Therefore, the suggestion of hyperinsulinemia based on the earlier studies has not been substantiated. Furthermore, the current management of Rh immunization has markedly reduced the severity of erythroblastosis fetalis and anemia in the fetus and the newborn infant. Nevertheless, the plasma glucose concentration should be carefully monitored in these infants after birth.

IATROGENIC CAUSES

Reactive hypoglycemia may occur after abrupt cessation of hypertonic glucose infusions, including those used for parenteral nutrition. Marked variability of blood glucose values may also occur as a result of changing rates of glucose infusion.

Refractory hypoglycemia has been associated with an umbilical artery catheter positioned near the origin of the vessels supplying the pancreas (T11 to L1). Direct glucose infusion into the vessels of the pancreas can lead to hyperinsulinemia and hypoglycemia. Hypoglycemia was also reported with a normally positioned catheter at T8 to T9; it responded to catheter repositioning.

Intravenous indomethacin infusion in premature infants with patent ductus arteriosus causes a drop in glucose to potentially hypoglycemic levels. The indomethacin-induced drop in glucose starts as soon as 1 hour after the beginning of intravenous indomethacin administration and is the lowest at 6 to 12 hours.

CONGENITAL CARDIAC MALFORMATIONS

The mean blood glucose concentration in neonates and older children with congenital cyanotic heart disease or congestive heart failure may be lower than that in healthy controls. Glucose disappearance rates and fasting insulin and GH values are normal, but glucose values after glucagon administration are lower than those in healthy children. Although the mechanism is unknown, chronic hypoxia, leading to decreased glycogen stores, may be a contributing factor. Hypoglycemia may also lead to cardiomegaly and congestive heart failure in the absence of congenital malformations. Therefore, the presence of either hypoglycemia or congestive heart failure should be considered when one or the other appears (see Chapter 45).

Persistent or Recurrent Hypoglycemia

HYPERINSULINISM

Nesidioblastosis-Adenoma Spectrum

Persistent neonatal hyperinsulinemic hypoglycemia (PNHH) can result from various pathologic lesions generally included under the heading of *nesidioblastosis-adenoma spectrum*.[67] The concept of nesidioblastosis has been questioned by several investigators because it is a common feature of the immature or developing pancreas in normoglycemic neonates and infants. This disorder is usually seen sporadically, but familial PNHH has been reported in at least 15 families; therefore, autosomal recessive inheritance must be considered. The neonates are usually LGA but may be appropriate for gestational age. At birth, they lack positive physical findings, although some facial dysmorphism has been reported in some of these infants during later infancy and childhood. Hypertrophic cardiomyopathy was reported in one infant. Maternal history is noncontributory, but a careful history may reveal previous neonatal deaths or unexplained seizures or mental restriction in other siblings. The diagnosis has been made at birth in asymptomatic infants and prenatally based on familial history. Most infants present during the first 24 to 48 hours after birth with such severe symptoms as seizure, hypotonia, apnea, and cyanosis. Asymptomatic hypoglycemia has been diagnosed in the siblings shortly after birth. Sudden infant death has also been linked to nesidioblastosis. The diagnosis is suspected when hypoglycemia appears soon after birth, requiring high rates of glucose infusion.

These infants typically have high blood insulin levels; even if they are in the normal range, insulin levels are likely to be inappropriately high in relation to the prevailing glucose concentration. Measurements of C peptide may be useful because it has twice the half-life of insulin. Tolerance tests may be difficult to perform because of the inability of the patient to fast for even short periods. Other measurements, such as branched-chain amino acids and ketones, have been suggested but are difficult to evaluate because of the high glucose infusions required to maintain normoglycemia. Other diagnostic methods (e.g., radiologic imaging of the pancreas) are not very helpful in cases of nesidioblastosis but may occasionally help visualize a pancreatic tumor.

A definitive diagnosis can be made only by pathologic examination and may require immunocytologic and electron-microscopic studies. Two basic lesions have been described: diffuse and focal. The two forms cannot be separated by clinical or laboratory investigations. The focal lesions, called *focal adenomatous hyperplasia*, consist of the confluence of apparently normally organized islets separated by a few exocrine acini but maintaining a normal lobular pancreatic structure.[20] This disorder is associated with the loss of the maternal allele from the imprinted chromosomal region 11p15 and partial mutation of the sulfonylurea receptor (*SUR1*) gene.[19,89] These lesions are quite different from the "true" islet cell adenomas, which are usually seen in adults but rarely in infants. Diffuse nesidioblastosis involves the whole pancreas and is distinguished by islets of irregular size and ductuloinsular complexes that contain hypertrophied insulin cells. In some cases, immunofluorescent and Feulgen techniques show an increased size of the nuclear area and absorbance of the B cells as the only pathologic findings.

With the use of various molecular biologic and genetic epidemiologic methods, the molecular basis for the abnormal insulin secretion in these disorders has been elucidated. As described in Figure 49-8, insulin secretion by the β cells requires an increase in the intracellular adenosine triphosphate (ATP) concentration as a result of glycolysis and the oxidation of glucose. After entry into the β cell, which is facilitated by a specific glucose transporter protein (GLUT2), glucose is phosphorylated to form glucose-6-phosphate. The latter enters the glycolytic pathway to form pyruvate and is oxidized in the tricarboxylic acid cycle. One of the other substrates entering this cycle is glutamate, which forms α-ketoglutarate, a reaction catalyzed by glutamate dehydrogenase. The increase in ATP concentration and the consequent increase in the ratio of ATP to adenosine diphosphate (ADP) affect the ATP-sensitive potassium (K^+) channel (K_{ATP}), resulting in the depolarization of the β-cell membrane. This process in turn results in the activation of voltage-gated calcium channels and the entry of Ca^{2+} into the cell. An increase in the intracellular Ca^{2+} concentration results in the release of insulin into the circulation.

Thomas and coworkers[87] identified two separate *SUR* gene splice site mutations that segregated from the disease phenotype in affected individuals from nine different families with familial PNHH. Both mutations resulted in aberrant processing of the RNA sequence and disruption of the putative second nucleotide binding domain of the SUR protein. The authors concluded that abnormal insulin secretion in PNHH appears to be caused by the mutations in the *SUR* gene.

Since that first report, a number of other families with the same genetic defect and new mutations in the insulin-secretory mechanism have been identified.[24] The K_{ATP} channels consist of *SUR1* and an inward-rectifying K^+ channel ($KIR_{6.2}$). One patient with a nonsense mutation of the $KIR_{6.2}$ gene associated with familial hyperinsulinism has been identified.[87] Another mutation of $KIR_{6.2}$ associated with hyperinsulinemic hypoglycemia has been reported. Other genetic defects described so far are those related to mutations of genes for glucokinase and glutamate dehydrogenase[31,84] and phosphomannose isomerase deficiency. Additional genetic defects causing hypersecretion of insulin may be identified in the future. It is important to note that

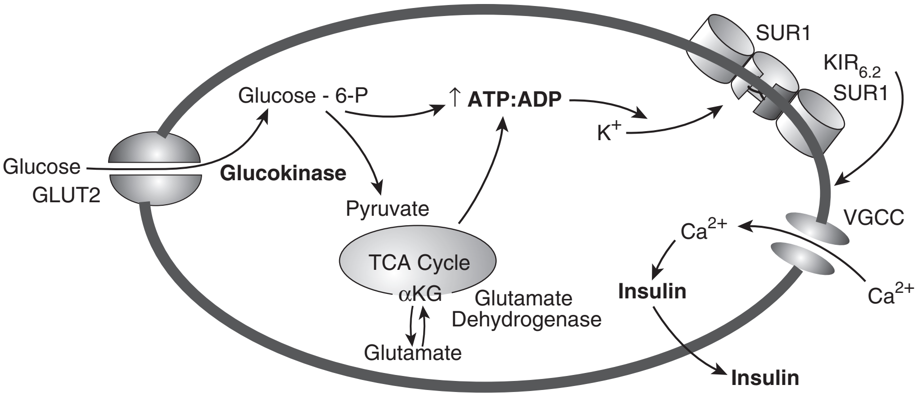

Figure 49–8. Mechanism of glucose-induced insulin secretion by the β cell of the pancreas. Glucose entry into the β cell is facilitated by a specific glucose transporter protein (GLUT2). Intracellular metabolism of glucose through glycolysis and in the tricarboxylic acid (TCA) cycle increases the intracellular concentration of adenosine triphosphate (ATP). The increase in the ratio of ATP to adenosine diphosphate (ADP) affects the ATP-sensitive potassium (K^+) channel, causing an efflux of K^+ and depolarization of the β-cell membrane that in turn activate the voltage-gated calcium (Ca^{2+}) channel (VGCC) and entry of Ca^{2+} into the cell. The increase in free intracellular Ca^{2+} initiates release of insulin. As discussed in the text, mutations of glucokinase, glutamate dehydrogenase, *SUR1*, and *KIR*$_{6.2}$ have thus far been associated with hyperinsulinemic hypoglycemia. αKG, α-ketoglutarate; Glucose-6-P, glucose-6-phosphate; KIR, inward-rectifying potassium channel; SUR, sulfonylurea receptor.

the mutation of glutamate dehydrogenase is manifested with hyperammonemia in addition to hyperinsulinemic hypoglycemia.[84]

Other genetic disorders (e.g., short-chain 3-hydroxyacyl-coenzyme A dehydrogenase) have also been reported to present with hyperinsulinemic hypoglycemia.

The definitive therapy for infants with hypoglycemia in the nesidioblastosis-adenoma spectrum is early subtotal (85%) or total (95% to 98%) pancreatectomy. Total pancreatectomy has been advocated as the procedure of choice, although some infants with recurrent hypoglycemia after subtotal pancreatectomy have been treated successfully with alloxan (mesoxalyl urea). A major advance in the preoperative diagnosis of focal and diffuse lesions was presented by deLonlay-Debeney and coworkers.[20] By using transhepatic pancreatic vein catheterization, they were able to identify the site of hypersecretion of insulin in 17 of 19 neonates with focal adenomatous lesions so that the disorder could be successfully managed by partial pancreatectomy. [^{18}F]-DOPA positron emission tomography has also been used successfully for the identification and localization of focal form of lesions.[35] Zinc protamine glucagon, as intramuscular injections or orally administered starch, has also been used postoperatively. However, in most instances, preoperative medical therapy consisting of various combinations of glucose infusion, diazoxide, glucagon, and somatostatin[43] fails to control hypoglycemia. Continuous somatostatin infusion with the addition of glucagon to correct somatostatin-induced hypoglucagonemia has been used for temporary preoperative medical control. A long-acting somatostatin analogue (octreotide) with 50 to 100 times greater potency than endogenous somatostatin has been used both preoperatively and postoperatively. Conservative (nonsurgical) management has been successful in some asymptomatic hypoglycemic infants who were diagnosed at birth. Infants with the nesidioblastosis-adenoma spectrum have a high incidence of neurologic damage, which is probably a reflection of the severity of symptomatic hypoglycemia and the delay in diagnosis. Because *SUR1* genes are also expressed in neuronal cells, it has been suggested that the neurologic deficit in these infants may be related to an *SUR1* mutation in the brain. Long-term follow-up data in infants with total pancreatectomy demonstrate variable responses—some develop no pancreatic insufficiency, whereas others develop frank diabetes as well as exocrine pancreatic insufficiency.

Beckwith-Wiedemann Syndrome

The characteristic features of Beckwith-Wiedemann syndrome include macroglossia, omphalocele, and hyperplastic visceromegaly, often also called *congenital overgrowth syndrome*. Since the original description by Beckwith and Wiedemann, a number of other clinical findings of this syndrome have been described,[71] which are listed in Box 49-4. The frequency of these clinical manifestations is variable. Macroglossia, a uniform enlargement of the tongue, is present in more than 80% of cases. Other craniofacial characteristics include midface hypoplasia, a prominent occiput, and nevus flammeus. Characteristic ear creases or pits are present in about 75% of individuals. Anterior abdominal wall defects, which are present in about 80% of cases, include omphalocele, umbilical hernia, and diastasis recti abdominis. Cardiac defects are reported in about 25% of cases; however, no specific cardiac abnormality is prominent.

Most (more than 75%) of these infants are above the 90th percentile in length and weight for gestational age and tend

BOX 49–4 Major Findings in Beckwith-Wiedemann Syndrome

CLINICAL FINDINGS

- Advanced bone age
- Ear anomalies
- Pits and/or creases
- Facial nevus flammeus
- Hemihypertrophy
- Macroglossia
- Maxillary underdevelopment
- Muscular hypertrophy
- Neonatal hypoglycemia
- Neonatal polycythemia
- Prenatal and postnatal gigantism
- Prominent occiput
- Abdominal wall defects
- Diastasis recti abdominis
- Omphalocele
- Umbilical hernia
- Cardiac defects
- Clitoromegaly
- Cryptorchidism
- Tumors (Wilms tumor)
- Visceromegaly: Kidney, liver, spleen

PATHOLOGIC FINDINGS

- Adrenal cortical cytomegaly and cysts
- Hypertrophy and hyperplasia of islets of Langerhans
- Medullary dysplasia and medullary sponge kidneys
- Nephromegaly with prominent lobulation
- Persistent nephrogenesis

to remain at the 90th percentile during early infancy and childhood. No differences between male and female infants have been reported.

Hypoglycemia is present in at least half the cases[71] and may be manifested soon after birth. Endocrine evaluation of the few reported cases has not been consistent. However, based on the clinical features of hypoglycemia with low FFAs and ketones and autopsy findings of islet cell hyperplasia, it is believed that hypoglycemia is caused by hyperinsulinism in this syndrome. Plasma GH levels have been reported to be normal, and somatomedin levels were reported to be increased in one infant. These infants may require glucose infusion at high rates in the immediate neonatal period. Spontaneous regression of hypoglycemia is suggested in most infants. Hypocalcemia has also been reported in some instances.

Patients with Beckwith-Wiedemann syndrome are also predisposed to certain malignancies (adrenal carcinoma, nephroblastoma) and appear to have an increased risk for malignancies associated with hemihypertrophy.

Chromosomal studies have been reported in several patients with Beckwith-Wiedemann syndrome. They have ranged from normal chromosomal patterns on unbanded studies to abnormal karyotypes such as duplication of 11p, balanced translocation (11p,22q), duplication of the distal two thirds of 8q, and deletion of the upper half of 12p.[71] It has been suggested that some of the symptoms of Beckwith-Wiedemann syndrome may be related to the known genes in the area of abnormalities in the chromosomes—genes for insulin and Wilms tumor as well as others—as a contiguous gene syndrome.

Fetal growth is influenced by paternally expressed, growth-promoting *IGF2* and maternally expressed, growth-suppressing *H19* genes. In addition, the cell cycle–regulating gene *CDKN1C* has been demonstrated to be involved in fetal growth. Altered imprinting of these genes on chromosome 11p15.5 has been implicated in the pathogenesis of Beckwith-Wiedemann syndrome. Genetic studies in patients with Beckwith-Wiedemann syndrome have identified three major subgroups of patients: familial, sporadic, and chromosomally abnormal. A large proportion of patients with the familial and sporadic forms of Beckwith-Wiedemann syndrome have no underlying cytogenetic abnormalities. However, 20% of the sporadic cases have been found to involve uniparental disomy for 11p15.5.[57] Altered imprinting of the candidate genes for Beckwith-Wiedemann syndrome (*IGF2* and *H19*) has also been described in the sporadic form.[57] The most frequent abnormality detected in the familial form involves mutations in the *CDKN1C* gene.

ENDOCRINE DISORDERS

Pituitary Insufficiency

Neonatal hypoglycemia associated with anterior pituitary hypofunction may represent a series of separate syndromes, with defects ranging from no structural abnormalities in the brain to septo-optic dysplasia, craniofacial defects, and anencephaly. Although this disorder is considered rare, the true incidence is unknown because it usually goes unrecognized as a result of the absence of characteristic physical findings in the newborn.

CLINICAL AND LABORATORY MANIFESTATIONS

Symptoms of hypoglycemia may begin during the first hours of postnatal life and are marked by their severity. They include sudden and profound limpness, convulsions, apnea, cardiovascular collapse, and cardiac arrest. The infants are of normal length and weight and born at or after term. Males predominate at a ratio of 2:1. The physical examination may be unrevealing; however, some male infants have a microphallus, poorly developed scrotum, small and undescended testes, or some combination of these features. Facial abnormalities consisting of a cleft lip and palate, a poorly developed nasal septum, hypotelorism or hypertelorism, abnormalities of antidiuretic hormone secretion, or widely spaced nipples have been described. Although the infants are of normal size at birth, growth restriction and delayed bone age may be found in children as young as 6 to 8 weeks of age.

Serum GH values are not measurable or in the normal adult range, in contrast to the elevated values usually found in normal newborns. The paradoxical increase in GH during glucose infusion in normal newborns does not occur when hypoglycemia is associated with pituitary deficiency. The cortisol concentration may be low (see Appendix B) at the time of symptomatic hypoglycemia. Hypothyroidism is common. A deficiency in hypothalamic hormones has been shown by a rise in thyroid-stimulating hormone (TSH), or thyrotropin, after stimulation with thyrotropin-releasing hormone (TRH) and by increased prolactin levels with a poor luteinizing hormone (LH) response after stimulation with releasing hormone. The adrenals respond to adrenocorticotropic hormone (ACTH) stimulation, but a deficiency in ACTH may be demonstrated by the use of metyrapone.

PATHOLOGY

At postmortem examination, the pituitary gland may be hypoplastic or aplastic, the thyroid and adrenal glands small, and the cellular architecture of the adrenals disorganized, with atrophy or absence of the fetal cortex. Multiple congenital anomalies of the central nervous system (CNS), including holoprosencephaly and arrhinencephalia, may be found. Radiographic studies have demonstrated the absence of the septum pellucidum and massa intermedia. Hypoplasia or aplasia of the adenohypophysis without cerebral or facial anomalies may also occur. There may be different expressions of the same syndrome, depending on the extent of pituitary hypoplasia or other CNS anomalies, or both.

PATHOGENESIS

The underlying pathogenic mechanisms remain unclear, although aplasia of the anterior pituitary was found in siblings of three patients and in two patients with familial histories of consanguinity. This finding is consistent with a possible autosomal recessive inheritance. Whether the disorder is caused by failure of the pituitary to form or by degeneration of the pituitary is unknown. It is also possible that abnormalities of the hypothalamus with a deficiency in hypophysiotropic releasing hormones is responsible for the multiple endocrinopathies observed in these infants. The pathophysiologic relationships among pituitary hypoplasia, CNS anomalies, and other pituitary hypofunctions are unknown. The exact mechanism of hypoglycemia in these disorders remains undefined.

TREATMENT

Therapy consists of replacement with synthetic GH. Cortisol is replaced cautiously, with maintenance doses of hydrocortisone for proven hypoadrenalism. Thyroxine (T_4) replacement is started once hypothyroidism is documented.

Cortisol Deficiency

Familial isolated glucocorticoid deficiency has been described in a family of five siblings; in two of the infants, glucocorticoid production was normal initially and deficient at a later age. This finding suggests that in some families there may be a degenerative process in the adrenal gland.

Maternal steroid therapy resulting in neonatal subclinical adrenal insufficiency was reported in an infant with cushingoid facies, transient hypoglycemia, and a poor response to intravenous corticotropin at 20 hours. However, maternal steroid therapy, such as that for chronic asthma, only rarely has been related to neonatal adrenal insufficiency and hypoglycemia.

ACTH unresponsiveness is a hereditary disorder in which the adrenal glands fail to produce adequate cortisol but aldosterone secretion is normal and ACTH levels are increased. There are feeding problems, a failure to thrive, and regurgitation in the neonatal period; hypoglycemia, convulsions, and shock or even death may occur in infancy or early childhood. The syndrome is characterized by hyperpigmentation, normal serum electrolyte concentrations, and an unusually severe, untoward response to illness or stress. There is often a history of affected siblings, and an autosomal recessive mode of inheritance has been suggested. The pathogenesis of this syndrome is poorly understood. The differentiation of the zones of the adrenal cortex in utero requires ACTH except for the zona glomerulosa, which is primarily under renin-angiotensin control. The histologic examination of the adrenal glands of patients with ACTH unresponsiveness has revealed an intact zona glomerulosa and atrophy of the zona fasciculata and zona reticularis. An abnormality at the site (or sites) of ACTH action or cortisol biosynthesis has been postulated.

Adrenal hemorrhage is discussed in Chapter 28.

Congenital adrenal hyperplasia (see Part 4 of this chapter) may be diagnosed in the neonatal period because of the presence of hypoglycemia. The diagnosis is difficult in male infants when there are no positive physical findings. Family history may reveal previously unexplained neonatal deaths.

Congenital Glucagon Deficiency

Two male infants have been reported with glucagon deficiency; the disorder became evident on the second to third day of postnatal life, with repeated convulsive movements, hypotonia, weak crying, and poor sucking. In both infants, the diagnosis was based on a low basal glucagon concentration and a strong hyperglycemic response to glucagon. In one of the infants, the response to glucagon was lacking, and in the other, there was a lack of response to hypoglycemia and alanine infusion. The parents of this second infant were closely related and had partly deficient glucagon secretion; two siblings of this infant died before 5 months of age with probable hypoglycemia. Therefore, an autosomal recessive inherited disorder is suggested.

Epinephrine Deficiency

This disorder is extremely rare. In infants who are SGA, it has been described secondary to adrenal hemorrhage. The diagnosis may be suspected in an infant who has been acutely ill (i.e., hypotensive) during the perinatal period and can be confirmed by measuring plasma or urine catecholamine levels. Some of these infants may develop adrenal calcification, which may be identified on follow-up.

INBORN ERRORS OF CARBOHYDRATE METABOLISM

Galactosemia

See Chapter 50.

Hepatic Glycogen Storage Disease

See Chapter 50.

Fructose Intolerance

See Chapter 50.

Fructose is the main sweetening agent in nature, occurring mostly in fruits, vegetables, and honey, and is often added as a sweetener to foods and beverages in the form of disaccharide sucrose. In humans, the liver is the main site of fructose metabolism, with significantly less important sites being the kidney, gut, and other tissues. Absorption of fructose in the gut does not appear to require an active transport system. Fructose is rapidly metabolized, disappearing from the circulation almost twice as fast as glucose. Fructose is metabolized by specific enzymes that convert it into intermediates of the glycolytic-gluconeogenetic pathway. The key enzymes associated with disorders of fructose metabolism have been identified. Fructose is first phosphorylated to fructose-1-phosphate by fructokinase. Fructose-1-phosphate is split into dihydroxyacetone phosphate and glyceraldehyde by the action of aldolase. Glyceraldehyde is converted to glyceraldehyde-3-phosphate by the action of triokinase. Dihydroxyacetone phosphate and glyceraldehyde-3-phosphate are the intermediates in the glycolytic-gluconeogenetic pathway. Additionally, fructose-1,6-bisphosphatase is a key gluconeogenetic enzyme that catalyzes the conversion of fructose-1,6-biphosphate into fructose-6-phosphate.

It has been suggested that intravenous fructose be used for the treatment of hypoglycemia in both adults and newborn infants because of the lack of hyperglycemia associated with its administration and therefore the lack of reactive hypoglycemia. However, caution should be exercised because the metabolism of fructose in the liver causes increased lactate formation, high-energy phosphate depletion, increased uric acid formation, and inhibition of protein synthesis. The use of fructose in the treatment of hypoglycemia in the neonate, or for that matter in an adult, is not recommended.

Essential fructosemia is a rare and harmless disorder characterized by the appearance of fructose in the urine. This disorder is the consequence of a deficiency of fructokinase, which results in an inability to metabolize fructose.

Hereditary fructose intolerance, or aldolase-B deficiency, results in an inability to split fructose-1-phosphate into triose phosphates. The enzymatic activity contributing to the formation of fructose-1,6-biphosphate from triose phosphates is also reduced.

Affected babies can breastfeed without any ill effects, and symptoms do not appear until fructose or sucrose is introduced in the diet (e.g., cow milk formulas with added sucrose) or at weaning, when fruits and vegetables are introduced. Clinical manifestations include hypoglycemia after the ingestion of meals containing fructose, lethargy, nausea, vomiting, pallor, sweating, and evidence of liver dysfunction such as jaundice, hepatomegaly, a bleeding tendency, and proximal renal tubular dysfunction. The symptoms are reported to be much worse in younger infants than older children. Genetically, it is a heterogeneous disorder with wide variation in manifestations. Treatment consists of the complete elimination of all sources of fructose from the diet, including foods and medications.

Fructose-1,6-bisphosphatase deficiency should actually be called a defect in gluconeogenesis rather than a disorder of fructose metabolism because these infants can tolerate fructose in their diets. Fructose-1,6-bisphosphatase is the key regulatory enzyme in the gluconeogenetic pathway involved in the formation of fructose-6-phosphate, the immediate precursor of glucose-6-phosphate, and finally glucose. A deficiency of this enzyme results in an inability to make glucose from all gluconeogenetic precursors (i.e., pyruvate, amino acids, and glycerol) and therefore results in hypoglycemia when gluconeogenesis is the major source of glucose, such as that occurring during fasting. These infants can present in the neonatal period with hypoglycemia and severe metabolic acidosis. The clinical manifestations are related to hypoglycemia and acidosis and include lethargy, tachycardia, apnea, hypotonia, and tachypnea. Laboratory findings include hypoglycemia during fasting (i.e., when glycogen stores are low), high plasma lactate, alanine, and ketones with metabolic acidosis. The defect is inherited as an autosomal recessive disorder and is seen more often in girls than boys.

Treatment is aimed at the maintenance of plasma glucose through frequent feedings and avoidance of prolonged periods of fasting. A therapeutic regimen consisting of the continuous nighttime administration of glucose by the nasogastric route, as in glycogen storage disease, should be successful.

Hereditary fructose intolerance may manifest in the neonatal period if the susceptible infant is fed a sucrose-containing formula or given table sugar, fruits, or fruit juices. Symptoms include vomiting, failure to thrive, excessive sweating, and unconsciousness or convulsions. Hypoglycemia is frequently seen, as are fructosemia and fructosuria, after the ingestion of fructose.

NEUROHYPOGLYCEMIA (HYPOGLYCORRHACHIA) CAUSED BY DEFECTIVE GLUCOSE TRANSPORT

Glucose is transported from the blood to the brain and cerebrospinal fluid by a carrier-facilitated diffusion process in which the combination of glucose and a plasma membrane carrier protein facilitates its rapid transfer across the membrane and into the cell. At least five such membrane carrier proteins, designated glucose transporters, have been identified in various tissues. The transport protein (designated GLUT1) that facilitates glucose transport across brain microvessels has the same properties as the one that transports glucose into red blood cells, which has allowed investigators to infer glucose transport into the brain by studying the GLUT1 protein in red blood cells.[28] DeVivo and colleagues[22] described two children who presented with seizures and developmental delay. In both infants, the seizures appeared at about 2 months of age. Repeated laboratory studies showed low glucose and lactate in the cerebrospinal fluid in the presence of normal blood glucose levels. A detailed evaluation revealed no other abnormalities, such as meningitis or intracranial hemorrhage, as a possible cause. The glucose levels in the cerebrospinal fluid ranged between 18 and 35 mg/dL when the blood glucose concentration ranged between 86 and 120 mg/dL. The investigators suspected a defect in glucose transport from the blood to the brain and demonstrated a decreased density of GLUT1 protein in the patients' red blood cells. In addition, immunobinding studies suggested subtle biochemical alterations in the GLUT1 protein of one of the patients. Since this original description, 16 other infants have been identified.[50] Seidner and coworkers[80] identified two distinct classes of mutation as the molecular basis for the functional defect of glucose transport: the hemizygosity of GLUT1 and a nonsense mutation resulting in truncation of the GLUT1 protein. These patients are of clinical importance and point to the need to measure cerebrospinal fluid glucose and lactate levels in those with seizure disorders. Because the brain can use ketones for oxidative metabolism, and the transport of ketones across the blood-brain barrier is not mediated by GLUT1 proteins, attempts have been made to treat this disorder with a ketogenic diet.[50]

Management of Neonatal Hypoglycemia

The clinical management of neonatal hypoglycemia should include (1) anticipation of the group at high risk, (2) correction of hypoglycemia, and (3) investigation and treatment of the cause of hypoglycemia. Often, it is not possible to identify the cause of hypoglycemia, and the treatment remains limited to correction of the low blood glucose concentrations.

Because hypoglycemia is asymptomatic in a large number of neonates, it has become an accepted practice to monitor blood glucose in newborn infants who are at risk for hypoglycemia. This monitoring practice includes (1) infants who are LGA (>90th percentile) or SGA (<10th percentile), (2) macrosomic infants with birthweight greater than 4000 g, (3) IDMs, and (4) acutely ill infants in the intensive care unit with septicemia, asphyxia, respiratory distress, prematurity, and other illnesses. In the last category, the symptoms of hypoglycemia are overshadowed by those of the acute clinical problems. In addition, blood glucose should be routinely monitored in small preterm infants who are receiving total parenteral nutrition even if they appear clinically well and stable. Glucose monitoring in healthy infants born at term gestation is not recommended.

In asymptomatic infants at risk for hypoglycemia, blood glucose should be determined during the first few hours after birth until feeding is established; thereafter, blood glucose should be monitored randomly before feeding. Although the routine for monitoring glucose immediately after birth varies from institution to institution, a rational approach can be outlined based on physiologic changes in plasma glucose in healthy, full-term infants. As discussed previously, the blood glucose levels in all neonates decline, reaching a nadir between 30 and 60 minutes after birth, and then rise to reach a stable plateau between 90 and 180 minutes after birth. Therefore, a blood glucose measurement obtained during these time periods necessitates a follow-up measurement to document whether the glucose level is decreasing or returning to normal, stable levels. If two consecutive blood glucose concentrations obtained 15 minutes apart 2 hours after birth are less than 45 mg/dL, the infant should be closely monitored; if the values are less than 36 mg/dL, the infant is considered to have hypoglycemia, and intervention strategies are initiated. It should be emphasized that these thresholds are arbitrary values derived from data from otherwise normal infants.[16] There are no clearly defined values for hypoglycemia during the initial period of transition (birth to 2 hours). Various cutoff values for the definition of hypoglycemia have been proposed, ranging from 30 to 45 mg/dL. Furthermore, all bedside measurements of blood glucose concentration obtained by enzyme-strip methods should be considered only as screening results and confirmed by appropriate laboratory measurements. The enzyme-strip methods are not particularly accurate in the low blood glucose range, which is commonly observed in the newborn nursery or in the neonatal intensive care unit.

The treatment strategies for hypoglycemia depend on whether it is transient or persistent and asymptomatic or symptomatic. All infants with symptomatic hypoglycemia, regardless of cause or age, should be treated with parenteral glucose infusion. The greatest variance in the management of hypoglycemia is seen in the asymptomatic infant diagnosed soon after birth (i.e., during the first 2 hours). This type of hypoglycemia is often transient and recovers spontaneously. However, in clinical practice, it is often treated with early feedings. Controlled studies examining the benefits or impact of this early feeding on recovery from hypoglycemia have not been performed. It has been suggested that as many as 10% of the healthy infants who are the appropriate size for gestational age develop transient asymptomatic hypoglycemia, which in most cases is managed by the initiation of early, normal feeding. Symptomatic infants should be treated only by parenteral glucose and not by oral feeding.

Persistent hypoglycemia is ascribed to the group of infants who continue to require high rates of intravenous glucose administration over several days to maintain normal glucose concentrations. Such persistent hypoglycemia is often related to hyperinsulinemia and may require pharmacologic interventions, as discussed later.

INTRAVENOUS GLUCOSE INFUSIONS

Parenteral glucose is administered at a rate of 6 to 8 mg/kg per minute, corresponding to 3.6 to 4.8 mL/kg per hour of a 10% dextrose solution. This infusion rate is based on the rate of endogenous glucose production in healthy newborn infants. The aim of therapy is to maintain the plasma glucose concentration at a level higher than 45 mg/dL. Plasma glucose levels are monitored frequently (every 1 to 2 hours) until they are stable and then less frequently (every 4 to 6 hours). If the glucose concentrations do not increase to normal levels, the rate of infusion should be increased by 1 to 2 mg/kg per minute every 3 to 4 hours while monitoring the glucose response. Infants with severe hypoglycemia and those who require high rates of glucose infusion may benefit from having a securely placed intravenous line such as a central line or an umbilical vein catheter placed above the liver. Caution should be exercised in administering glucose through the umbilical artery catheter—if the catheter is placed near the celiac axis, the administered glucose may preferentially perfuse the pancreas and thus inadvertently cause an increased insulin response and hypoglycemia.

In symptomatic infants and when there is a need to rapidly increase the plasma glucose level, a minibolus of 200 mg/kg (2 mL/kg of 10% dextrose in water) may be given over 1 minute (Fig. 49-9).[53] However, any glucose bolus must be administered through a secure intravenous line so that a constant-rate infusion of glucose may follow. In fact, in most instances, an attempt should be made to first start the intravenous infusion and then give the intravenous bolus infusion for the immediate correction of low plasma glucose.

Feedings may be initiated when the blood glucose level has been stable for a reasonable time period (3 to 6 hours). Some investigators suggest that the feeding should be given only as a constant-rate nasogastric drip to avoid hormonal excursion. Although such a concept is theoretically logical, there are no observed data to support it. Nevertheless, infants

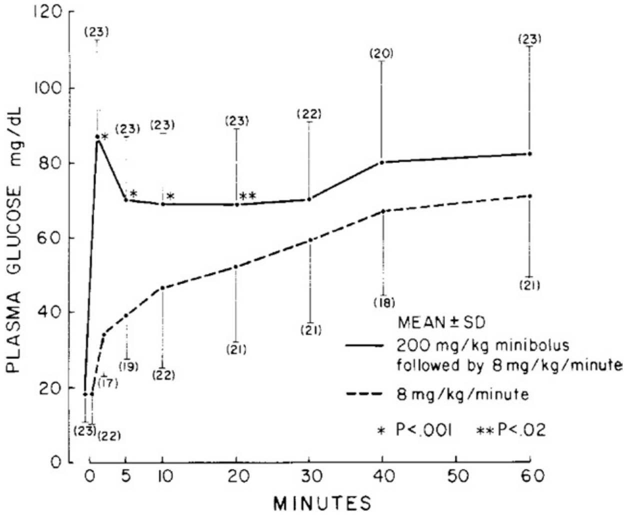

Figure 49–9. A comparison of the results of two treatment regimens for hypoglycemic neonates. A group of 23 hypoglycemic infants were treated with 200 mg/kg of glucose given in a minibolus, followed by a constant glucose infusion of 8 mg/kg per minute; a separate group of 22 hypoglycemic neonates received only the constant glucose infusion (8 mg/kg per minute). *(From Lilien LD, et al: Treatment of neonatal hypoglycemia with minibolus and intravenous glucose infusion,* J Pediatr *97:25, 1980.)*

with persistent hypoglycemia, those who are symptomatic, and those who require high rates of glucose infusion are best managed exclusively by parenteral glucose infusion and without oral feeding until their plasma glucose concentrations have stabilized.

The infant can be weaned from parenteral glucose infusion after the plasma glucose concentration has been stable at about 50 to 70 mg/dL for 2 to 3 days. Glucose infusions can be decreased every 3 to 4 hours as long as the blood glucose concentration remains stable. The concentration of glucose in the blood should be monitored with each change in the rate of intravenous glucose infusion. Such a regimen leads to the successful discontinuation of glucose infusion in almost all infants.

If the infant continues to require high rates of intravenous glucose infusion, a diagnosis of hyperinsulinism should be considered and pharmacologic intervention planned. The following pharmacologic agents are used for the treatment of hypoglycemia.

GLUCAGON

Except for the rare patient with a deficiency of this peptide, glucagon is seldom used to increase the plasma glucose concentration at an acute rate. It has been used most often for the diagnosis of hepatic glycogen storage disease, a condition in which no or a minimum increase in plasma glucose concentration is seen in response to glucagon. This single-chain peptide is secreted primarily by the alpha cells of the pancreas. Glucagon increases the blood glucose concentration by increasing both glycogenolysis and gluconeogenesis. An acute administration of glucagon, for example, 150 to 300 μg/kg given intravenously or intramuscularly, results in an increase in blood glucose by more than 50% in most normal infants. However, the effect is transient, and the administration of glucagon should be followed by intravenous glucose infusion to maintain blood glucose levels. Long-acting glucagon preparations (zinc protamine glucagon) have been used for glucagon deficiency states or in combination with somatostatin for the treatment of nesidioblastosis.

EPINEPHRINE

Although the use of epinephrine to increase blood glucose concentration was recommended in the past, it is rarely used because of its other systemic effects. Its absolute indication would be in the rare infant with epinephrine deficiency. Epinephrine acts by increasing hepatic glucose output through glycogenolysis and decreasing peripheral glucose uptake, mostly in muscle. In addition, epinephrine suppresses insulin secretion and increases lipolysis so that the blood levels of FFAs and glycerol can increase after epinephrine administration.

DIAZOXIDE

Diazoxide is a benzothiadiazine derivative that is structurally closely related to the thiazide diuretics yet has none of the diuretic effects of thiazides. Initially introduced as an effective antihypertensive agent, it is more often used for the treatment of hypoglycemia due to hyperinsulinism. Diazoxide has been shown to cause decreased insulin secretion, both in vivo and in vitro, and catecholamine release. The combined effect of decreased insulin secretion and increased epinephrine release results in an increase in hepatic glucose production and a decrease in the peripheral utilization of glucose. In addition, increased lipolysis results in an increase in plasma levels of FFAs and glycerol. The drug is eliminated for the most part by glomerular filtration, and hepatic transformation is quantitatively less important than renal excretion. Ninety percent of circulating diazoxide is bound to albumin. The estimated half-life in adults is 20 to 30 hours. Serum levels have not been related to the hypotensive effects of the drug. The usual effective dose for the management of hyperinsulinemic hypoglycemia in the newborn is 5 to 20 mg/kg per day, administered orally in an 8- to 12-hour dose. The drug has been used effectively for long periods without any significant side effects, which include sodium and water retention, expansion of plasma volume and edema, hypertrichosis lanuginosa, thrombocytopenia, anorexia, vomiting, and sometimes extrapyramidal symptoms. However, these side effects are relatively uncommon except for hypertrichosis lanuginosa and fluid retention.

SOMATOSTATIN

Somatostatin, a tetradecapeptide (a peptide containing 14 amino acids), was originally isolated from the rat hypothalamus and shown to inhibit the release of GH. Subsequent work has shown the presence of a number of somatostatin-related peptides distributed widely in the body, including the hypothalamus, nervous tissue, gut, and endocrine and exocrine glands (including the pancreas). When administered exogenously, somatostatin inhibits the secretion of glucagon, insulin, GH, and thyrotropin. In addition, it has a number of physiologic effects on the gut, in particular the inhibition of exocrine secretion, changes in gut motility, and reduction of splanchnic blood flow. It has been used extensively in physiologic studies to examine the role of insulin and glucagon in the regulation of glucose metabolism. Infused into a normal human, it suppresses the secretion of both insulin and glucagon, causing a fall in plasma glucose due to the suppression of glucagon secretion, followed by a transient increase. The ability of somatostatin to suppress hormone secretion has been used in the short-term treatment of a variety of hyperfunctioning endocrine tumors, such as insulinomas, glucagonomas, gastrinomas, and GH-secreting adenomas. In the neonate, somatostatin has been used to treat nesidioblastosis (hyperinsulinemic hypoglycemia) as an emergency measure, with variable success, and evaluate the usefulness of pancreatectomy.

The clinical use of somatostatin has been hampered by its short half-life of less than 3 minutes and a short duration of action. Therefore, attempts have been made to synthesize long-acting analogues. Octreotide, the first somatostatin analogue introduced for clinical use, is significantly more potent in its hormone-suppressive effect. After subcutaneous injection, its elimination half-life is reported to be 2 hours. It has been used with some success in the management of islet cell tumors, insulinomas, and nesidioblastosis. However, the response has been variable because octreotide receptors are not consistently expressed in all of these conditions.

GROWTH HORMONE

Treatment with GH should be used only when its deficiency or hypopituitarism has been confirmed.

GLUCOCORTICOIDS

In the past, steroids were widely used in hypoglycemic infants. With the advent of diazoxide and octreotide, together with recognition of the side-effect profile of steroids, such therapy is used less frequently.

PANCREATECTOMY

Subtotal (85% to 90%) or total removal of the pancreas is recommended in cases of persistent hypoglycemia due to pancreatic nesidioblastosis when hyperinsulinemia has been demonstrated and aggressive medical therapy with glucose and diazoxide has been unsuccessful. Total pancreatectomy is preferred because of the high incidence of hypoglycemia at follow-up, which may require treatment with diazoxide and somatostatin. Most of these infants develop insulin-dependent diabetes during puberty.

Prognosis of Neonatal Hypoglycemia

The long-term impact of hypoglycemia in the newborn has remained a subject of controversy and debate. The controversy stems in part from the common belief (not based on scientific data) that the brain of the newborn infant can tolerate a significantly lower blood glucose concentration than that of the adult. This belief was supported by the lower mean blood glucose concentrations observed in asymptomatic and otherwise healthy full-term neonates and the even lower mean glucose concentrations observed in preterm neonates.

The brain is an obligatory consumer of glucose which is transported to the brain by specific glucose transporter proteins that are not under the influence of hormonal regulation by insulin. It has been speculated that the availability and utilization of alternative energy sources (i.e., ketones and lactate) may explain the apparent tolerance of lower plasma glucose concentrations by the neonate. Although the fetal and neonatal brain has been shown to have the ability to use ketones as alternative fuels, clinical data regarding the quantitative contribution of ketones to neonatal brain metabolism have not been secured.

Neuropathologic studies in animals have demonstrated the injurious effect of hypoglycemia in both adults and newborns. It has been shown that insulin-induced hypoglycemia in newborn rat pups results in the generalized diminution of brain weight, cellularity, and protein content. Studies in newborn infants who had died after prolonged hypoglycemia showed acute degeneration of neurones and glial cells and fragmentation of nuclei throughout the CNS.[2] These findings are not specific to hypoglycemia and are also seen in severe hypoxia. Therefore, in the limited number of human studies, it has been difficult to correlate clinical hypoglycemia with the neuropathologic findings. The magnetic resonance neuroimaging of infants who had hypoglycemia in the newborn period showed dilation of the lateral ventricles, cerebral edema, and a loss of gray and white matter differentiation. A consistent involvement of the occipital lobes or parieto-occipital cortex was reported in 825 of the infants.[1] Mechanisms of the vulnerability of the occipital region to hypoglycemic injury are unclear but are similar to those reported in animal studies. It is important to underscore that all the infants who had neuroimaging studies had symptomatic hypoglycemia and that no clinical correlate of these occipital cortex injuries have been reported thus far.[63,88] Studies in rhesus monkeys after 10 hours of hypoglycemia in the newborn period demonstrated motivational and adaptability problems at 8 months of age. However, if special attention was devoted to these animals, there were no cognitive or behavioral deficits.[79]

The associated clinical problems of hypoxemia, birth trauma, respiratory distress, prematurity, and other conditions make it difficult to assess the long-term effects of hypoglycemia in the human neonate. The problem has been confounded by incomplete follow-up, the lack of adequate control groups, and the lack of a uniform definition of hypoglycemia. A few broad conclusions can be drawn. Transient asymptomatic hypoglycemia in an otherwise healthy neonate has been associated with a good prognosis. Several studies of small groups of subjects have suggested that symptomatic hypoglycemia in the infant results in long-term neurologic damage. However, these data should be interpreted with caution because of a number of confounding variables. Griffiths and colleagues[33] retrospectively compared 41 hypoglycemic neonates with 41 controls and found evidence of cerebral damage in 6 (14.6%) members of the hypoglycemia group. However, 5 (12.2%) of the controls also had evidence of cerebral damage. There were no differences in IQ, locomotor scores, behavioral disorders, or history of convulsion in infancy and childhood. None of the 12 infants with asymptomatic hypoglycemia showed cerebral sequelae. This study was performed in infants who were admitted to the intensive care unit for other reasons or who had birthweight of less than 2000 g, and follow-up data were obtained in only 41 of the 115 hypoglycemic infants.

Koivisto and coworkers[51] monitored 151 infants treated for neonatal hypoglycemia for 1 to 4 years and compared them with 56 control infants without hypoglycemia or other demonstrable diseases. They reported that 4 of the 8 (50%) children with convulsions had evidence of cerebral damage, including infantile spasms, severe hypotonia, and cataracts, and one was classified as doubtful. Of the 77 children with symptomatic hypoglycemia but no convulsions, 9 (11.7%) exhibited pathologic conditions. In the group of 66 children with asymptomatic hypoglycemia, 4 (6.1%) were classified as pathologic on the basis of ophthalmologic findings only. Among controls, 3 (5.4%) of 56 exhibited pathologic conditions. There was a statistically significant impact of symptomatic hypoglycemia on long-term neurologic outcome compared with controls.

Pildes and associates[73] investigated the effects of treated hypoglycemia in 39 infants monitored prospectively for 5 to 7 years compared with 41 nonhypoglycemic controls. They observed that mean head circumference remained smaller in the hypoglycemia group than it did in controls. The incidence of neurologic abnormality at ages 2, 3, and 6 years was higher (35.7% [5 of 14]) in hypoglycemic children, and the incidence of IQ scores below 86 at age 5 to 7 years was higher (52% [13 of 25] of the hypoglycemic children versus 22% [6 of 27] of the controls). This study suffered from incomplete follow-up and lack of control for potential confounding variables. Finally, although the number of infants with low IQ scores was statistically significantly higher in the hypoglycemia group, the mean IQ scores were not different between the hypoglycemia group and controls. In summary, although they are suggestive of neurologic sequelae, the data on the long-term neurologic consequences of symptomatic hypoglycemia remain for the most part inconclusive because of the number of problems identified with each study.

Evaluation of physical growth and psychomotor development of preterm (≤34 weeks of gestation) and SGA (<10th percentile) neonates who had recurrent episodes of hypoglycemia demonstrated neurodevelopmental and physical growth deficits until 5 years of age.

Until recently, brain injury patterns identified on early MRI scans and their relationships to the nature of the hypoglycemic insult and neurodevelopmental outcomes have been poorly defined. Burns[11a] studied 35 term infants with early brain MRI scans after symptomatic neonatal hypoglycemia (median glucose level: 1 mmol/L) without evidence of hypoxic-ischemic encephalopathy. They reported that white matter abnormalities occurred in 94% of infants with hypoglycemia, being severe in 43%, with a predominantly posterior pattern in 29% of cases. Cortical abnormalities occurred in 51% of infants; 30% had white matter hemorrhage, 40% basal ganglia/thalamic lesions, and 11% an abnormal posterior limb of the internal capsule. Three infants had middle cerebral artery territory infarctions. Twenty-three infants (65%) demonstrated impairments at 18 months, which were related to the severity of white matter injury and involvement of the posterior limb of the internal capsule. They concluded that the patterns of injury associated with symptomatic neonatal hypoglycemia were more varied than described previously. White matter injury was not confined to the posterior regions; hemorrhage, middle cerebral artery infarction, and basal ganglia/thalamic abnormalities were seen, and cortical involvement was common. Early MRI findings were more instructive than the severity or duration of hypoglycemia for predicting neurodevelopmental outcomes.

Only one study has examined the effects of hypoglycemia in the preterm neonate. Lucas and colleagues[55] examined the neurodevelopmental outcome of 661 preterm infants weighing less than 1850 g at birth in a multicenter, randomized, controlled trial of feeding. Moderate hypoglycemia (a plasma glucose concentration < 46.8 mg/dL) occurred in 433 infants and was found in 104 infants on 3 to 30 separate days. The number of days on which moderate hypoglycemia occurred was strongly related to reduced mental and motor developmental scores at a corrected age of 18 months, even after statistical adjustments for a wide range of factors known to influence development. When hypoglycemia was recorded on 5 or more separate days, the incidence of neurodevelopmental impairment was 42% (13 of 31). This study was significant because it showed that even moderate degrees of hypoglycemia (i.e., about 47 mg/dL), when frequently observed, could be correlated with abnormal neurodevelopmental outcome. A longer follow-up showed only a decrease in arithmetic and motor scores at 7½ to 8 years of age, suggesting that either the earlier observations were transient or any improvement over time was the result of adaptation.[56]

HYPERGLYCEMIA

A high blood glucose concentration is less frequently observed in newborn infants than hypoglycemia. This partially results from the ability of normal infants, both preterm and full-term, to adapt to exogenous glucose administration by (1) decreasing or suppressing endogenous glucose production and (2) increasing glucose uptake in the periphery. The net effect of such an adaptive response is the maintenance of normal blood glucose concentrations, even during high rates of glucose infusion. The definition of hyperglycemia in the newborn remains unclear. Obviously, hyperglycemia should be defined in the context of its clinical implications. Similar to other situations in older infants and adults, hyperglycemia increases blood osmolarity and may cause electrolyte disturbances, osmotic diuresis, and the associated loss of electrolytes in the urine. Because renal function in the neonate is significantly different from that in adults, all of the effects of hyperglycemia may not be seen. Specifically, the plasma glucose level at which renal glycosuria may occur is highly variable, depending on the maturity of renal function, so that renal glycosuria may be seen in extremely immature infants at plasma glucose levels that would be considered within the normal range. In general, most clinicians consider a plasma glucose range of higher than 180 to 200 mg/dL to represent hyperglycemia. Whether such hyperglycemia requires treatment depends on the associated abnormalities. Studies have demonstrated that even in the presence of significant hyperglycemia (a blood glucose concentration of 197 ± 15 mg/dL, mean ± SEM), the amount of glucose excreted or lost in the urine was less than 1% of the infused glucose. In addition, there was no significant diuresis, suggesting that such hyperglycemia (and minimum glycosuria) does not require the adjustment of intravenous fluids or insulin therapy. It should be emphasized that a change in blood glucose concentration from 90 mg/dL to 180 mg/dL results in a change in blood osmolarity of 5 mOsm/L, which is relatively small compared with the normal range of plasma osmolarity (280 to 300 mOsm/L). The clinical circumstances in which hyperglycemia is observed in the newborn are described here.

Hyperglycemia in the infant with low birthweight is probably the most commonly observed perturbation of glucose metabolism in neonatal intensive care units. In the past, it was often attributed to the "immaturity" of glucose homeostasis in the infant with low birthweight or to the inability of the neonate to tolerate exogenous glucose infusion. However, studies have demonstrated that glucose metabolism, even in an infant with extremely low birthweight, is comparable to that in the full-term infant. These studies showed that (1) infants with low birthweight produce glucose at rates similar to those in full-term infants; (2) hepatic glucose production is regulated both by glucose and insulin and is suppressed in response to exogenous glucose infusion, hyperglycemia, or increased insulin levels; (3) hepatic glucose production is completely suppressed when glucose and amino acids are infused simultaneously, as in parenteral nutrition; (4) intravenous lipids do not cause any change in glucose production; and (5) peripheral glucose uptake increases normally in response to an increase in circulating insulin levels. The reasons for the observed hyperglycemia in the infant with low birthweight appear to involve stress related to the clinical problems. That hyperglycemia is not related to low circulating insulin levels was demonstrated by Lilien and associates,[52] showing that circulating insulin levels in hyperglycemic infants were appropriately increased and that there was a good linear correlation between plasma glucose and insulin levels in both normoglycemic and hyperglycemic infants.

In conclusion, hyperglycemia in the infant with low birthweight is most likely related to the secretion of glucose counter-regulatory hormones as a result of stress or to the release of cytokines in infected infants. In fact, the levels of circulating catecholamines were noted to be high in infants with low birthweight and were attributed to clinical manipulations such as ventilatory support. Therefore, a high glucose concentration in an infant with low birthweight should be considered an indicator of clinical problems not primarily related to glucose metabolism. In addition to having their blood glucose concentrations managed, these infants must be evaluated for the possible cause of hyperglycemia, which in most could be systemic septicemia.

DIABETES MELLITUS IN THE NEWBORN

Neonatal diabetes mellitus, a relatively rare condition, is often manifested as hyperglycemia, glycosuria, dehydration, weight loss, and the presence or absence of ketonemia, ketonuria, or metabolic acidosis. Most of these infants are born SGA (Fig. 49-10). The time of presentation for the infants reported in the literature has been between the second day of birth and 6 weeks of age. Plasma insulin levels during the basal state and in response to a glucose load have been reported to be low. Previously, neonatal diabetes was only a rare case report in the literature; however, clinical and genetic studies have made major contributions toward our understanding of this disorder. Based on studies of large groups of reported infants, two clinical phenotypes can be recognized—transient diabetes and permanent diabetes.

Most patients with transient neonatal diabetes have intrauterine growth restriction, underscoring the important role of insulin in fetal growth. In a large French cohort of 29 infants reported by Metz and coworkers,[60] gender distribution was similar, and intrauterine growth restriction was present in 74% of the patients with the disorder. The median age at diagnosis was 6 days (range, 1 to 81 days). Birth defects were reported in 2 patients, one with macroglossia and the other with a congenital heart defect. Mean insulin and C peptide levels were low at the time of diagnosis.

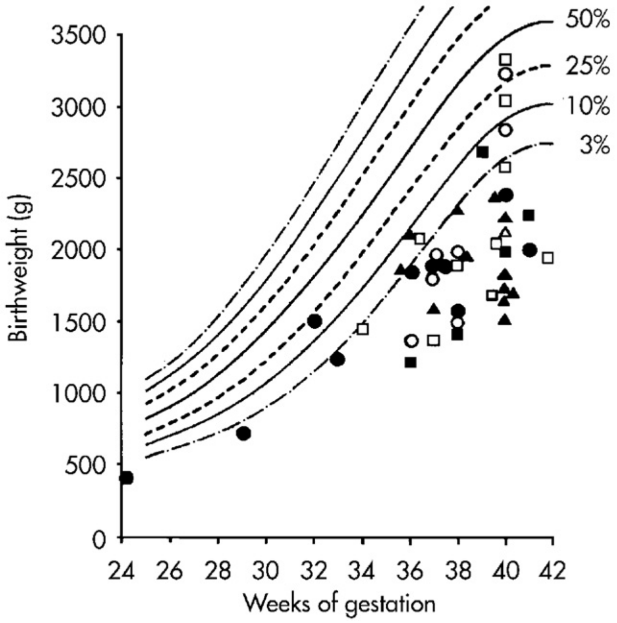

Figure 49–10. Birthweight of 45 infants with neonatal diabetes mellitus. *Closed symbols* denote girls; *open symbols* denote boys; circles, transient diabetes; triangles, transient diabetes with later recurrence; squares, permanent diabetes. *(From Von Mühlendahl KE, et al: Long-term course of neonatal diabetes,* N Engl J Med *333:704, 1995.)*

Transient neonatal diabetes gets its name from the observation that remission occurs after a variable period, and the infants do not require insulin therapy. However, diabetes may manifest later, particularly around puberty. Three genetic anomalies on chromosome 6 have been identified to be associated with the condition. They are paternal uniparental isodisomy of chromosome 6, unbalanced paternal duplications of 6q24, and methylation defects at 6q24, all implying a disorder of imprinting whereby the expression of a gene or genes is affected by parental origin. These anomalies were reported in 11 of 19 patients examined by Metz and colleagues.[60] Patients with anomalies of chromosome 6 could be offered genetic counseling. With uniparental disomy, the risk for recurrence in a sibling or child of the index patient is small, whereas the risk for transmitting the disease to the children of a man with 6q trisomy would be high.

In contrast to the so-called transient diabetes, infants with permanent neonatal diabetes present a little later, usually within the first 3 months, and require insulin treatment for life. Some of these patients have been successfully switched to oral sulfonylureas.[91] Mutations in genes encoding glucokinase account for a minority of patients. Another rare form of autosomal recessive diabetes has been mapped to chromosome 10p12.1-p13. Gloyn and associates[32] have identified six novel heterozygous missense mutations in 10 of the 29 patients with permanent diabetes. Four of these 10 patients also had severe developmental delay and muscle weakness. The authors hypothesized that an activating mutation in the gene encoding the inward-rectifying potassium channel $Kir_{6.2}$, a subunit of the K_{ATP} channel, causes monogenic diabetes because the inactivating mutation in this gene leads to uncontrolled insulin secretion and hyperinsulinemic hypoglycemia (see Fig.49-8). The authors confirmed this hypothesis by expressing the mutation in *Xenopus laevis* oocytes.[69] Since K_{ATP} channels and their $Kir_{6.2}$ pore-forming subunits are expressed in the skeletal muscle and neurons throughout the brain, it was speculated that the severe developmental delay observed in some of the patients may be related to the altered activity of these channels in the brain and skeletal muscle.

With the development of sophisticated molecular techniques, it is likely that additional mutations or defects in β-cell function and insulin synthesis and secretion will be identified as the causes of diabetes mellitus in the neonate.

Treatment includes correction of fluid-electrolyte disturbances and hyperglycemia. These infants are often extremely sensitive to insulin and respond well to a daily insulin dose of 3 to 4 U/kg of body weight. Insulin dosage must be adjusted based on plasma glucose concentration, glycosuria, or both. Because of the risk for hypoglycemia, careful and frequent monitoring of plasma glucose levels should be performed.

Diabetes mellitus due to pancreatic lesions is extremely rare and is usually manifested soon after birth. The metabolic abnormalities are the result of either the absence of a pancreas (or pancreatic hypoplasia) or the congenital absence of insulin-secreting B cells. Both lesions result in a lack of insulin secretion. Because insulin is a primary growth-promoting hormone in utero, these infants are severely growth restricted at birth. They rapidly become hyperglycemic soon after birth, often to extremely high levels, and require immediate insulin therapy. There may be other associated congenital abnormalities, such as congenital heart defects. In infants with pancreatic hypoplasia, the insufficiency of the exocrine pancreas has also been reported. Very few infants have been reported to survive, primarily because of associated lethal congenital anomalies.

INSULIN THERAPY IN THE BABY WITH LOW BIRTHWEIGHT

Intravenous insulin in infants with low birthweight has been used by several investigators to (1) treat hyperglycemia and (2) enhance the delivery and assimilation of nutrients and consequently accelerate growth. The rationale for such an approach is based on the observation that hyperglycemia and the inability to use glucose and other nutrients may be related to resistance to insulin action in those infants, resulting from either so-called immaturity or a heightened counter-regulatory “stress” response, that is, increased levels of catecholamines, glucagon, growth hormone, and cortisol. Data from studies in critically ill adults in intensive care units and some studies in extremely low-birthweight babies have demonstrated a correlation between hyperglycemia and adverse outcome, risk for organ failure, risk for death, and prolonged length of stay in the intensive care unit. In addition, when carefully undertaken with frequent monitoring of the plasma glucose concentration, insulin administration in infants with low birthweight is considered safe.

Insulin, the critical glucoregulatory hormone, is also the major growth factor for the fetus and anabolic hormone after birth. It stimulates protein and fat accretion by stimulating whole-body protein synthesis and de novo lipogenesis, thereby suppressing lipolysis. Insulin affects these processes either directly or by regulating the production of insulin-like growth factor-1 and insulin-like growth factor binding proteins.

The usual dose for a continuous intravenous infusion is 0.04 to 0.10 units/kg per hour administered in a minimum volume (0.04 to 0.1 mL) of isotonic saline solution. The intravenous tubing is flushed with the insulin solution to saturate the binding sites on the tubing so that insulin cannot stick to the plastic tubing. The dose should be adjusted with increasing caloric intake, with the goal being to maintain the blood glucose concentration at a level between 100 and 150 mg/dL.[9] The higher glucose levels are suggested to maintain an adequate margin of safety.

Limited information published in the literature on the use of intravenous insulin has given equivocal results. In a retrospective review of their 34 insulin-treated infants and 42 controls, Binder and associates[9] did not observe an impact of insulin administration on energy intake or growth. Nonetheless, insulin administration did reduce glucose intolerance. In contrast, it also has been shown that the delivery of significantly greater amounts of calories as glucose with insulin administration results in greater weight gain. Whether this weight gain represents an increase in lean body mass or an increase in lipid synthesis is not known. However, based on physiologic observations in adults, it is likely that the increased assimilation of glucose with insulin results in the increased synthesis of fat from glucose.

A large multicenter, international study of early insulin therapy for 7 days in infants with very low birthweight failed to show significant differences in the intended primary outcome measures, that is mortality at the expected date of delivery, and secondary measures such as somatic growth, incidence of sepsis, retinopathy, intracranial lesions at 28 days of age, and length of stay in the intensive care unit.[7] However, an intention-to-treat analysis showed statistically significant higher mortality at 28 days in the early insulin group ($P = .04$). Lack of a significant effect on primary outcome, and subsequent observation of an increased incidence of brain parenchymal lesions (periventricular leukomalacia and evidence of porencephalic cysts), in the intervention group caused the data safety monitoring board to suspend the study. It is significant to note that 36% of patients in the conventional group were also treated with insulin.

In addition, it has been noted that the control of plasma glucose during periods of high energy intake and clinical deterioration requires the frequent adjustment of insulin infusion and is extremely time consuming. Similar experiences have been reported by others. It is for this reason that insulin therapy has been used sparingly, and only then to treat hyperglycemia. When administering insulin to the neonate, frequent glucose monitoring and adjustment in the rate of glucose infusion are required to prevent hypoglycemia.

In a carefully performed study of four infants, Poindexter and colleagues[74] showed that exogenous insulin administration was associated with a high rate of glucose infusion and high plasma lactate levels. Plasma insulin levels in their study had increased 10-fold (from 7 to 79 μU/mL), and the rate of glucose infusion had to be increased from 6.8 to 15.7 mg/kg per minute. These data point to the importance of careful monitoring when insulin therapy is used for the management of hyperglycemia in the infant with low birthweight.

The large clinical trial also raises the issue as to why multicenter trials are unsuccessful when compared with small, single center trials. This may be due, in part, to the difficulty in achieving the targeted goals in several centers, particularly when caring for critically sick babies with low birthweight in the intensive care unit. For example, in the study of Beardsall and associates,[7] the nutrient intake, particularly protein intake, remained low during the period of insulin therapy, and a significant number of subjects in the control group (36%) were also treated with insulin. Additionally, the outcomes measured, that is, death before the expected date of delivery, sepsis, length of stay, and so forth, are complex with multiple factors and may not be expected to be influenced by insulin treatment of 1 week's duration.

PART 2

Disorders of Calcium, Phosphorus, and Magnesium Metabolism

Jacques Rigo, Mohamed W. Mohamed, and Mario De Curtis

Ninety-eight percent of the calcium, 80% of the phosphorus, and 65% of the magnesium in the body are in the skeleton; these elements are also constituents of the intracellular and extracellular spaces. The metabolic homeostasis of calcium, phosphorus, and magnesium and mineralization of the skeleton are complex functions that require the intervention of various parameters; an adequate supply of nutrients; the development of the intestinal absorption process; and the effects of several hormones, such as parathormone, vitamin D, and calcitonin, as well as optimal renal and skeletal controls.[98] Bone formation requires protein and energy for collagen matrix synthesis, and an adequate intake of calcium and phosphorus is necessary for correct mineralization.[97] During development, nutrients are transferred mainly across the placenta. From the analysis of stillbirths and deceased neonates, it has been calculated that during the last trimester of gestation, the daily accretion per kilogram of body weight represents around 120 mg of calcium, 70 mg of phosphorus, and 3 mg of magnesium.[118] Therefore, at birth, the whole-body content of a term infant represents about 30 g of calcium, 16 g of phosphorus, and 0.75 g of magnesium. After birth, the use of the gastrointestinal tract to provide nutrients for growth causes a reduction in calcium availability for bone accretion,[114] promoting the occurrence of relative osteopenia in preterm infants and to a lesser extent in term infants. Thus, during infancy, absolute values of whole-body mineral accretion per day are similar to the relative values per kilogram of body weight during fetal life. In addition to their roles in bone formation, calcium, phosphorus, and magnesium play important roles in many physiologic processes, such as transport across membranes, activation and inhibition of enzymes, intracellular regulation of metabolic pathways, secretion and action of hormones, blood coagulation, muscle contractility, and nerve conduction. The 20% of phosphorus not complexed within bone is present mainly as adenosine triphosphate, nucleic acids, and cell and organelle membranes. Magnesium, an essential intracellular cation, is critical in energy-requiring metabolic processes, protein synthesis, membrane integrity, nervous tissue conduction, neuromuscular excitability, muscle contractility, hormone secretion, and intermediary metabolism.

CALCIUM, PHOSPHORUS, AND MAGNESIUM PHYSIOLOGY

Calcium Physiology

SERUM CALCIUM

Serum calcium represents a minimum fraction of total-body calcium because only about 1% of calcium is present in extracellular fluid and soft tissues. In the circulation, calcium is distributed among three interconvertible fractions. About 50% of total serum calcium is in ionized form at the normal serum protein concentration and represents the biologically active component of the total serum calcium concentration. Another 8% to 10% is complexed to organic and inorganic acids (e.g., citrate, lactate, bicarbonate, sulfate, and phosphate); together, the ionized and complexed calcium fractions represent the diffusible portion of circulating calcium. About 40% of serum calcium is protein bound, primarily to albumin (80%) but also to globulins (20%).[55] Ionized calcium is the only physiologically active fraction. The protein-bound calcium is not biologically active but provides a rapidly available reserve of calcium. Under normal circumstances, the serum calcium concentration is tightly regulated by parathyroid hormone (PTH) and calcitriol (1,25-dihydroxy vitamin D_3; $1,25[OH]_2D_3$), which increase serum calcium (Fig. 49-11), and by calcitonin, which decreases serum calcium.

Serum total and ionized calcium concentrations are relatively high at birth but decrease sharply during the first hours of life to reach a nadir at 24 hours and increase progressively thereafter up to the end of the first week of life (Table 49-2). Sudden changes in the distribution of calcium between ionized and bound fractions may cause symptoms of hypocalcemia even in children with functioning hormonal mechanisms for the regulation of the ionized calcium concentration. Increases in the extracellular fluid concentration of anions such as phosphate, citrate, or bicarbonate increase the proportion of bound calcium and decrease ionized calcium. Alkalosis

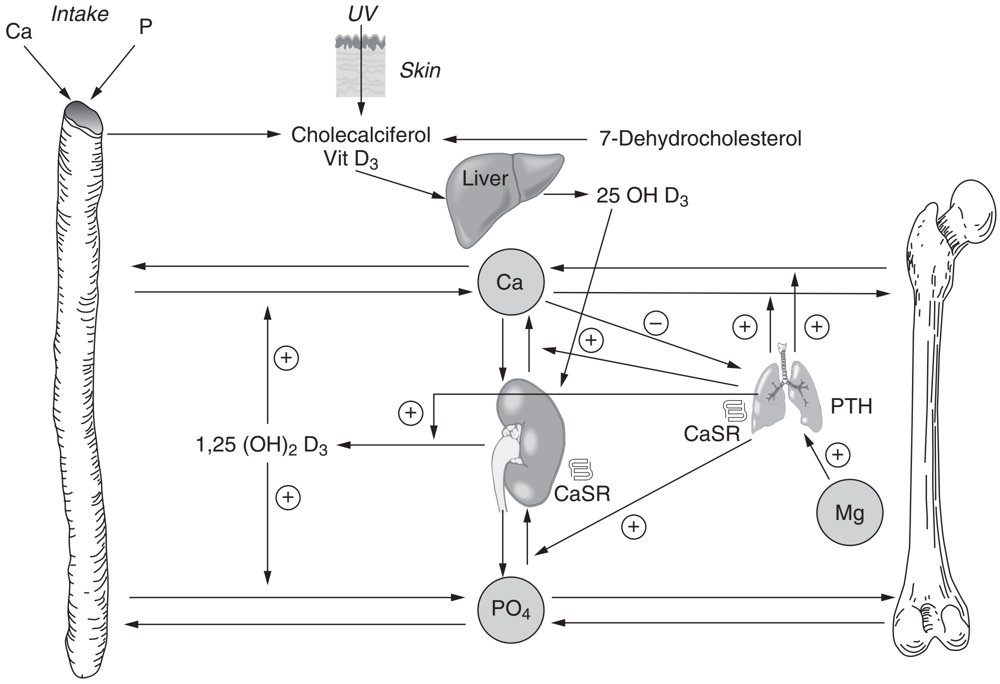

Figure 49–11. Regulation of calcium (Ca) and phosphate (PO_4) homeostasis. Parathyroid hormone (PTH) increases Ca release from bone, Ca resorption in the kidney, and $1,25(OH)_2D_3$ excretion from the kidney. PTH production is stimulated by low Ca and inhibited by low Mg and high $1,25(OH)_2D_3$. Vitamin D increases Ca release from bone and Ca and PO_4 absorption from the intestine. Vitamin D production is stimulated by high PTH and low PO_4. CaSR, calcium-stimulating response; OH, hydroxylase; P, phosphorus; UV, ultraviolet light; Vit, vitamin.

TABLE 49–2 Evolution of Serum Calcium Concentrations (mmol/L*) during the First 10 Days of Life in Term and Preterm Infants

	TERM		PRETERM	
Age	Mean	95% Confidence Interval	Mean	95% Confidence Interval
Birth (cord blood)	2.55	2.25-2.85	2.24	1.58-2.90
24 hr	2.25	1.95-2.55	1.94	1.64-2.24
48 hr	2.39	2.14-2.64	1.85	1.47-2.23
120 hr	2.46	2.25-2.68	2.22	1.84-2.60
240 hr	2.48	2.26-2.69	2.45	2.45-2.89

*Conversion to mg/dL: 0.2495 × mg/dL = mmol/L.

increases the affinity of albumin for calcium and thereby decreases the concentration of ionized calcium. In contrast, acidosis increases the ionized calcium concentration by decreasing the binding of calcium to albumin. Although it is conventional to measure the total serum calcium concentration, more physiologically relevant information is obtained by direct measurement of the ionized calcium concentration. This measurement is particularly important when evaluating patients who have abnormal circulating proteins and after blood transfusion for the correction of acidosis and hyperventilation. For example, total serum calcium decreases about 1 mg/dL, or 0.25 mmol/L, for each 1 g/dL of decrease in serum albumin, without any change in ionized calcium. When it is not possible or practical to determine the ionized calcium concentration directly, a corrected total calcium concentration can be derived by using one of several proposed algorithms that are based on albumin or total protein concentrations.[55]

PLACENTAL TRANSPORT

During pregnancy, there is an active calcium transfer from the mother to the fetus, reaching a peak of 120 to 150 mg/kg of fetal weight per day during the third trimester. To meet the high demand for mineral requirements of the developing skeleton, the fetus maintains higher blood calcium and phosphorus levels than the ambient maternal levels. This process is the result of the active transport of calcium across the placenta by a calcium pump in the basal membrane that maintains a gradient of maternal-to-fetal calcium of 1:1.4. The main regulator of fetal ionized calcium appears to be parathormone-releasing protein (PTHrP), which is produced by the placenta as well as by the fetal parathyroid glands.[120] Animal data suggest that both PTH and PTHrP act in the regulation of fetal mineral metabolism. PTHrP regulates placental calcium transfer, fetal blood calcium, and differentiation of the cartilaginous growth plate into endochondral bone. By contrast, PTH may play a more dominant role than PTHrP in regulating fetal blood calcium. Blood calcium and PTH levels are rate-limiting determinants of skeletal mineral accretion, and the lack of both PTH and PTHrP induces fetal growth restriction.[62]

The role of vitamin D in fetal physiology is not well understood. Cord concentrations of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D correlate significantly with those found in the maternal circulation, suggesting that the vitamin D pool of the fetus depends entirely on that of the mother. Fetomaternal relationships of 1,25-dihydroxyvitamin D concentrations are still debated, although a significant correlation was reported in infants. Most of the 1,25-dihydroxyvitamin D found in fetal plasma is due to fetal kidney hydroxylation activity; nevertheless, cord blood concentrations of 1,25-dihydroxyvitamin D in fetal plasma from infants with renal agenesis (Potter syndrome) are still one third of those observed in healthy newborns. Thus, it has been demonstrated that the placenta is able to synthesize and metabolize 1,25-dihydroxyvitamin D through the activity of 25-hydroxyvitamin D-1α hydroxylase and 1,25-dihydroxyvitamin D-24 hydroxylase, two key enzymes for vitamin D metabolism.[12] It has been suggested that methylation of the vitamin D-24-hydroxylase gene plays an important role in maximizing active vitamin D bioavailability at the fetomaternal interface.[84] The effect of 1,25-dihydroxyvitamin D on placental calcium transfer could be related to the expression of the placental calcium transporter PMCA3 messenger RNA (mRNA).[69] In addition, active transplacental calcium and phosphate transfer is at least partly dependent on insulin-like growth factor-1 (IGF-1), itself a stimulating factor of fetal and placental 1,25-dihydroxyvitamin D synthesis. Fetal IGF-1 is frequently downregulated in conditions leading to intrauterine growth restriction (IUGR).[15]

Bone mass of the newborn may be related to the vitamin D status of the mother. The results of dual-energy x-ray absorptiometry (DEXA) show that vitamin D status in winter is correlated with a marked reduction in total bone mineral content in newborn infants. Whole-body bone mineral content values could be 20% lower in countries in which milk products are not supplemented with vitamin D than in countries in which milk products are supplemented.[107] Studies of malnourished populations show that infants of mothers severely deficient in vitamin D may be born with rickets and can suffer fractures in the neonatal period.[16,107]

INTESTINAL ABSORPTION

Calcium absorption is the main determinant of its retention; consequently, it has a significant impact on bone mineral content. Calcium absorption occurs in the small intestine by both active and passive processes. Ionization of calcium compounds, which requires an acid pH, develops in the stomach and is a prerequisite for absorption. Vitamin D is essential for the active absorption of calcium, which involves carriers such as calcium-binding proteins.

After birth, calcium absorption limits the rate of bone mineralization for growth. There may be a reduction in calcium bioavailability, although the absorption rate is higher than that during all other periods of life.[25] The average reported absorption of calcium in the newborn is about 60% of its intake. The absorption of calcium added to human milk with commercially available fortifiers parallels that of the calcium endogenous to human milk. Its absorption occurs in the small intestine by two main routes—either through or between cells.[80] Movement through the cell takes place by active transport. Calcium enters the cell across the brush border membrane down a chemical gradient through a channel or carrier. It moves across the cell bound to a cytosolic calcium-binding protein (calbindin D_{9k}) and is extruded against a gradient by using a calcium–adenosine triphosphatase pump. Active transport is dependent on vitamin D. The major role of vitamin D in transcellular calcium transport involves the biosynthesis of calcium-binding protein. However, it also appears that vitamin D could modulate the entry and extrusion of calcium from intestinal cells. At present, the rate-limiting step of calcium transport is still controversial. Another less likely manner of calcium absorption involves pinocytosis. Calcium is engulfed by membrane vesicles and moves across the cell, fusing with the plasma membrane and releasing calcium into the extracellular space. Passive calcium transport is driven by chemical gradients that represent movement of calcium among the cells (paracellular transport). It accounts for most of the calcium absorption, particularly in premature infants, in whom the transport, which is transcellular and dependent on vitamin D, is not completely expressed.[23,24] In addition to vitamin D status, various other factors affect calcium absorption.[9,24] Ionization of calcium compounds, which requires an acid pH, occurs in the stomach and is a prerequisite for absorption. Therefore, low availability could be the result of an insoluble fraction of calcium intake or the precipitation of calcium in the gut. Calcium chloride, citrate, and carbonate have higher solubilities than calcium phosphate, which should be avoided in formulas.[9] By contrast, the higher solubility of organic calcium, such as that found in calcium gluconate or glycerophosphate, improves its absorption.[9] The quantity and quality of fat intake may also influence calcium absorption through the formation of calcium soap. It has been suggested that the free palmitate content in the gastrointestinal tract after the hydrolysis of triglyceride may impair calcium absorption.[27] The lower bioavailability of calcium in preterm formulas than that found in human milk would be partly due to palmitate, which is predominantly esterified at the glycerol 1,3 positions (Sn-1, Sn-3) in preterm formulas, in contrast to human milk. However, human milk contains a bile salt–stimulated lipase that is not specific to the Sn-1 and Sn-3 positions. The improvement of calcium absorption with the use of medium-chain triglycerides is probably the result of the reduction of total saturated long-chain fatty acid content in formula. At present, with the use of a well-absorbed fat blend (±85% fat absorption), the influence of calcium soap formation and the β-palmitate content formula could be relatively minimal in clinical practice. A relatively low gastrointestinal pH content or the lactose and casein content of the formula may also have an additional positive effect on calcium absorption.[25,126] In light of the considerable requirements of preterm infants, all these factors probably play a significant role in the amount of calcium retained and deposited in the skeleton.

Medications also interfere with calcium absorption; for example, glucocorticoids inhibit intestinal transfer. Some anticonvulsants can also inhibit calcium absorption either directly (phenytoin) or indirectly through interference with vitamin D metabolism (phenobarbital and phenytoin). In newborn infants, a significant amount of calcium is secreted in the intestinal lumen through digestive fluid. With the use of stable isotopes, endogenous fecal calcium excretion and true calcium absorption may be evaluated. Considering that fecal calcium excretion may represent about 15 mg/kg per day in preterm infants, the true calcium absorption rate is significantly higher than the apparent rate measured by conventional metabolic balances.[48] Numerous metabolic balance studies have been performed in preterm infants fed human milk or a formula (Table 49-3)[23,27,95,98,100] to evaluate apparent calcium absorption. In preterm infants fed human milk, calcium absorption ranges from 60% to 70%, depending on the calcium intake, whereas calcium retention is related to the phosphorus supply. Supplementation of human milk with phosphorus alone normalizes calciuria and allows calcium retention to reach about 35 mg/kg per day. When calcium and phosphorus are provided together or as human milk fortifiers, calcium retention and absorption rates parallel that of human milk, reaching 60 mg/kg per day. The use of new human milk fortifiers containing highly soluble calcium glycerophosphate improves calcium retention to 90 mg/kg per day (see Table 49-3).[98] In formula-fed infants, the percentage of net calcium absorption is less than that with human milk, ranging from 35% to 60%. Most of the difference probably results from the various factors affecting calcium solubility and absorption. At present, the use of a preterm formula with a high mineral content does not necessarily improve mineral retention.[95] Indeed, because of the poor solubility of calcium salts, especially calcium phosphate, the calcium content measured in formulas may be significantly lower than the claimed value, and an additional loss due to precipitation may occur before feeding.[95] In metabolic studies, the actual amount of calcium provided by feeding needs to be measured. As shown in Table 49-3, calcium retention

TABLE 49–3 Calcium, Phosphorus, and Magnesium Absorption and Retention in Preterm Infants Fed Human Milk (without or with a Human Milk Fortifier) and Preterm Formulas*

	HUMAN MILK AND HUMAN MILK FORTIFIER			PRETERM FORMULAS

*In human milk groups, calcium and phosphorus absorption and retention are related to intake, in contrast to formula groups, in which a plateau is reached rapidly due to a decrease in net absorption (%). Magnesium absorption and retention are similar in human milk and formula groups and are related to intake.

†Gestational age at the time of the balance study.

CGA, corrected gestational age.

limited to 90 mg/kg per day could presently be expected in preterm infants fed a preterm formula with a highly soluble calcium content. Nevertheless, those values are still relatively far from the reference values calculated during the last trimester of gestation (120 to 130 mg/kg per day), which is still considered the target mineral accretion rate for infants with very low birthweight (VLBW).

RENAL EXCRETION

Under normal circumstances, calcium status is maintained by a balance between its intestinal absorption and renal excretion. Urinary excretion is the result of glomerular filtration followed by the sum of the processes of tubular reabsorption and secretion. About 70% of the filtered load of calcium is reabsorbed in the proximal tubule and 20% in the thick ascending limb of the loop of Henle in association with Na^+ reabsorption. Although it is responsible for only 5% to 10% of Ca^{2+} reabsorption, the major regulation of Ca^{2+} reabsorption occurs in the distal convoluted tubule by a mechanism independent of Na^+ reabsorption but regulated by PTH and $1,25(OH)_2D_3$. Calcium reabsorption is increased by both PTH and $1,25(OH)_2D_3$. It is also regulated by ionized calcium concentration, phosphate concentration, and acid-base status and increases with Ca^{2+} depletion and alkalosis but decreases with hypercalcemia, phosphate depletion, and acidosis. The effects of diuretics on renal calcium excretion vary considerably. Furosemide markedly increases renal calcium losses and is a risk factor for neonatal nephrocalcinosis. Thiazides increase renal tubular calcium reabsorption, thereby reducing calciuria (see Chapter 51).[89,113]

The ability of the kidney to dispose of excess calcium represents a major homeostatic mechanism. Under normal circumstances, nearly all filtered calcium (98%) is reabsorbed in the renal tubule. However, preterm and term infants differ from the adult in three main aspects: (1) Renal function is far from being completely developed. (2) Mineral requirements for growth are very high. (3) Renal calcium load results solely in the difference between net absorption and net bone and soft tissue retention. Considering that calcium soft tissue retention is negligible, renal calcium load is highly dependent on bone calcium deposition associated with phosphorus in the form of hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ containing a molar calcium-to-phosphorus ratio of 1.67 (2.15 wt/wt). Therefore, the main determinant of the urinary loss of calcium in preterm and term neonates is relative to phosphorus depletion,[64,113] which has been illustrated in balance studies performed in growing preterm infants fed human milk. When human milk is provided exclusively, there is an increase in the urinary excretion of calcium associated with very low urinary phosphate excretion. In contrast, when human milk is supplemented with phosphate, significant phosphaturia appears at the same time that calciuria decreases to a minimum level. Therefore, hypercalciuria can be explained by a relative phosphate depletion that cannot meet the phosphate demand necessary for skeletal mineralization (Fig. 49-12).

INTAKE

Mature human milk contains approximately 340 mg of calcium per liter, corresponding to 50 mg per 100 kcal. Considering the smaller amount of calcium absorption with the use of formula, the guidelines of a recent Life Sciences Research Office Report on term infant formula nutrient requirements and those of the Scientific Committee on Food of the European Commission for infant formulas during the first 6 months of life recommended a content of 50 to 140 mg of calcium per 100 kcal.[38,92]

For preterm infants, recommendations are based on fetal accretion rates. In 1985, the American Academy of Pediatrics recommended that formulas contain 140 to 160 mg of calcium per 100 kcal.[3] More recently, the Life Sciences Research Office recommended a calcium content of 123 to 185 mg per 100 kcal for preterm infant formula, and an international expert panel suggested a similar value of 90 to 180 mg per 100 kcal.[10,58] However, the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) committee of nutrition considers that those calcium needs are based on data obtained in infants fed preterm formulas with low calcium bioavailability. It suggests that after birth, bone metabolism is designed to accelerate bone turnover, reducing calcium requirements, and that the relative osteopenia observed in preterm infants could be considered at least partially physiologic. Because a calcium retention level ranging from 60 to 90 mg/kg per day ensures appropriate mineralization and decreases the risk for fracture in infants with VLBW, the ESPGHAN Committee on Nutrition recommended the use of highly bioavailable calcium salts providing a calcium content of 110 to 130 mg per 100 kcal.[39]

Phosphorus Physiology

Unlike calcium, phosphorus remains in the soft tissues, mainly in the form of phosphate esters, and in extracellular fluid in the form of inorganic phosphate ions. It represents about 15% of the whole-body content. Given its widespread distribution, phosphorus plays a critical role in many biologic processes, including energy metabolism, membrane composition, nucleotide structure, cellular signaling, and bone mineralization. It is, therefore, not surprising that a deficiency of phosphorus results in clinical disease, including muscle weakness, impaired leukocyte function, and abnormal bone metabolization.

SERUM PHOSPHORUS

In serum, about two thirds of phosphorus is organic (lipid phosphorus and phosphoric ester phosphorus) and one third inorganic. In routine clinical practice, only inorganic phosphorus is measured. About 85% of the inorganic phosphorus is ionized, circulating as monohydrogen or dihydrogen phosphate; 5% is complexed with sodium, magnesium, or calcium; and 10% is protein bound. Because so many phosphorus species are present, depending on pH and other factors, the serum concentration is conventionally expressed as the mass of the elemental phosphorus (mmol/L, or mg/dL). In contrast to calcium, the serum phosphorus concentration varies widely depending mainly on intake and renal excretion but is also influenced by age, gender, pH, and a variety of hormones. At birth, the mean serum phosphorus concentration is relatively low (2.6 mmol/L, or 6.2 mg/dL) but thereafter rises rapidly to reach 3.4 mmol/L, or 8.1 mg/dL, owing to both endogenous phosphorus release and low renal excretion.[64,113] Serum phosphorus subsequently varies. The diet partially determines the serum phosphorus content: It is higher in formula-fed than breast-fed infants. Serum phosphorus is inversely related to serum calcium concentration. After the neonatal period, the serum phosphorus concentration progressively decreases to 2.1 mmol/L, or 5 mg/dL, at the age of 1 to 2 years; 1.8 mmol/L, or

PLACENTAL TRANSPORT

During pregnancy, there is transfer of phosphorus from the mother to the fetus that reaches a peak of 60 to 75 mg/kg per day during the third trimester; 75% is retained for bone mineralization, and 25% is retained in other tissues. The transplacental transport of phosphorus is an active process against a concentration gradient and is sodium dependent. Both 1,25(OH)$_2$D$_3$ and fetal PTH may be involved in the regulation of placental phosphorus transfer.

INTESTINAL ABSORPTION

Intestinal phosphorus absorption takes place primarily in the duodenum and jejunum and to a lesser extent in the ileum and colon. It occurs by two mechanisms: an active, sodium-dependent transcellular process localized to the mucosal surface, and passive diffusion through the paracellular pathway. It depends on both the absolute amount of dietary phosphorus and the relative concentrations of calcium and phosphorus (an excessive amount of either can decrease the absorption of the other). Vitamin D may stimulate active phosphorus absorption, although it is largely independent of vitamin D intake. The efficiency of this absorption is high (close to 90% of intake) regardless of the type of milk given.[89,113] However, the use of poorly soluble calcium salt such as calcium triphosphate in formulas is associated with a significant reduction in phosphorus absorption.[80,98] In contrast to calcium, a small amount of phosphate is secreted in the intestinal lumen through digestive fluid.

RENAL EXCRETION

The kidney contributes to a positive phosphate balance during growth by the reabsorption of a relatively high fraction of filtered inorganic phosphate (99% in newborns, 95% in infants fed human milk, and 80% in adults). Preterm infants have an increased fractional excretion of phosphate and are at a greater risk for developing signs and symptoms of phosphate deficiency. The bulk of filtered phosphate is reabsorbed in the proximal tubule through a sodium-dependent transporter, the Na^+-phosphate cotransporter. A change from breast milk with a low phosphate content to a formula with a high content is associated with a rapid downregulation of Na^+-phosphate cotransporter-2 mRNA and protein in the brush border membrane. The age-related decrease in phosphate reabsorption observed after the weaning period appears to be correlated with the smaller phosphate needs of adult and older animals than those of growing animals. It is surprising that the fractional reabsorption of phosphate is higher in growing than fully grown animals and humans.[52] The kidney is the major determinant of the plasma phosphate concentration. There is no extrarenal mechanism for regulating plasma phosphorus except the net input of phosphorus into extracellular fluid from all sources. Because the intestinal absorption of phosphorus is very efficient and fairly unregulated, renal phosphorus excretion plays an important role in maintaining its balance. Filtered load depends on the plasma phosphorus level and glomerular filtration rate (GFR). Tubular reabsorption is an active and saturable process that gives rise to a maximal rate of tubular reabsorption (T_m). There is a plasma minimal threshold below which phosphorus reabsorption is almost complete and urinary excretion close to zero and a maximal threshold above which all tubular reabsorptive systems are saturated, so each additional increment in filtered load is associated with a parallel increment in excretion.[64,89,113] In the intermediate zone, there is a functional relationship between GFR and T_m, known as the *glomerulotubular balance*, in which a change in GFR is compensated for by a change in T_m in order to regulate phosphorus excretion. In preterm infants, the minimal and maximal threshold levels are 1.75 mmol/L (5.4 mg/dL) and 2.45 mmol/L (7.6 mg/dL), respectively (Fig. 49-13).[113] The level of PTH activity in plasma is probably the single most important physiologic regulator of phosphorus excretion. PTH inhibits phosphorus reabsorption, but its activity appears to be limited to the intermediate zone between the minimal and maximal plasma threshold levels. In contrast, $1,25(OH)_2$ vitamin D synthesis, stimulated by a decrease in plasma phosphorus concentration, has an indirect effect on phosphorus reabsorption by its effect on mineral absorption and mobilization from bone, resulting in an increase in plasma calcium concentration and the suppression of PTH release. During early postnatal life, the phosphate response to PTH is blunted, whereas PTH increases tubular calcium reabsorption. Together, these actions result in the retention of both calcium and phosphate in infants, which is favorable for growth. The role of newly discovered phosphatonin peptides such as FGF23 in the regulation of phosphorus excretion during early life remain to be established. FGF23 principally functions as a phosphaturic factor and counter-regulatory hormone for $1,25(OH)_2$ vitamin D production. Excess FGF23 secreted by osteocytes in bone causes hypophosphatemia through inhibition of Na-phosphate cotransporter-2. Excess FGF23 also suppresses $1,25(OH)_2$ vitamin D through inhibition of 25-hydroxyvitamin D-1α-hydroxylase and stimulation of 24-hydroxylase, which inactivate $1,25(OH)_2$ vitamin D in the proximal tubule of the kidney. In contrast, deficiency of FGF23 results in the opposite renal phenotype consisting of hyperphosphatemia and elevated production of $1,25(OH)_2$ vitamin D. Downregulation of FGF23 could promote the relative hyperphosphatemia and the relative increase in $1,25(OH)_2$ vitamin D promoting bone mineralization during early rapid growth in the neonatal period.[91] Absorbed phosphate enters the extracellular phosphate pool, which is in equilibrium with bone and soft tissue. In adults with neutral phosphorus balance, the amount of phosphorus excreted by the kidney is equal to the net amount absorbed by the intestine; in growing infants, it is less than the net amount absorbed owing to the deposition of phosphorus in soft tissues and bone. In growing infants, phosphorus will preferentially go to soft tissue with a weight-to-weight nitrogen-to-phosphorus ratio of 15:1 and to bone with a weight-to-weight calcium-to-phosphorus ratio of 2.15:1. The residual phosphorus constitutes the renal phosphorus load influencing plasma concentration and urinary excretion. In the face of a limited total phosphorus supply, bone mineral accretion may be limited, leading to significant calcium excretion associated

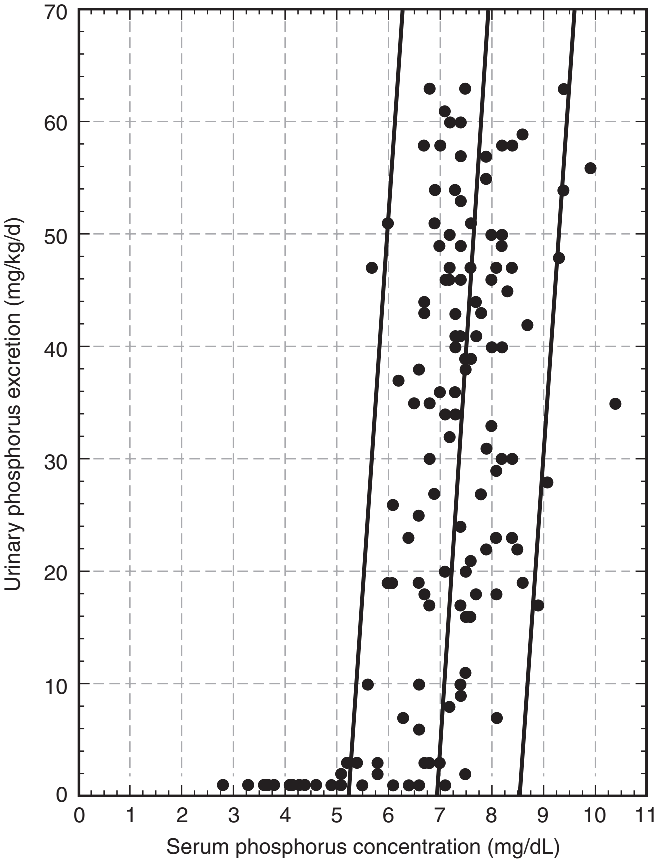

Figure 49–13. Relationship between urinary excretion of phosphorus and serum phosphate level ($n = 198$) in preterm infants. Regression lines represent the minimal, mean, and maximal plasma phosphate concentration thresholds for tubular reabsorption of phosphate. Points to the left of the minimal threshold were considered hypophosphatemia associated with phosphorus depletion. Points to the right of the maximal threshold were considered hyperphosphatemia due to low glomerular filtration rates and relative phosphorus overload.

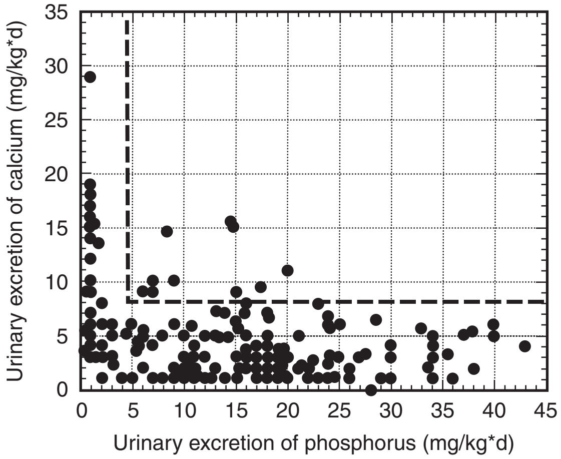

Figure 49–14. Relationship between urinary excretion of calcium and urinary excretion of phosphorus in preterm infants (*n* = 198). Hypercalciuria (>8 mg/kg/day) is related to low phosphate excretion (<3 mg/kg/day). Conversely, urinary excretion of calcium below 8 mg/kg/day is usually observed in preterm infants with phosphorus excretion over 4 mg/kg/day.

with very low urinary excretion of phosphorus (Fig. 49-14). This particular situation is illustrated in Figure 49-12, showing calcium and phosphorus metabolism in term infants fed human milk or formula.

INTAKE

Mature human milk contains about 140 mg of phosphorus per liter, corresponding to 21 mg per 100 kcal. The recent guidelines for infant formulas in the first 6 months of life recommend minimal and maximal contents of 20 and 70 mg/100 kcal, respectively.[38,92] However, to avoid the occurrence of hypocalcemia or hypercalcemia resulting from an unbalanced diet containing the minimal calcium combined with the maximal phosphorus content (or inversely), the Life Sciences Research Office and the Scientific Committee on Food of the European Commission recommend that the calcium-to-phosphorus ratio be maintained at more than 1.1:1 but less than 2.0:1.

For preterm infants, the recommendations are based on fetal accretion rates. In 1985, the American Academy of Pediatrics recommended 95 to 108 mg of phosphorus per 100 kcal for preterm formulas, whereas more recently, the Life Sciences Research Office and the International Expert Panel recommended similar values, with a calcium-to-phosphorus ratio maintained at more than 1.7:1 but less than 2.0:1.[3,10,58] Considering a nitrogen retention ranging from 350 to 450 mg/kg per day and a calcium retention from 60 to 90 mg/kg per day, the ESPGHAN Committee on Nutrition recommended an adequate intake of 65 to 90 mg/kg per day of a highly absorbable source of phosphate (90%) with a calcium-to-phosphorus ratio between 1.5 and 2.0.[3]

Magnesium Physiology

To less of an extent than calcium and phosphorus, the skeleton represents the largest magnesium store (60%), which is divided into two compartments: one firmly bound to apatite and nonmobilizing, and the other absorbed to the surface of the mineral crystals and contributing to magnesium homeostasis.[63]

The remaining magnesium is distributed in skeletal muscle, the nervous system, and other organs with a high metabolic rate. Magnesium is the second most abundant intracellular cation, playing a crucial role in many physiologic functions. It is critical in energy-requiring metabolic processes, protein synthesis, membrane integrity, nervous tissue conduction, neuromuscular excitability, muscle contraction, hormone secretion, and intermediate metabolism.

SERUM MAGNESIUM

In serum, about one third of the magnesium is bound to protein, mainly albumin; the remaining two thirds is ultrafilterable, being about 92% free and 8% complexed to citrate, phosphate, and other compounds.[7,63] The plasma magnesium concentration is elevated in preterm and term infants (0.8 ± 0.16 mmol/L, or 2.0 ± 0.4 mg/dL) and decreases soon after infancy to adult values.[59] The sum of ionized and complexed magnesium constitutes its diffusible or ultrafilterable form. Although the concentration of this form of magnesium in plasma remains almost constant (0.45 ± 0.1 mmol/L, or 1.1 ± 0.2 mg/dL), the proportion of this diffusible form in relation to total magnesium increases progressively with age (preterm newborn infants, 52%; term newborns, 62%; infants, 66%; and children, 70%). The concentration of magnesium in red blood cells (about 2.5 mmol/L) appears to be genetically controlled and represents an acceptable indicator of magnesium content in other tissues.[7,67]

PLACENTAL TRANSPORT

Magnesium freely crosses the placental barrier and accumulates in the fetus mainly during the first trimester of pregnancy.[7] Placental transfer continues throughout gestation, at a daily rate of 3 to 5 mg.[77] The transfer of magnesium across the placenta depends on an active transport mechanism different from that of calcium, which is necessary to maintain higher fetal than maternal concentrations. There is currently no clear information on the regulation of placental transport.[115] Obviously, situations of magnesium excess or deficiency in the mother are also reflected in the fetus.[77]

INTESTINAL ABSORPTION

About 40% of ingested magnesium is absorbed in the gut, mainly in proximal parts of the small intestine. Newborn infants, especially preterm infants, have an increased capacity for intestinal absorption of magnesium.[7,63] Net magnesium absorption is the sum of the absorbed magnesium from ingested foods and digestive fluids. There are two mechanisms of absorption: One is passive and the other active and saturable. Passive absorption occurs by means of a paracellular pathway, following a favorable electrochemical gradient as a function of water and solute movement, and appears to be proportional to dietary intake. Regulated, active transport depends on a saturable carrier present in the luminal membrane and operates only under conditions of low magnesium intake. The factors regulating the intestinal absorption of magnesium are largely unknown. The magnesium concentration in the digestive tract is the most important determinant of the amount of magnesium absorbed; nevertheless, food elements capable of influencing magnesium absorption should be taken into account in the investigation of cases of low magnesium intake. Substances that increase magnesium solubility favor its absorption, whereas substances that form insoluble complexes decrease its likelihood. Data show that no competition exists between magnesium and calcium for absorption because calcium supplementation does not decrease magnesium absorption. In contrast, phosphates can inhibit magnesium absorption through the formation of insoluble magnesium complexes in the intestine. Magnesium absorption in the gut is not stimulated by $1{,}25(OH)_2$ vitamin D.

RENAL EXCRETION

The kidney plays a major role in magnesium homeostasis. It conserves magnesium in response to a deficiency and increases excretion in proportion to the load presented to the kidney.[63] About 70% to 80% of serum magnesium is filtered through the glomerular membrane, but only 5% to 15% of the filtered magnesium is reabsorbed along the proximal tubule, which is considerably less than the amount of fractional reabsorption of sodium or calcium. The primary site for magnesium reabsorption is the thick ascending limb of the loop of Henle, where about 65% of the filtered magnesium is reabsorbed. At this site, magnesium reabsorption is associated with NaCl cotransport. Reabsorption takes place transcellularly, following the favorable transepithelial magnesium concentration gradient, resulting from water absorption. The thick ascending limb of the loop of Henle has a major role in the reabsorption of magnesium, absorbing 70% to 80% of the filtered magnesium. This reabsorption is mainly passive and depends on the favorable transepithelial electric gradient. The distal convoluted tubule reabsorbs only the remaining 10% to 15%, but the reabsorption is especially important because it determines the final amount of magnesium present in the urine. In this part of the nephron, magnesium is transcellularly reabsorbed by an active mechanism.[30] Analyzing magnesium intake and urinary excretion, one can observe that there is an average volume of elimination of about one third of the dietary magnesium in the urine. When the magnesium intake is severely restricted in humans with normal kidney function, urine output decreases. Supplementing a normal intake increases urinary excretion without altering normal serum levels as long as renal function is normal and the amounts given are not excessive. Overall, the tubular reabsorption of magnesium is a process that is quantitatively limited; the maximal rate of this reabsorption appears to be lower than that of calcium and phosphorus.[71]

Renal homeostasis of magnesium is regulated by many hormonal and nonhormonal factors. The hormonal factors interact to modify the transepithelial electric gradient, tubular permeability at the level of the loop of Henle, or mechanism of active transport at the level of the distal convoluted tubule. PTH, calcitonin, glucagon, vasopressin, and insulin all increase the tubular reabsorption of magnesium. The role of aldosterone is misunderstood, but magnesium reabsorption follows sodium reabsorption; it increases under conditions of volume depletion and decreases under conditions of volume expansion. The nonhormonal factors include the concentration of magnesium in the tubular lumen, acid-base equilibrium, and plasma concentrations of potassium and inorganic phosphate. The tubular reabsorption of magnesium is closely linked to that of calcium. It has been recently shown that epithelial cells of the loop of Henle loop and the distal convoluted tubule have receptors that sense the extracellular concentrations of both Mg^{2+} and Ca^{2+}. Metabolic acidosis also increases the urinary excretion of magnesium.[63] Daily urinary excretion in normal children oscillates between 1.6 and 2.8 mg/kg of body weight daily. Normal values for the ratio of urinary magnesium to urinary creatinine (mg/mg) change with age.[6,71] An increased value observed during infancy does not represent a higher excretion of magnesium but is related to the diminished excretion of creatinine per unit of lean body mass during this age period.

INTAKE

Mature human milk contains about 26 mg of magnesium per liter, corresponding to 3.9 mg per 100 kcal. Guidelines for infant formulas during the first 6 months of life[38,92] recommend minimal and maximal contents of 4 to 5 mg and 15 to 17 mg/100 kcal, respectively. For preterm infants, the recommendations are based on fetal accretion rates, and values similar to those at term have been suggested (6.8 to 17 mg/100 kcal and 7.9 to 15 mg/kg per day, respectively).[10,39,58]

HORMONAL REGULATION

Parathyroid Hormone

The four parathyroid glands, through the secretion of PTH, regulate serum calcium concentrations and bone metabolism. PTH is synthesized as a larger (115–amino acid) precursor (prepro-PTH) but is stored and secreted mainly as an 84–amino acid peptide, with the 1-34,N-terminal portion conferring bioactivity.[70,103]

EFFECTS

The effects of PTH on mineral metabolism are initiated by the binding of PTH to the type 1 PTH receptor in the target tissues. Another PTH receptor (type 2) has been found in the brain and intestine. Its main ligand is a peptide different from PTH; the functions of this receptor are not known. As a result, PTH regulates large calcium fluxes across bone, kidneys, and intestine (see Fig. 49-11). PTH increases serum calcium concentrations directly by increasing bone resorption and renal calcium reabsorption and indirectly by increasing renal synthesis of $1{,}25(OH)_2D_3$, thereby increasing intestinal calcium absorption. PTH also lowers serum phosphorus concentrations through its phosphaturic action on the renal proximal tubule. This action minimizes the possibly adverse effect of hyperphosphatemia related to bone resorption on calcium homeostasis.

REGULATION OF SECRETION

Serum calcium concentration regulates PTH secretion; high concentrations inhibit the secretion of PTH, and low concentrations stimulate it. Low or falling serum calcium concentrations act within seconds to stimulate PTH secretion, initiated by means of a calcium-sensing receptor on the surfaces of parathyroid cells. This receptor is a heptahelical molecule, like the receptors for light, odorants, catecholamines, and many peptide hormones. The calcium-sensing receptor is expressed in the parathyroid glands, where it regulates PTH secretion, and in the kidneys, where it regulates tubular calcium reabsorption. Decreases in ionized calcium of as little as 0.4 mmol/L stimulate PTH secretion, and increases suppress it (although usually not completely). Acute decreases in magnesium concentrations also stimulate PTH secretion, and increases depress it. However, chronic magnesium deficiency paradoxically decreases PTH secretion, probably by altering the calcium-sensitive, magnesium-dependent adenylate cyclase involved in PTH secretion.

Slower regulation of PTH secretion occurs over a period of hours as a result of cellular changes in PTH mRNA. Vitamin D and its metabolites 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D, acting through vitamin D receptors, decrease the level of PTH mRNA, and hypocalcemia increases it. The slowest regulation of PTH secretion occurs over days or even months and reflects changes in the growth of the parathyroid glands. Metabolites of vitamin D directly inhibit the mass of parathyroid cells; hypocalcemia stimulates the growth of parathyroid cells independent of the contrary action of vitamin D metabolites.

Both activating and inactivating calcium-sensing receptor (CaSR) mutations have been identified. Loss-of-function CaSR mutations elevate the set point for both PTH secretion and tubular calcium reabsorption, causing hypercalcemia. The associated clinical syndromes are familial benign hypocalciuric hypercalcemia and neonatal severe hyperparathyroidism. Gain-of-function CaSR mutations decrease the set point for both PTH secretion and tubular calcium reabsorption in response to hypocalcemia. The associated clinical syndrome is autosomal dominant hypocalcemic hypercalciuria. These syndromes are discussed later. Some cases of nonfamilial idiopathic hypoparathyroidism may also be caused by gain-of-function CaSR mutations.

The human calcium receptor gene contains seven exons and is located at 3q13.3-21. In the parathyroid gland, the calcium receptor mediates inhibition by extracellular Ca^{2+} concentration of PTH secretion, of *PTH* gene expression, and of parathyroid cellular proliferation. In the kidney, the receptor mediates the direct inhibition of the reabsorption of divalent cations in the thick cortical ascending limb of the loop of Henle.[102]

FETAL PARATHYROID FUNCTION

Human parathyroid glands are functionally active as early as 12 weeks of gestation. However, fetal parathyroid glands are functionally suppressed by high intrauterine calcium concentrations, and PTH levels in cord blood are frequently below the detection limit.[109] PTH does not appear to cross the placenta in either direction, and the role of fetal PTH in maternal-fetal calcium transport is not clearly established. Nevertheless, fetal PTH levels contribute importantly to fetal ionized calcium levels and mineralization of the bone matrix.[62] In contrast, a midregion fragment of PTHrP, produced by the fetal parathyroid glands and various fetal tissues, appears mainly responsible for regulating the maternal-fetal calcium gradient. It has been shown that PTHrP directly affects adenosine triphosphate–dependent calcium transport across the basal plasma membrane of the human syncytiotrophoblast at a concentration within the physiologic range (5 pg/mL).[121] Therefore, both PTH and PTHrP act synergistically during fetal life to promote calcium transfer, high blood calcium concentration, bone development, and matrix mineralization.

Maternal hyperparathyroidism results in maternal hypercalcemia, which leads to fetal hypercalcemia and suppression of fetal and neonatal parathyroid glands. Conversely, untreated maternal hypoparathyroidism leads to maternal hypocalcemia, fetal hypocalcemia, and secondary fetal and neonatal hyperparathyroidism.

NEONATAL PARATHYROID FUNCTION

After birth, with the abrupt termination of the maternal calcium supply, serum calcium in the newborn decreases, and serum PTH increases correspondingly. Both term and preterm infants may show a PTH response to falling serum calcium. Infants with VLBW have a decreased PTH surge compared with full-term infants. Infants of diabetic mothers may have impaired PTH production during the beginning days of life. Infants with birth asphyxia may also have decreased PTH responses to hypocalcemia.

PARATHYROID HORMONE REFERENCE VALUES

Current assays for serum PTH are conducted at two sites that are designed to detect both amino-terminal and carboxy-terminal epitopes of the peptide. The better assays are those that are well standardized, do not cross-react with PTH-related peptide, and are sufficiently sensitive so that normal values can be distinguished from subnormal values. PTH molecules that are reactive in these two-site immunoassays are considered intact, but some have no bioactivity. For example, a loss of only six amino acids to yield PTH (7-84) eliminates all bioactivity but does not affect the immunoreactivity measured in most or all of these assays.

In full-term newborns, serum PTH concentrations tend to be low in cord blood but increase within the first 48 hours of life in response to the decrease in serum calcium. In preterm infants, the serum immunoreactive, intact PTH concentrations increase immediately after birth, indicating that, in them, the secretion of the hormone responds physiologically to the hypocalcemic stimulus. This increase in immunoreactive PTH concentration could be blunted when premature infants receive calcium by infusion, with the calcium load buffering the postnatal depression of serum calcium. By day 10, the serum concentrations of intact PTH return to euparathyroid values (Table 49-4).[107] The multiplication factor for serum PTH from picograms per deciliter to picomoles per liter (pg/dL to pmol/L) is 0.11.

Vitamin D

SYNTHESIS AND METABOLISM

Vitamin D is synthesized endogenously in the skin (cholecalciferol or vitamin D_3) after sunshine exposure to high-energy ultraviolet photons (ultraviolet B, 290 to 315 nm) or is absorbed from dietary sources in the duodenum and jejunum as either vitamin D_3 (from animal sources) or vitamin D_2 (ergocalciferol [from vegetable sources]). Regardless of its origin, vitamin D_2 and D_3 are transported bound to the vitamin D–binding protein to the liver, where it is hydroxylated at

carbon 25 to form vitamin D_3 (25[OH]D_3, or calcidiol), the most abundant vitamin D metabolite. The generation of calcidiol is not regulated, and circulating concentrations of 25[OH]D_3 provide a useful index of vitamin D status (reflecting both dietary intake and sunshine exposure). Subsequently in the kidney, 25[OH]D_3 is further hydroxylated at carbon 1 to form the final active metabolite, 1,25$(OH)_2D_3$, or calcitriol. This last transformation is tightly regulated and is the rate-limiting step in vitamin D metabolism. 1,25$(OH)_2D_3$ can also be synthesized by various cells, including monocytes and skin cells, as well as by the placenta during pregnancy. However, this local production of 1,25$(OH)_2D_3$ is not associated with calcium homeostasis but could contribute to regulating cell growth.[50]

EFFECTS

Normal vitamin D status is necessary to maintain calcium and phosphorus homeostasis. The effects of 1,25$(OH)_2D_3$ (calcitriol) on target tissues are initiated by its binding to a steroid receptor (vitamin D receptor) distributed in numerous tissues, leading to the synthesis of a variety of proteins. Therefore, 1,25$(OH)_2D_3$ acts on the small intestine, increasing the absorption of calcium and phosphorus by the synthesis of calcium-binding (calbindin-D) proteins; on bone, mobilizing calcium and phosphorus by increasing the number of osteoclasts; and on the kidney, increasing calcium reabsorption in the distal nephron segments by increasing the expression of the epithelial calcium influx channel. There is a natural polymorphism in the genotype of the vitamin D receptor that contributes to skeletal metabolism in early childhood and to the genetic determinant of the peak bone mass.

REGULATION OF SECRETION

In contrast to hepatic 25-hydroxylation, renal 1-hydroxylation, which leads to the active metabolite, appears to be tightly regulated. The main factors increasing the synthesis of calcitriol through stimulation of renal 25(OH)D_3-1α-hydroxylase are PTH, PTHrP, hypocalcemia, hypophosphatemia, and other hormonal factors, such as IGF-1, estrogen, prolactin, and growth hormone. The production of calcitriol is inhibited by elevated serum levels of calcium and phosphorous, but also by the newly discovered phosphatonin peptides implicated in phosphorus homeostasis. Thus, an increase in FGF23 production suppresses 1,25$(OH)_2$ vitamin D through inhibition of 25-hydroxyvitamin D-1α-hydroxylase and stimulation of 24-hydroxylase inactivating 1,25$(OH)_2$ vitamin D in the proximal tubule of the kidney.[91]

FETAL VITAMIN D FUNCTION

Serum 25-hydroxyvitamin D concentration depends on vitamin D intake and production. The production of vitamin D is influenced by geographic location, season, skin pigmentation, and latitude. Vitamin D deficiency is very common during pregnancy, especially in areas with a prolonged winter season. It is lower in black pregnant women in contrast to white pregnant women. In the northern United States, about 45% of black pregnant women are vitamin D deficient (25-hydroxyvitamin D <37.5 nmol/L) as opposed to 5% of white women in late pregnancy. On the other hand, 50% to 60% of white and black pregnant women are vitamin D insufficient (25-hydroxyvitamin D: 37.5 to 80 nmol/L).[20]

1,25-Dihydroxyvitamin D concentration increases from the beginning of pregnancy. In humans, a proportion of the circulating active metabolite appears to be derived from maternal decidual cells, but increased 1,25-dihydroxyvitamin D synthesis by the mother's kidneys is not excluded. In addition, serum concentrations of vitamin D–binding protein increase during pregnancy.[108]

Cord concentrations of the major vitamin D metabolites are consistently lower than those measured in the mother's serum. Placental vein 25-hydroxyvitamin D concentrations correlate significantly with those found in the maternal circulation, suggesting that calcidiol easily diffuses across the placental barrier and that the vitamin D pool of the fetus depends entirely on that of the mother. The fetomaternal relations of 1,25-dihydroxyvitamin D concentrations are more complex, but a correlation between fetal and maternal concentrations was found in both full-term and preterm infants. Nevertheless, most of the 1,25-dihydroxyvitamin D in fetal plasma is due to fetal kidney activity, as suggested by studies in fetal plasma from infants with renal agenesis. Actually, the precise role of the placental 1,25-dihydroxyvitamin D activity in the mineral homeostasis during the fetal life needs to be evaluated.

In malnourished populations with vitamin D deficiency, osteomalacia in the mother and abnormal skeletal metabolism in the fetus and infant have been reported. Infants of severely malnourished mothers may be born with rickets and can suffer fractures during the neonatal period. Therefore, bone mass of the newborn may be related to the vitamin D status of the mother. Comparison of the results of DEXA from different countries shows that infant whole-body bone mineral content values are lower in countries in which milk products are not supplemented with vitamin D than in those in which milk products are supplemented. In contrast, vitamin D supplementation of malnourished mothers results in improved growth of the fetus and child in terms of both birthweight and subsequent linear growth during infancy. Moreover, maternal vitamin D status during pregnancy may have influence on the fetal skeletal development starting as early as 19 weeks' gestation[68] and can persist long after infancy. At the age of 9 years, children whose mothers had deficient or insufficient concentrations of 25-hydroxyvitamin D in late pregnancy had a reduced bone size and bone mineral content.[56]

It is worth mentioning that maternal vitamin D deficiency has been linked to other short- and long-term health problems in offspring, including type 1 diabetes and childhood asthma.[26,33,37] Moreover, it appears that vitamin D insufficiency during pregnancy is potentially associated with an increased risk for preeclampsia,[19] insulin resistance, and gestational diabetes mellitus,[29,65] primary cesarean delivery,[75] and bacterial vaginosis.[18]

Current guidelines recommend a vitamin D supplement of 200-400 IU/day during pregnancy, with increased doses of 1000 IU/day reserved for at-risk populations (particularly in the 3rd trimester). Future guidelines may suggest that doses of 2000-4000 IU/day for all pregnant women during the 2nd and 3rd trimester are safe and more effective in preventing complications associated with vitamin D deficiency in pregnancy.[56a]

NEONATAL VITAMIN D: FUNCTION AND RECOMMENDATIONS

Plasma 25(OH) D_3 concentration is a useful vitamin D biomarker reflecting vitamin D supply and use over a period of time. Unfortunately, the cutoff used for serum 25(OH) D_3 concentrations varies among researchers, leading to various prevalence of vitamin D deficiency or insufficiency. Nevertheless, several surveys show a high rate of poor maternal vitamin D status throughout the world, particularly in countries without vitamin D supplementation, with poor sun exposure, extensive clothing, or with deeply pigmented skin. Thus, the rate of cord blood vitamin D insufficiency ($<$20 nmol/L; $<$8.3 ng/mL) may reach up to 70% in European populations.[86]

The concentration of vitamin D is low in human milk (20 to 60 IU/L), and lower than that in regular formulas (400 to 600 IU/L). In breast-fed infants not receiving vitamin D supplements, vitamin D stores could be depleted within 8 weeks of delivery, suggesting the need for vitamin D supplementation.[45] A minimum daily intake of 400 IU (10 µg/day) of vitamin D is recommended by the American Academy of Pediatrics for all infants beginning soon after birth, including those who are exclusively breastfed.[5] Moreover, in breast-fed full-term infants born to mothers who are vitamin D deficient, maternal supplementation with vitamin D could be required to increase the human milk vitamin D concentration and in turn improve infant vitamin D status. In addition, vitamin D is metabolized in the liver, and anticonvulsants such as phenobarbital and diphenylhydantoin increase its hepatic catabolism and requirements.

In preterm infants, as a result of the decrease in serum calcium during the first days of age, the postnatal surge in PTH induces increased synthesis of 1,25(OH)$_2$D$_3$ during the first days day of life. Provision of 1000 IU of vitamin D_3 increases the 25-hydroxyvitamin D pool of the newborn at birth, followed by rapid renal synthesis of 1,25-dihydroxyvitamin D during the early postnatal days (Fig. 49-15). In infants with VLBW ($<$1500 g), immaturity of the vitamin D activation pathway, either alone or in combination with other abnormalities, particularly transient hypoparathyroidism, hypercalcitoninemia, and end-organ resistance to hormonal effects, may promote late neonatal hypocalcemia. However, after 28 weeks of gestation, activation of vitamin D is operative as early as 24 hours after birth. Vitamin D supplementation just after birth improves its nutritional status, as evidenced by rises in both plasma 1,25- and 25-hydroxyvitamin D concentrations.

In countries with high vitamin D status, plasma 25-hydroxyvitamin D remained normal for 6 months while infants received about 400 IU/day ($<$10 µg/day). By contrast, in France and other countries where dairy products are not enriched with vitamin D, sunshine exposure is restricted,[16] and mean cord concentrations of 25-hydroxyvitamin D are low, the administration of vitamin D (from 1000 IU/day, or 25 µg/day) resulted in a rapid increase in circulating concentrations of total 1,25-dihydroxyvitamin D by 5 days of age, promoting calcium absorption and mineral accretion rates during the neonatal period.[23,114] Therefore, vitamin D recommendations may differ significantly between North American (400 IU/day) and European (800 to 1000 IU/day) countries.[39]

REFERENCE VALUES

New information on the additional role of vitamin D on glucose homeostasis, immune system, cardiovascular disease, and cancer has resulted in defining vitamin D deficiency in adults as a 25-OH-D concentrations of $<$50 nmol/L and vitamin D insufficiency as a 25-OH-D concentration of 50 to

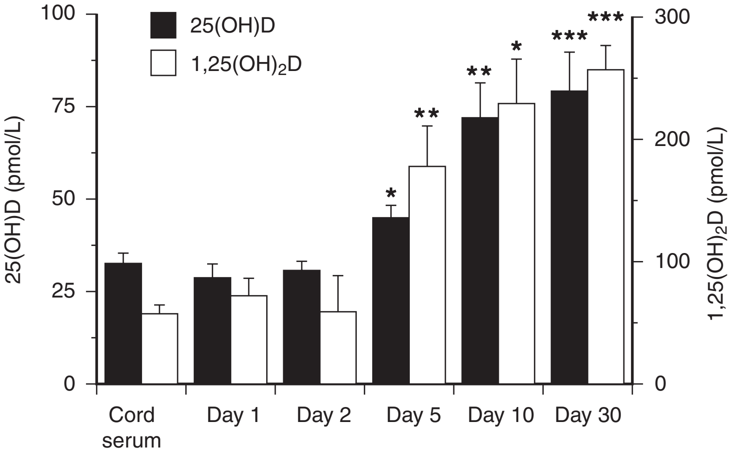

Figure 49–15. Mean (±SEM) serum total 25-hydroxyvitamin D [25(OH)D] and 1,25-dihydroxyvitamin D [1,25(OH)$_2$D] concentrations as a function of age in 15 preterm infants (birthweight, 1578 ± 78 g; gestational age, 31.7 ± 0.5 wk) who received 1000 IU/d of vitamin D (25 µg/d) from birth. Significantly different from cord serum: *$P < .05$, **$P < .01$, ***$P < .001$. *(From Salle BL, et al: Perinatal metabolism of vitamin D,* Am J Clin Nutr *71:1317S, 2000.)*

80 nmol/L. At the present time, however, consensus has not been reached with regard to the concentration of 25-OH-D to define vitamin D insufficiency for infants and children. Universal units of measure for 25-OH-D and 1,25-OH2-D are in nanomoles per liter (nmol/L). Conversion to nanogram per milliliter (ng/mL) is made by dividing the value expressed in nmol/L by 2.496. Thus, 80 nmol/L becomes 32 ng/mL.[5]

Calcitonin

SYNTHESIS AND METABOLISM

Calcitonin is a 32–amino acid peptide secreted by the thyroidal C cells, which also produce the calcitonin gene–related protein (CGRP). Calcitonin is also produced in other tissues, notably pituitary cells and other neuroendocrine cells in which calcitonin has a local paracrine effect but does not contribute to its peripheral effect. Both the *calcitonin/CGRP* and *PTH* genes are located on chromosome 11. The primary RNA transcript of the *calcitonin/CGRP* gene encodes two distinct peptides, calcitonin and calcitonin gene–related peptide-α (CGRPα). Cell-specific alternative RNA processing results in calcitonin being produced almost exclusively by the thyroidal C cell, and in CGRPα being produced throughout the central and peripheral nervous systems, acting as a vasodilator and a neuromodulator. The physiologic effects of CGRPα on bone are unclear.[49]

EFFECTS

The CaSR regulates serum calcium by suppressing the secretion of PTH; it also regulates renal tubular calcium excretion. It has recently been recognized that CaSR mRNA is also expressed by the C cells of the thyroid, the source of calcitonin. The CaSR has a dual physiologic response to acute increases in ionized calcium, which includes the inhibition of PTH release, the stimulation of calcitonin release, and the reverse effects in response to a decrease in calcium.[42]

The effects of calcitonin are independent of PTH and vitamin D action. Both ends of the molecule contain species-invariant residues that are required for its binding to receptors coupled with high-affinity G proteins on the osteoclast. Calcitonin inhibits extracellular Ca^{2+} sensing, a potent antiresorptive signal, and by implication, calcitonin withdrawal should enhance Ca^{2+} sensing and limit resorption. The principal effect of calcitonin is to decrease osteoclastic bone resorption and the amount of calcium and phosphorus released from bone. Additionally, calcitonin increases calcium and phosphorus excretion, so the overall effect of calcitonin is to decrease serum calcium and phosphorus concentrations. With regard to magnesium, calcitonin may decrease both its release from bone and renal tubular reabsorption. In humans, serum calcitonin rises during pregnancy, growth, and lactation. It is during these periods of calcium stress that a tonic antiresorptive hormone will best exert its effects to limit skeletal loss and promote mineral accretion. An additional effect of calcitonin is its stabilizing effect on bone microarchitecture, which precedes the changes in bone mineral density observed in its therapeutic use for Paget disease, hypercalcemia of malignancy, and osteogenesis imperfecta. Calcitonin has a very short half-life and is cleared mainly by the kidney. In general, however, the precise physiologic role of calcitonin in humans is still not well understood.[124]

REGULATION OF SECRETION

Secretion of calcitonin varies with acute changes in serum calcium concentrations: it increases when serum calcium increases and decreases when serum calcium falls. Under usual circumstances, calcitonin is secreted only when serum calcium reaches about 2.37 mmol/L (9.5 mg/dL). When serum calcium exceeds such concentrations, serum calcitonin and calcium concentrations are directly correlated. The calcitonin response to chronic changes in calcium is still controversial.

FETAL CALCITONIN FUNCTION

The role of calcitonin in fetal mineral metabolism has not been extensively examined. Calcitonin is expressed by human thyroidal C cells early in gestation, and it circulates in fetal blood at levels that are higher than those in the mother. In animal studies, the pharmacologic administration of calcitonin or calcitonin antiserum altered the serum calcium of fetal rats in predictable and opposite directions. However, fetal thyroidectomy with subsequent thyroxine replacement did not appear to affect fetal blood calcium, indicating that the physiologic amounts of calcitonin derived from the fetal thyroid may not be required to maintain normal serum calcium. In a study using a *calcitonin/CGRP* gene knockout model in mice, McDonald and colleagues[74] suggested that calcitonin and CGRP are not needed for normal fetal calcium metabolism—they may instead regulate some aspects of fetal magnesium metabolism. In human pregnancy, calcitonin concentrations are elevated in the fetus presumably because of the high fetal serum calcium concentrations, but the contributions of calcitonin to normal skeletal growth and reduced bone remodeling during fetal life have not been demonstrated.

NEONATAL CALCITONIN FUNCTION

At birth, serum calcitonin concentrations are higher in cord blood than maternal blood, and they increase further in the first 24 hours of life. Serum calcitonin may be higher in preterm than full-term infants and higher in hypocalcemic preterm infants than normocalcemic ones. Serum calcitonin is also higher in asphyxiated than nonasphyxiated, full-term infants. The physiologic importance of the postnatal increase of calcitonin is unclear. On the one hand, it may protect the skeleton from excessive bone resorption; on the other hand, it may contribute to neonatal hypocalcemia in some infants. It is uncertain whether calcitonin plays a specific role in neonatal hypocalcemia. Excess calcitonin would not explain the hyperphosphatemia commonly associated with neonatal hypocalcemia.

BONE DEVELOPMENT

Ontogenesis

The perinatal development of bone occurs through two separate but interrelated processes: intramembranous and endochondral.[98] In both mechanisms, bone is made in a precursor area occupied by fibrous mesenchyme or in an area of cartilaginous tissue. Intramembranous bone is the first to begin ossification. It does not have cartilaginous precursors, occurring largely in the bone of the skull, maxilla, and mandible, and results in mesenchymal cell differentiation to produce preosteoblasts and then osteoblasts, with the subsequent formation of an organic bone matrix (osteoid). The elaborated bony trabeculae then fuse to form the primary spongiosa. Osteoblasts cover the surface of the spongiosa and deposit new layers of the bone matrix while new bone is being removed from other surfaces by a special group of multinucleated phagocytic cells called *osteoclasts*. During development, the structure of the fibrous mesenchyme is continuously formed, allowing growth, whereas the osteoblastic and osteoclastic activities induce a remodeling process, with the net result of membranous bone formation and mineral deposition.

In contrast, all bones of the appendicular and axial skeleton grow by the transformation of growth plate cartilage into bone through a series of cell and matrix changes referred to as *endochondral ossification*. During development, the cartilaginous template increases in size by appositional and interstitial chondrocyte growth and by the continuous synthesis of a hyaline matrix. As the cartilage model continues to grow, the central chondrocytes hypertrophy and increase their cellular volumes. Calcium salts begin to precipitate in the matrix partitions separating the hypertrophic cells, and capillary buds penetrate the perichondrium and begin to invade the hypertrophic cell area. Osteoblasts appear in the wake of the capillary invasion and begin to lay down a thin collar of osteoid around the midsection of the cartilage model. Therefore, a medullary cavity is formed in the area that will become the midshaft of the long bone, establishing the first center of ossification. The perichondrium is called the *periosteum*. In this vascularized environment, the osteoblasts deposit layers of osteoid on the residual calcified cartilage, and bone tissue gradually replaces the formerly solid mass of cartilage. The cartilage, which is left at either end of the bone, forms the growth plate, permitting longitudinal growth of the bone. At the distal (epiphyseal) end of the growth plate the chondrocytes proliferate, lengthening the bone. Proximal to these cells, the cartilage becomes calcified. The calcified cartilage is partially resorbed by osteoclasts and subsequently replaced by woven bone. There is further remodeling in which woven bone is progressively replaced with lamellar bone. For long bone, the key features of its formation include the development of the primary ossification site, the appearance of a tubular diaphysis and marrow cavity, the location and geometry of the growth plate, and finally the appearance and location of the secondary ossification center, which develops mostly after term in the human neonate.

Detailed qualitative descriptions of metaphyseal bone histology during early development have been available for decades. More recently, histomorphometric data from femoral metaphyses in a group of 35 fetuses and newborns with gestational ages ranging from 16 to 41 weeks established morphometric reference data and provided the opportunity to gain insight into long-bone growth in humans. Despite a rapid rate of net bone gain, osteoid indexes were relatively low, indicating that mineralization occurred very rapidly after bone deposition and then suggesting that modeling, not remodeling, is the predominant mechanism responsible for the development of femoral metaphyseal cancellous bone in utero.[107] Therefore, during fetal life, various environmental factors are specifically oriented to promote growth, high mineral transfer, and increases in the physical mineral density of the skeleton.

Factors Affecting Growth and Mineralization

During gestation, the fetus receives an ample provision of nutritional supply through the placenta. Nitrogen, energy, minerals, and vitamins allow a high velocity of body length growth, representing about 1.2 cm per week during the last trimester of gestation. The fetus maintains its hypercalcemic state in a high calcitonin and estrogen environment, promoting the modeling-to-remodeling ratio in favor of modeling and thus increasing endocortical bone. In addition, according to the mechanostat theory of bone development, fetal bone is also driven by the mechanical force applied to the fetal skeleton during the intrauterine resistance training provided by regular fetal kicks against the uterine wall.[93,94] Consequently, at term, the newborn skeleton has a high physical density (bone mass divided by bone volume), with elevated cortical thickness and relatively small marrow cavities.

Various factors influence the processes of growth, mineralization, and bone structure. Growth is directly related to protein and energy supplies but also to the hormonal environment comprising insulin, IGF-1, and IGF-2, among others. Bone formation, mineralization, and structure are related to mineral supply and hormonal factors such as PTH, recombinant PTH, vitamin D, and calcitonin, as well as others, such as genetics and physical activity. Several factors have been found to have a significant impact on newborn bone mineral content and developing fetal bone.[81] Reduced calcium supply, vitamin D deficiency, ethanol consumption, and smoking during pregnancy are all factors affecting fetal skeletal development in addition to low weight related to gestation and diabetes in the mother.

Evaluation of Fetal Mineral Accretion

From cadaver analysis, the whole-body calcium accretion rate and bone composition have been determined and histomorphometric evaluation performed. At present, about 163 whole-body carcass analyses have been performed in deceased fetuses and newborn infants, allowing the estimation of intrauterine whole-body composition and the calculation of weight gain composition.[118] From these studies, it appears that in preterm and term infants who are appropriate for gestational age, whole-body calcium accretion was exponentially related to gestational age and linearly related to body weight. Similar values have been obtained with the use of neutron activation techniques.[36]

DEXA is becoming the most accurate and precise noninvasive technique for assessing bone mineralization in vivo. Validation of its use in subjects with low body mass has supported its increasing use in preterm and term infants.[118] After this validation study, normative data for bone mineral content (BMC) and projected bone area in 106 healthy preterm and term infants near birth were established to get reference intrauterine values (Fig. 49-16). BMC and bone area were positively related to body weight, body length, and gestational age.

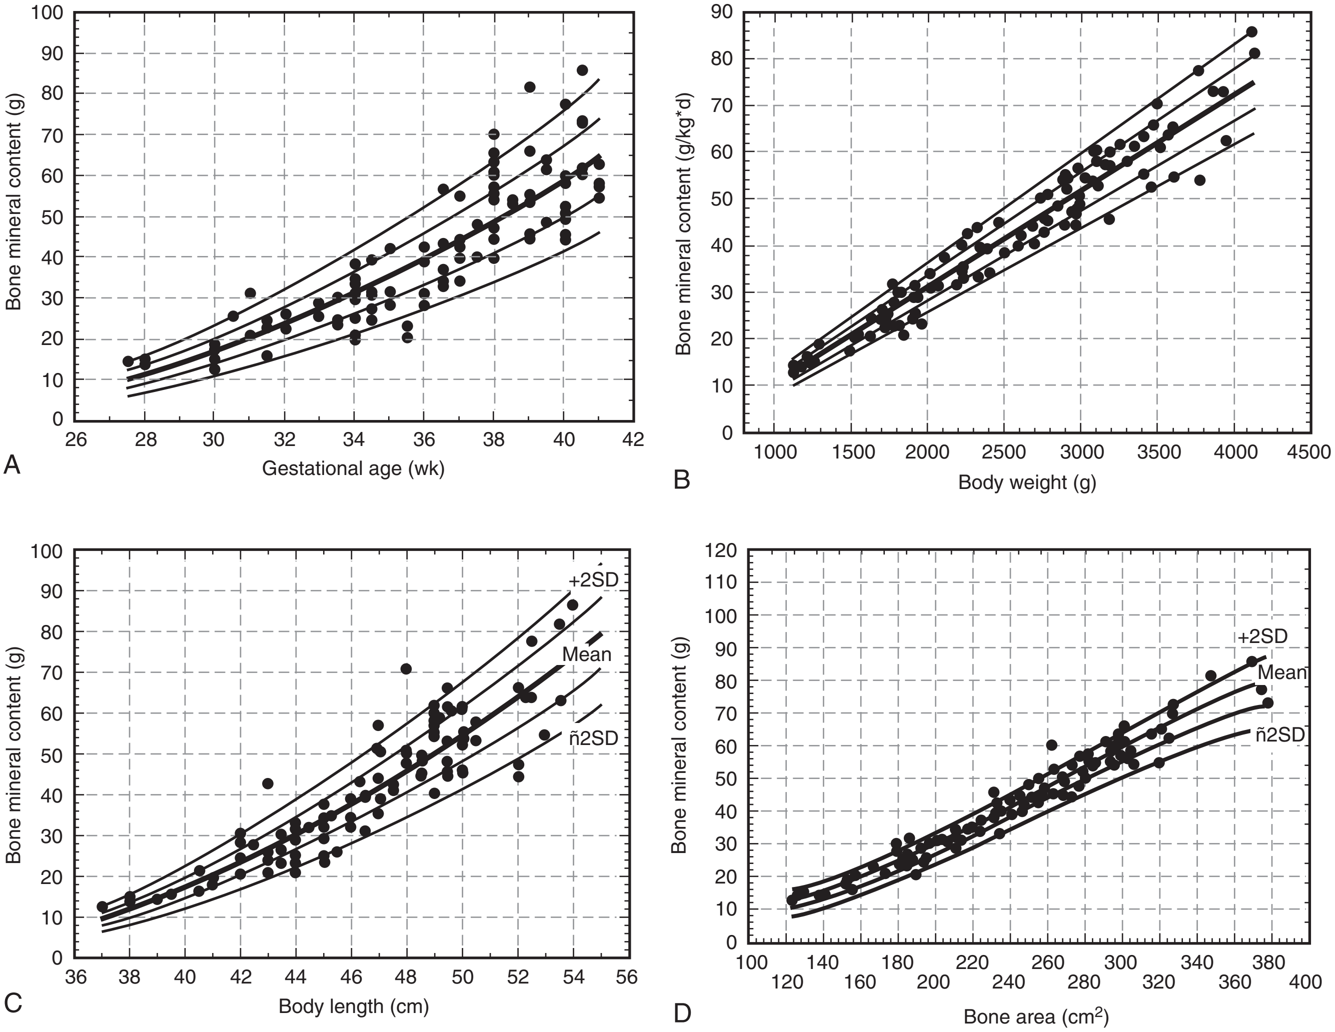

Figure 49–16. Reference values for bone mineral content related to gestational age (**A**), body weight (**B**), body length (**C**), and projected bone area (**D**) determined at birth in preterm and term infants ($n = 106$). *(From Rigo J, et al: Reference values of body composition obtained by dual energy X-ray absorptiometry in preterm and term neonates,* J Pediatr Gastroenterol Nutr *27:184, 1998.)*

However, in multivariate analysis, body weight was the major and also the only predictor of those parameters. The conversion equation for BMC to calcium allowed the calcium content to be compared with the data obtained from carcass analysis or with neutron activation analysis.[96] The perfect agreement between the in vivo calcium estimations and reference values suggests that the translation equation calculated in newborn piglets may be applied to newborn infants scanned with identical equipment soon after birth. However, the validity of the conversion of BMC to calcium content after the first few days of life was not confirmed in view of the major changes in bone growth and mineral deposition that occur after birth. Normative data for preterm and term infants are extremely limited and the results frequently difficult to compare because of the different equipment and software used.[46,60,88,107]

Isolated femurs obtained from human fetuses and newborn infants deceased near birth have been analyzed for chemical composition[34] and histomorphometric evaluation.[44,108] From those studies, it appears that the ratios of calcium to nitrogen and the mineralized bone volume to the total (mineralized and nonmineralized) femoral volume increase progressively during the second part of gestation. These and other data[96] suggest that during the last trimester of gestation, there is disproportionate mineral accretion. The ratio of mineralized to total bone volume increases continuously, leading to a progressive change in volumetric bone mineral density.

Quantitative ultrasound (QUS) has been proposed as a diagnostic tool to evaluate bone mineralization in newborn infants. It measures the speed of sound (SOS) propagation through the bone, which reflects, in addition to bone density, other bone properties such as cortical thickness, elasticity, and microstructure, thus providing more a complete picture of the bone strength. QUS has the advantage of being nonionizing, inexpensive, and portable. However, the values of SOS can be influenced by the operator's experience, humidity, and

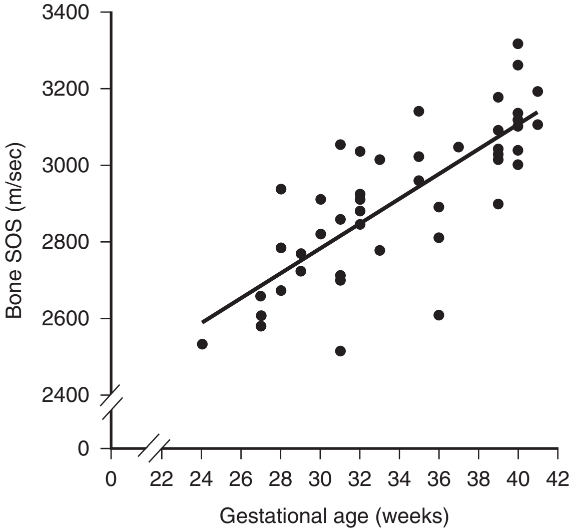

Figure 49–17. Cross-sectional relationship between tibial speed of sound (SOS) and gestational age (r = 0.78, $P < .0005$). *(From Nemet D, et al: Quantitative ultrasound measurements of bone speed of sound in premature infants,* Eur J Pediatr *160:736, 2001.)*

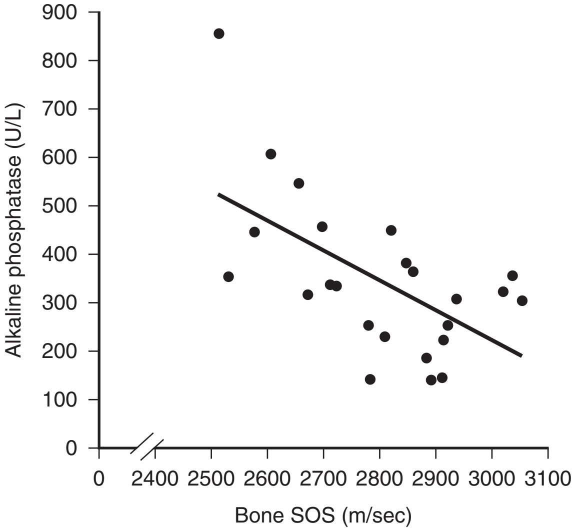

Figure 49–18. Cross-sectional relationship between tibial speed of sound (SOS) and serum alkaline phosphatase in premature infants (r = −0.59, $P < .005$). *(From Nemet D, et al: Quantitative ultrasound measurements of bone speed of sound in premature infants,* Eur J Pediatr *160:736, 2001).*

temperature. At birth, there is a significant correlation between tibial SOS values and gestational age (Fig. 49-17), birthweight, and birth length. The SOS values are significantly lower in preterm infants at birth compared with term infants and appear to fall when measured longitudinally in preterm infants. This indicates less mineral content in preterm infants than in term infants. The correlation between SOS values and biochemical markers of osteopenia of prematurity is controversial. Although some studies showed an inverse relation between alkaline phosphatase and SOS values (Fig. 49-18),[8,82] others failed to show this relationship.[72] QUS has potential use to assess bone health in the newborn, but it is not widely available, nor has it gained traction in clinical use.

Physiologic Skeletal Changes in the Early Postnatal Period

TERM INFANTS

At birth, there is an abrupt interruption of the nutrient supply from the mother through the placenta, and nutritional support is progressively provided by the gastrointestinal route. As a result, the relatively hypercalcemic fetus becomes a relatively hypocalcemic newborn, inducing a stimulation of PTH secretion. Therefore, there is a large reduction in calcium availability for bone mineralization compared with the prenatal situation. Indeed, in normal term infants fed human milk or a regular term formula, the calcium retention falls dramatically from 100 mg/kg per day to 20 to 30 mg/kg per day, whereas the growth rate remains relatively similar and close to 30 g/day. The hormonal environment changes postnatally because the placental supply of estrogen and many other hormones has been cut off. In addition, mechanical stimulation is likely to be lower postnatally. The infant's movements typically occur without much resistance, thus putting smaller loads on the skeleton.[76,93,94] Therefore, there is a need for postnatal adaptation of the skeleton, and some of the factors implied in the fetal modeling-to-remodeling ratio disappear, inducing an increase in endosteal bone resorption. The physical density of long bones such as the femoral diaphysis decreases by about 30% during the first 6 months of life. This change is mostly the result of an increase in marrow cavity size, which is faster than the increase in the cross-sectional area of the bone cortex.

In term infants, these postnatal changes have been classically called *physiologic osteoporosis of infancy*, but they appear to occur without an increase in bone fragility. This phenomenon is well illustrated by the evolution of bone mineral apparent density (BMAD, g/cm^3) during fetal life, in which there is a continuous increase that contrasts with that obtained from birth to the first months of life, at which time a rapid reduction in BMAD is observed (Fig. 49-19).

INFANTS WITH VERY LOW BIRTH WEIGHT

The goal of feeding regimens for infants with VLBW is to obtain a prompt postnatal resumption of growth to a rate approximating intrauterine growth (see Chapter 35). In practice, at birth there is an abrupt interruption of the nutrient supply from the mother through the placenta, and the nutritional support needs to be provided by parenteral and enteral routes. From preterm to term birth, the mineral supplies are far from those provided during fetal life, whereas length and skeletal growth remain relatively high. In addition, postnatal adaptations of the skeletal system to extrauterine conditions also occur in premature infants, with the difference being that they take place earlier than they do in term babies.[98] The process of birth interrupts active fetal bone mineralization and,

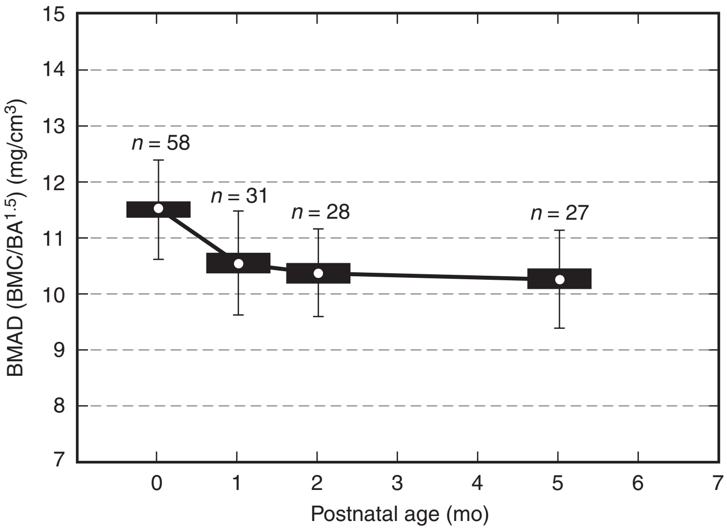

Figure 49–19. Change in bone mineral apparent density (BMAD) according to postnatal age in healthy term infants ($n = 144$). BMC, bone mineral content; BA, bone area.

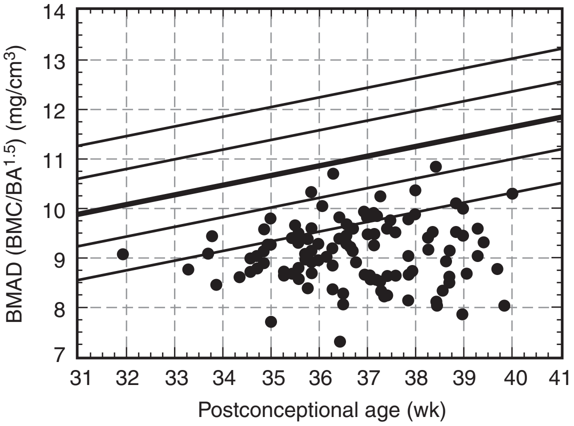

Figure 49–20. Comparison between bone mineral apparent density (BMAD) at discharge in infants with very low birthweight (•, $n = 108$) and reference values (regression lines, $n = 106$). BMC, bone mineral content; BA, bone area.

combined with the reduction in calcium availability, contributes to a reduction in bone physical density. These postnatal changes have been classically called *preterm osteopenia*, but contrary to those observed in term infants, these changes can be accompanied by an increase in bone fragility and the risk for fracture. In this situation, there is a sharp postnatal decrease in BMAD during the early postnatal weeks of life up to discharge near term (Fig. 49-20). The mechanisms of postnatal adaptation of the skeleton are not entirely clear, but it is probably of questionable benefit to require identical mineral supplies and retention in a fetus and preterm infant at similar postconceptional ages. Therefore, because of the difference between intrauterine and extrauterine conditions, the care of premature infants should not require the determination of intrauterine calcium accretion rates. Indeed, in the long run, the skeletons of these infants will adapt to the remodeling stimulation and the mechanical requirements, two factors that could reduce the nutritional requirements for calcium.

CLINICAL CONDITIONS ASSOCIATED WITH CALCIUM DISTURBANCES

Neonatal Hypocalcemia

Neonatal hypocalcemia has been variously defined as a calcium level of less than 2 mmol/L (1 mmol/L = 4 mg/dL), less than 1.87 mmol/L, or less than 1.75 mmol/L. This variance in definition is at least partially due to the lack of clinical signs in many neonates, even at a very low serum total calcium concentration.

A better definition of neonatal hypocalcemia would be based on the metabolically active component of calcium, ionized calcium, because changes in ionized calcium concentration are more likely to have physiologic significance. Under conditions of normal acid-base status and normal albumin levels, the serum total calcium level and Ca^{2+} are linearly correlated, so total serum calcium measurements remain useful as a screening test. However, because Ca^{2+} is the physiologically relevant fraction, in sick infants, it is preferable to directly determine Ca^{2+} in freshly obtained blood samples (see Appendix B).

Neonates at the greatest risk for symptomatic or asymptomatic neonatal hypocalcemia, such as the infants of diabetic mothers or preterm or asphyxiated neonates, are frequently sick for a multitude of reasons, and the contribution of neonatal hypocalcemia to signs related to their primary illness can be easily obscured. From a clinical viewpoint, because Ca^{2+} concentrations are maintained within narrow ranges under normal circumstances, the potential risk for disturbances of physiologic function increases as the Ca^{2+} concentration decreases. A useful approach to the classification of neonatal hypocalcemia is by time of onset. The early and late forms of hypocalcemia have different causes and occur in different clinical settings.

EARLY HYPOCALCEMIA

Refer to Boxes 49-5 and 49-6.

Term Infants

Early neonatal hypocalcemia occurs during the first 4 days of life and represents an exaggeration of the normal fall in serum calcium concentration that occurs during the first 24 to

BOX 49–5 Causes of Neonatal Hypocalcemia

EARLY HYPOCALCEMIA (1-4 DAYS OF AGE)

- Prematurity
- Maternal diabetes
- Perinatal stress, asphyxia
- Intrauterine growth restriction
- Maternal anticonvulsants

LATE HYPOCALCEMIA (5-10 DAYS OF AGE)

- Hyperphosphatemia (high phosphate load, advanced renal insufficiency)
- Hypomagnesemia
- Vitamin D deficiency
- Parathyroid hormone resistance (transient neonatal pseudohypoparathyroidism)
- Hypoparathyroidism
- Primary: parathyroid agenesis, 22q11 deletion, parathyroid hormone gene mutation
- Secondary: maternal hyperparathyroidism
- Calcium-sensing receptor defects, autosomal dominant hypocalcemic hypercalciuria
- Acquired or inherited disorders of vitamin D metabolism
- Neonatal hypocalcemia associated with skeletal dysplasia
- Other causes (alkalosis, citrated blood transfusions, phototherapy, viral gastroenteritis, lipid infusions)

BOX 49–6 Diagnostic Steps for Hypocalcemia

HISTORY

- Family
- Pregnancy (diabetes mellitus, hyperparathyroidism, intrapartum events, fetal distress, asphyxia)
- Nutritional supplies of the newborn infant

PHYSICAL EXAMINATION

- Jitteriness, apnea, cyanosis
- Seizures
- Associated features (prematurity, dysmorphism, congenital heart defect)

INVESTIGATIONS

- Total serum and ionized calcium, magnesium, phosphorus, glucose
- Acid-base balance
- Chest radiograph (e.g., thymic shadow, aortic arch position)
- Urinary calcium, magnesium, phosphorus, creatinine, drug screen
- Vitamin D metabolites
- Parathyroid hormone
- Calcitonin
- Others (e.g., malabsorption, lymphocyte count, T-cell numbers and function, maternal and family screening, molecular genetic studies)
- Genetic studies for 22g11 deletion

48 hours of life. At birth, there is an interruption of maternal calcium supply, and the serum calcium concentration in infants is maintained by either the increased calcium flux from bone or sufficient exogenous calcium intake. Trabecular bone, which is richly vascularized, represents the main source of potentially rapidly mobilized calcium. Because intestinal calcium absorption is correlated with intake and dietary calcium is usually low on the first day of life, the serum calcium concentration decreases on the first day of life.[55,104]

Normal serum concentrations for Ca^{2+} in full-term newborns reach a nadir at about 24 hours of age (1.10 to 1.36 mmol/L, or 4.4 to 5.4 mg/dL) and rise slowly thereafter. In full-term infants, hypocalcemia can be best defined as an ionized calcium concentration of less than 1.10 mmol/L (4.4 mg/dL), which is the standard nadir in normal infants. This concentration represents 2 standard deviations below the mean at 24 hours. This definition is a statistical one and is based on assumptions of normal distributions of physiologic variables. Further investigation needs to define physiologically important limits for term and preterm neonates. If an ionized calcium measurement is not available, the traditional definition—a total serum calcium concentration of less than 2.0 mmol/L (8.0 mg/dL)—can be used. Characteristically, early neonatal hypocalcemia occurs most frequently in preterm infants, asphyxiated infants, infants of diabetic mothers, and those with significant IUGR, and infants of mothers treated with anticonvulsants during pregnancy.

In preterm infants, the reference values for ionized calcium are available only for large, moderately premature infants who show values very similar to those for full-term infants. These cutoff values might not apply to smaller infants, given insufficient physiologic data on ionized calcium. At present, the traditional cutoff point, a total calcium content of less than 1.75 mmol/L (7.0 mg/dL), remains reasonable in infants with VLBW.

Preterm Infants

The frequency of hypocalcemia varies inversely with birthweight and gestational age. In preterm infants, the postnatal decrease in the serum calcium level typically occurs more rapidly than it does in term infants, the magnitude of the depression being inversely proportional to gestation. Many infants with low birthweight and nearly all those with extremely low birthweight (ELBW) exhibit total calcium levels of less than 7.0 mg/dL by day 2. However, the fall in Ca^{2+} is not proportional to that in total calcium concentration, and the ratio of ionized to total calcium is higher in these infants. The reason for the maintenance of Ca^{2+} is uncertain but is probably related to low serum protein concentration and pH associated with prematurity. The sparing effvect of Ca^{2+} may partially explain the frequent lack of signs in preterm infants with low total calcium levels.

Early neonatal hypocalcemia apparently results from the abrupt interruption of the placental supply and the low intake provided by oral and parenteral nutrition and also by the insufficient release of PTH by immature parathyroid glands or the inadequate responsiveness of the renal tubular cells to PTH. An exaggerated rise in calcitonin secretion in premature infants may play a contributory role.[55] In infants with VLBW, the high renal sodium excretion probably aggravates calciuric losses, and relative end-organ resistance to $1,25(OH)_2D_3$ may exist.

Hypocalcemia is temporary, and the serum calcium concentration gradually reverts to normal after 1 to 3 days. Factors contributing to serum calcium normalization include increased calcium intake with feedings, increased renal phosphorus excretion, and improved parathyroid function. Calcium supplementation may hasten the restorative process.

Maternal Diabetes

See Chapter 16.

Infants of diabetic mothers (IDMs) demonstrate an exaggerated postnatal drop in circulating calcium levels compared with controls of gestational age. Prematurity and birth asphyxia are frequently associated problems that independently increase the risk for hypocalcemia. In IDMs, hypocalcemia appears to be related to hypomagnesemia, the maternal form of which is caused by urinary magnesium losses with diabetes and leads to fetal magnesium deficiency and secondary functional hypoparathyroidism in the fetus and newborn. Hypocalcemia in IDMs is also correlated with the severity of maternal diabetes, which is classified by White's criteria. The natural history is usually similar to that of early neonatal hypocalcemia in preterm infants, but hypocalcemia sometimes persists for several additional days. Improved metabolic control for pregnant diabetic women has markedly diminished the occurrence and severity of early neonatal hypocalcemia in IDMs. The incidence of hypocalcemia is also increased in the infants of gestational diabetic mothers, and the role of hypomagnesemia has been demonstrated.[14]

Perinatal Asphyxia

In asphyxiated infants, the following factors may contribute to early hypocalcemia: a decreased calcium intake due to delayed feedings, an increased endogenous phosphorus load resulting from the reduction of the glomerular filtration rate, and an increased serum calcitonin concentration. Hyperphosphatemia may induce relative PTH resistance. Theoretically, the correction of acidosis with alkali may further aggravate hypocalcemia by inducing decreased calcium flux from bone to the extracellular fluid and by lowering the ionized calcium concentration.

Maternal Anticonvulsants

Anticonvulsants such as phenobarbital and diphenylhydantoin increase the hepatic catabolism of vitamin D and predispose to vitamin D deficiency in the absence of its appropriate supplementation. The infants of epileptic mothers may be at an increased risk for neonatal hypocalcemia. This complication can be prevented by maternal vitamin D supplementation (1000 IU/day) during pregnancy.

LATE HYPOCALCEMIA

Hypocalcemia is conventionally defined as late when it occurs after the first 4 days of life. Late neonatal hypocalcemia usually develops at about 1 week of age (see Box 49-5) and more frequently in term than preterm infants, and it is not correlated with maternal diabetes, birth trauma, or asphyxia. In some instances, the clinical distinction between early and late hypocalcemia may not be clear.

Phosphate Loading

Hypocalcemia induced by an elevated phosphorus supply usually occurs at the end of the first week of life. Late-onset hypocalcemia is considered to be a manifestation of relative resistance of the immature kidney to PTH. In these infants, the renal tubular cells are unable to respond appropriately to PTH, leading to renal retention of phosphorus and hypocalcemia. These biochemical features strongly resemble those of pseudohypoparathyroidism.[55,64,113] The normally low neonatal GFR may also play a role in limiting the ability to excrete the phosphorus load. Late hypocalcemia was frequently observed in infants fed cow's milk or evaporated milk because of their high phosphorus content. With the introduction of adapted infant formulas, late hypocalcemia, although not abolished, has become uncommon. However, even with current formulas, the formula-fed infants have lower serum ionized calcium and higher serum phosphorus in the first week of life than breast-fed infants. These differences correlate with the absolute phosphorus amount but not with the different calcium-to-phosphorus ratios in formulas. The phosphate load increases calcium bone deposition, leading to hypocalcemia. The normal response to hypocalcemia is an increase in PTH secretion, inducing an increase in both the urinary excretion of phosphate and the tubular resorption of calcium. The pathogenesis of this "transient hypoparathyroidism" in late neonatal hypocalcemia is poorly understood. The inadequate secretion of PTH, immaturity of PTH receptors, or transient change in the threshold of CaSR may play an important role.[120] Serum calcium levels frequently increase when these infants are given human milk, lower-phosphate formulas, and calcium supplements. After several days to weeks, serum PTH usually increases, and the infants are able to tolerate a higher dietary phosphate load. Some of these infants have a persistent or recurrent inability to mount an adequate PTH response to a hypocalcemic challenge and may have a form of congenital hypoparathyroidism.

Hypomagnesemia

Neonatal hypocalcemia usually accompanies hypomagnesemia because magnesium deficiency inhibits the secretion of PTH and reduces responsiveness to its action. Depression of the serum magnesium levels in newborns is due to primary hypomagnesemia with secondary hypocalcemia or transient hypomagnesemia.[55,104]

Primary hypomagnesemia with secondary hypocalcemia presents in infancy with persistent hypocalcemia and seizures that cannot be controlled with anticonvulsants or calcium gluconate. It is a rare autosomal recessive disorder resulting from primary defects in the intestinal transport of magnesium. The gene has been segregated to chromosome 9.[30] Serum magnesium is frequently less than 0.8 mg/dL (normally, 1.6 to 2.8 mg/dL), and circulating levels of PTH are low despite the presence of hypocalcemia. The administration of magnesium to these infants leads to spontaneous parallel increases in serum PTH levels, serum calcium levels, and renal phosphate clearance.

Transient neonatal hypomagnesemia often occurs in association with hypocalcemia. The decrease in the serum magnesium level is usually less severe (0.8 to 1.4 mg/dL) than that in magnesium transport defects. In many infants with transient hypomagnesemia, the serum magnesium level increases spontaneously as the serum calcium level returns to normal after the administration of calcium supplements.

Transient hypomagnesemia secondary to renal magnesium wasting can be caused by the administration of loop diuretics, aminoglycosides, amphotericin B, urinary tract obstruction, or the diuretic phase of acute renal failure. The disorder may be mistaken for a form of neonatal hypoparathyroidism because of tetany and hypocalcemia or confused with Bartter syndrome (hypokalemic alkalosis with hypercalciuria) because of secondary potassium wasting. The diagnosis can be made by finding low serum magnesium levels with inappropriately high urinary magnesium excretion. A common laboratory feature of magnesium depletion is hypokalemia. Attempts to restore the potassium deficit with potassium therapy alone are usually not successful without simultaneous magnesium therapy.

Neonatal Hypoparathyroidism

The biochemical characteristics of hypoparathyroidism are hypocalcemia and hyperphosphatemia in the presence of normal renal function. Serum PTH concentrations are low or undetectable. The causes of hypoparathyroidism are diverse, representing disruptions of one or more of the steps in the development and maintenance of PTH secretion.[70]

SECONDARY HYPOPARATHYROIDISM RELATED TO MATERNAL DISEASES

This transient condition may occur in the offspring of mothers with hyperparathyroidism or hypercalcemia from any cause. Maternal history may not be contributory because the maternal disease (usually a benign adenoma) may be asymptomatic and discovered only after the diagnosis is made in the newborn. Maternal hypercalcemia leads to fetal hypercalcemia and secondary fetal hypoparathyroidism. This condition resolves spontaneously in days to weeks, and supportive therapy with calcium, $1,25(OH)_2D_3$, or both usually suffices, but it may be temporally exacerbated by the feeding of high-phosphate diets.

DEVELOPMENTAL DEFECTS IN THE PARATHYROID GLANDS

The isolated absence of parathyroid gland development may be inherited in an X-linked or autosomal recessive fashion. The most well described example is DiGeorge syndrome (and the closely related velocardiofacial syndrome). Manifestations of these syndromes include incomplete development in the branchial arches, resulting in varying degrees of parathyroid and thymic hypoplasia; conotruncal cardiac defects; facial malformations; and learning disabilities. Both syndromes are associated with rearrangements and microdeletions affecting an unknown gene or genes on the short arm of chromosome 22q11. The constellation of abnormalities in DiGeorge syndrome has been referred to as CATCH 22 (*c*ardiac defects, *a*bnormal facies, *t*hymic hypoplasia, *c*left palate, *h*ypocalcemia). The presence of hypocalcemia with congenital abnormalities should prompt detailed genetic analysis, but it should be remembered that the calcium content may return to a normal level spontaneously (transient congenital hypoparathyroidism).

Isolated agenesis of the parathyroid glands in one family has been attributed to a recessive deletion in the gene on chromosome 6 that normally encodes a transcription factor.[70]

DEFECTS IN THE PARATHYROID HORMONE MOLECULE

A few cases of familial hypoparathyroidism have been described in which the cause was a mutation in the gene for PTH that resulted in the synthesis of a defective PTH molecule and undetectable amounts of PTH in serum.

DEFECTIVE REGULATION OF PARATHYROID HORMONE SECRETION

Hypocalcemia and hypercalciuria are the chief features of autosomal dominant hypercalciuric hypocalcemia, which is caused by activating mutations of the parathyroid and renal CaSR. These mutations cause excessive calcium-induced inhibition of PTH secretion. Hypocalcemia is usually mild and asymptomatic. When it is mild, it should be treated cautiously, if at all, because raising serum calcium concentrations further increase urinary calcium excretion and may cause nephrocalcinosis.[87]

Hypocalcemia Resulting from Vitamin D Disorder

Maternal vitamin D deficiency is the major risk for neonatal vitamin D deficiency presenting as hypocalcemia. Vitamin D deficiency is unusual in countries in which it is common practice to supplement the diet with vitamin D dairy products and other foods. However, it occurs in women in whom both sunlight exposure and the dietary intake of vitamin D are inadequate. At high risk are immigrants from the Middle East or South Asia who continue to wear traditional clothing. Therefore, if daily vitamin D supplementation during the duration of pregnancy can be undertaken, the amount given should be 400 IU/day (10 μg/day). In countries in which dairy products are not supplemented with vitamin D and sunshine exposure is low (e.g., in northern countries), or when presentation for antenatal care is delayed, 1000 IU/day (25 μg/day) should be given during the last 3 months of pregnancy, or 100,000 IU (2500 μg/day) in one dose at the beginning of the last trimester.[107] Breast-fed infants of strictly vegetarian mothers are also susceptible to early-onset hypocalcemic rickets. Daily supplementation of 400 IU for infants and 800 IU for pregnant and lactating women is considered sufficient to prevent neonatal rickets. The vitamin D requirements of preterm infants are influenced by body stores at birth, which in turn are related to the length of gestation and maternal stores. These factors should be taken into consideration when vitamin D supplementation policies are developed in each country. A daily dose of vitamin D of 400 IU (10 μg), independent of that contained in low-birthweight formulas, appears satisfactory in the United States. In contrast, a daily dose of vitamin D of 1000 IU (25 μg) has been recommended in the European Union, as in countries with poor maternal stores.[107]

Infantile Osteopetrosis

Autosomal recessive (“malignant”) osteopetrosis is a rare congenital disorder related to bone resorption abnormalities that may be fatal without hematopoietic stem cell transplantation. It is believed to arise as a result of the failure of osteoclasts to resorb immature bone, which leads to abnormal bone marrow cavity formation and to the clinical signs and symptoms of bone marrow failure. Impaired bone remodeling associated with the dysregulated activity of osteoclasts for such a condition may cause bony narrowing of the cranial nerve foramina, which in turn typically results in cranial nerve (especially optic nerve) compression. Abnormal remodeling of primary woven bone to lamellar bone results in brittle bone that is prone to fracture. Therefore, fractures, visual impairment, and bone marrow failure are the classic features of this disease.[28] Mutations in the *ATP6i* (*TCIRG1*) gene, encoding the α_3 subunit of the vacuolar proton pump, which mediates the acidification of the bone-osteoclast interface, are implicated in about 50% of the patients affected by this disease.[117] Osteopetrosis can present as late neonatal hypocalcemia (mean age at presentation, 12 days) and is diagnosed easily from its typical radiographic features.

Other Causes of Neonatal Hypocalcemia

Bicarbonate therapy, as well as any form of metabolic or respiratory alkalosis, decreases ionized calcium levels and bone resorption of calcium. Transfusion and plasmapheresis with citrated blood can form nonionized calcium complexes, thus decreasing Ca^{2+}. Furosemide and xanthine therapy promotes calciuresis as well as nephrolithiasis. Phototherapy appears to be an additional possible cause of neonatal hypocalcemia, although the mechanism is still uncertain. Lipid infusions may increase serum free fatty acid levels, which form insoluble complexes with calcium. Most of these effects are transient, and cessation of therapy is associated with a return to normal serum calcium levels.

CLINICAL MANIFESTATIONS OF HYPOCALCEMIA

The clinical manifestations of neonatal hypocalcemia in infants may be easily confused with other neonatal disorders (e.g., hypoglycemia, sepsis, meningitis, asphyxia, intracranial bleeding, narcotic withdrawal). The neonate with hypocalcemia may be asymptomatic; the less mature the infant, the more subtle and varied the clinical manifestations. In the neonatal period, the main clinical signs of hypocalcemia are jitteriness (increased neuromuscular irritability and activity) and generalized convulsions, although focal seizures have also been reported. Infants may also be lethargic, eat poorly, vomit, and have abdominal distention. The degree of irritability does not appear to correlate with serum calcium values. Furthermore, hypocalcemia may be asymptomatic. Therefore, suspicion of hypocalcemia should be confirmed by the measurement of total serum calcium and Ca^{2+}. The diagnostic workup for hypocalcemia (see Box 49-6) includes a history, physical examination, and relevant investigations. In clinical practice, the diagnosis of hypocalcemia is based on the determination of ionized or total calcium. Serum magnesium should also be measured because hypomagnesemia may coexist and cause identical signs. The measurement of calcium-regulating hormones is not routinely recommended unless hypocalcemia is prolonged, refractory, or recurrent. Chest radiographic examination for a thymic silhouette is indicated if DiGeorge syndrome is suspected. The measurement of electrocardiographic QT intervals, corrected for heart rate, is also of little value for the prediction of neonatal hypocalcemia. Assays of calciotropic hormones and 25(OH)D may be useful in the diagnosis of uncommon causes of neonatal hypocalcemia, such as primary hypoparathyroidism, malabsorption, and disorders of vitamin D metabolism. Molecular genetic studies may be needed to confirm a specific diagnosis and have potentially important clinical relevance for the patient's clinical outcome. Other investigations, which are listed in Box 49-6, may be important in the differential diagnosis and understanding of the pathophysiology of hypocalcemia

TREATMENT

Early Neonatal Hypocalcemia

The choice of treatment for early neonatal hypocalcemia is complicated by several factors, among them that (1) the condition may coexist with other neonatal complications (e.g., asphyxia, hypoglycemia) that cause similar signs; (2) it may be associated with seizures, which may have a different etiology; and (3) it may remain asymptomatic and in most newborns is a self-limited disorder.

SYMPTOMATIC HYPOCALCEMIA

The treatment of symptomatic hypocalcemia consists of the administration of calcium salts. Calcium gluconate is preferred over calcium chloride, which can cause metabolic acidosis. A 10% solution contains about 9.4 mg of elemental Ca per milliliter. In case of seizures, 2 mL/kg of calcium gluconate (about 18 mg/kg of elemental calcium) is given intravenously over 10 minutes, accompanied by heart rate monitoring. The infusion should be temporarily discontinued if bradycardia occurs. Toxic reactions may be avoided if the maximal intravenous dose of calcium gluconate administered at any one time does not exceed 2 mL/kg; doses above 3 mL/kg should be administered with caution. After the resolution of seizures, intravenous calcium solution may be continued at a dose of 1.87 mmol/kg (75 mg/kg) of elemental calcium per day until the serum calcium concentrations have remained consistently in the normal range. Thereafter, the intravenous calcium solution can be reduced in a stepwise fashion (i.e., 50% for 24 hours, 25% for another 24 hours) and then discontinued.

Complications of intravenous calcium therapy include extravasation into soft tissues (with calcium deposition and sometimes cutaneous necrosis) and bradycardia. Particular care should be exercised when calcium is infused into an umbilical venous catheter with the tip close to (or in) the heart. Because of the many potential risks, arterial infusions of calcium in high concentrations should be avoided. However, parenteral nutrition solutions containing standard mineral (including calcium) content can be safely infused through appropriately positioned umbilical venous or arterial catheters. The direct administration of calcium preparations with bicarbonate or phosphate solution results in precipitation and must be avoided.

As an alternative, if infants can tolerate oral fluids, the intravenous form of calcium gluconate can be given orally at the same dose after the initial correction. All calcium preparations are hypertonic, and there is the theoretical potential for precipitating necrotizing enterocolitis in infants at risk for this condition. The duration of supplemental calcium therapy varies with the course of hypocalcemia. As few as 2 or 3 days of therapy are usually required. However, the requirement for calcium therapy may be prolonged in the case of hypocalcemia caused by malabsorption or hypoparathyroidism. The serum calcium concentration should be measured daily during the first few days of treatment and for 1 or 2 days after its discontinuation until the serum calcium and Ca^{2+} concentrations are stabilized. Persistent hypocalcemia needs further investigation. A poor response to calcium therapy may often result from concurrent magnesium deficiency. The treatment of early neonatal hypocalcemia with vitamin D metabolites and exogenous PTH offers no practical advantage.

ASYMPTOMATIC HYPOCALCEMIA

In asymptomatic hypocalcemia, opinions vary on the need for and intensity of therapy. Some authors do not favor treatment because in most cases, hypocalcemia resolves spontaneously with time. However, hypocalcemia has potentially adverse effects on both the cardiovascular system and the central nervous system (CNS). It is common to treat asymptomatic full-term infants with an ionized calcium concentration of less than 1.10 mmol/L (4.40 mg/dL). For totally asymptomatic preterm infants, a cutoff point of 1.50 mmol/L (6.0 mg/dL) of total serum calcium is considered; however, clinical practice is extremely variable. The treatment of asymptomatic hypocalcemia can be instituted with oral or intravenous calcium salts by using the regimen indicated previously.

Late Neonatal Hypocalcemia

There is usually little debate regarding the treatment of late hypocalcemia. Because serum calcium is not routinely measured after the first few days of life, late hypocalcemia is usually symptomatic when diagnosed. In phosphorus-induced hypocalcemia, a low-phosphorus formula (or human milk) and oral calcium supplementation are indicated to decrease phosphorus absorption and increase calcium absorption.

In hypomagnesemia, the magnesium deficiency usually has to be corrected before hypocalcemia can be treated successfully. Magnesium may be administered intramuscularly or intravenously as a 50% solution of magnesium sulfate in a dose of 25-50 mg/kg (0.05-0.1 mL/kg). Intravenous infusions should be administered slowly with electrocardiographic monitoring to detect acute rhythm disturbances, which may include prolongation of atrioventricular conduction time and a sinoatrial or atrioventricular block. The magnesium dose may be repeated every 8-12 hours, depending on the clinical response and the (monitored) serum magnesium levels. Many infants with transient hypomagnesemia respond sufficiently to one or two injections of magnesium.

Infants with normal intestinal absorption who develop late hypocalcemia with vitamin D deficiency rickets usually respond within 4 weeks to 1000 to 2000 IU/day of oral vitamin D. These infants should receive at least 40 mg/kg per day of elemental calcium in order to prevent hypocalcemia because unmineralized osteoid is able to mineralize when vitamin D is provided (“hungry bones” syndrome).

Hypoparathyroidism requires therapy with vitamin D or one of its metabolites; $1,25(OH)_2D_3$ (or 1 α-hydroxyvitamin D_3, a synthetic analogue that undergoes hepatic 25-hydroxylation) has the advantage of a shorter half-life, and treatment may be more easily tailored to the individual patient. In the CaSR mutation, the need for therapeutic correction of hypocalcemia remains an open question considering that hypercalciuria and nephrocalcinosis may be deleterious to renal function.[66] Attention should be directed toward a number of concomitant treatments. Because thiazide diuretics can increase renal calcium reabsorption, the inadvertent institution or discontinuation of these drugs may increase or decrease, respectively, the plasma calcium level. In contrast, furosemide and other loop diuretics can increase the renal clearance of calcium and depress serum calcium levels. The administration of glucocorticoids antagonizes the action of vitamin D (and the analogues) and may also precipitate hypocalcemia. The development of hypomagnesemia may also interfere with the effectiveness of treatment with calcium and vitamin D.[55]

PREVENTION OF NEONATAL HYPOCALCEMIA

The most effective prevention of neonatal hypocalcemia includes the prevention of prematurity and birth asphyxia, the judicious use of bicarbonate therapy, and mechanical ventilation, for example, during the intentional induction of alkalosis in the treatment of persistent pulmonary hypertension, although this therapy has fallen out of favor. Maintenance of normal maternal vitamin D status with exogenous vitamin D supplements, if needed, may be helpful in maintaining normal fetal vitamin D status and may prevent late hypocalcemia in some neonates. The pharmacologic prevention of neonatal hypocalcemia, especially in infants with VLBW, is based on the prophylactic use of calcium salts, phosphorus salts, and vitamin D supplementation from the first day of life, with a regular survey of serum concentrations and urinary excretion.

Neonatal Hypercalcemia

Hypercalcemia is defined as a pathologic elevation in plasma ionized Ca^{2+} concentration greater than 1.35 mmol/L (5.4 mg/dL) with or without a simultaneous elevation in total calcium concentration of greater than 2.75 mmol/L (11.0 mg/dL).[55,101,102] Neonatal hypercalcemia is relatively uncommon, but it needs to be recognized because it can result in significant morbidity or mortality. The clinical symptoms of sustained hypercalcemia are not specific. Infants with mild increases in serum calcium (2.75 to 3.25 mmol/L, or 11 to 13 mg/dL) often fail to show specific symptoms of hypercalcemia. Nonspecific signs and symptoms such as anorexia, vomiting, and constipation (but rarely diarrhea) may occur with moderate to severe hypercalcemia. The presence of seizures, bradycardia, or arterial hypertension is very exceptional. On physical examination, infants may appear dehydrated, lethargic, and hypotonic. Those with chronic hypercalcemia may present with failure to thrive as the principal source of physical distress. Renal function is generally impaired, and polyuria and hypercalciuria are observed. However, renal complications such as nephrocalcinosis, nephrolithiasis, and hematuria may be the earliest clinical manifestations of hypercalcemia.

IATROGENIC HYPERCALCEMIA

Refer to Boxes 49-7 and 49-8.

Iatrogenic hypercalcemia is the most common type of hypercalcemia in the newborn and should be considered before starting extensive investigation of rare syndromes. It may result from excessive intravenous calcium administration during total parenteral nutrition or exchange transfusion. Other causes of iatrogenic hypercalcemia are the use of extracorporeal membrane oxygenation, which can cause transient hypercalcemia in up to 30% of infants, and vitamin D intoxication

BOX 49–7 Causes of Neonatal Hypercalcemia

IATROGENIC
Calcium salts, vitamin A
Hypophosphatemia (prematurity)
Hypervitaminosis D
Thiazide diuretics

DISORDERS OF PARATHYROID FUNCTION
Maternal hypocalcemia, hypoparathyroidism
Mutation of the parathyroid hormone–related protein receptor
- Jansen metaphyseal chondrodysplasia

Calcium-sensing receptor defects
- Familial hypocalciuric hypercalcemia
- Neonatal severe hyperparathyroidism

IDIOPATHIC INFANTILE HYPERCALCEMIA

HYPERPROSTAGLANDIN E SYNDROME

SEVERE INFANTILE HYPOPHOSPHATASIA

OTHER CAUSES
Congenital carbohydrate malabsorption
Distal renal tubular acidosis
Tumor-related hypercalcemia
Congenital hypothyroidism
Williams syndrome
Subcutaneous fat necrosis
Blue diaper syndrome

BOX 49–8 Diagnostic Steps in Hypercalcemia

HISTORY
Familial or maternal calcium or phosphorus disease
Traumatic birth
High maternal or neonatal supplies of vitamin D and/or A
Drugs during pregnancy (thiazide, lithium)

PHYSICAL EXAMINATION
Growth restriction
Lethargy, dehydration
Seizures, hypertension
Associated features (e.g., elfin facies, congenital heart disease, mental retardation, subcutaneous fat necrosis)

INVESTIGATIONS
Total and ionized calcium, phosphorus, magnesium, alkaline phosphatase
pH, total protein, creatinine
Urinary calcium, phosphorus, creatinine, cyclic adenosine monophosphate
Chest and long-bone radiographs
Renal ultrasound
Parathyroid hormone, 25-OH vitamin D, 1,25-OH vitamin D
Ophthalmologic evaluation, electrocardiography (QT interval)
Others: parathormone-releasing hormone, parental serum calcium and phosphorus concentrations, vitamin A
Molecular genetic studies

from the administration of excessive vitamin D supplements. Vitamin A toxicity is rare and can cause severe hypercalcemia. As vitamin A is metabolized by the kidney, renal insufficiency causes toxic accumulation, which probably directly acts on bone to cause increased resorption and hypercalcemia. Moderate hypercalcemia may also be the result of phosphorus deficiency in premature infants receiving unbalanced calcium and phosphorus regimens in oral and parenteral nutrition. In this situation, hypercalcemia is accompanied by hypophosphoremia. Infants with VLBW who are fed mineral-unsupplemented human milk may develop hypophosphatemic hypercalcemia. The low phosphorus concentration in human milk causes phosphorus deficiency, leading to an increased calcium concentration and hypercalciuria. The absorbed phosphorus is preferentially oriented for soft tissue formation, whereas the remaining phosphorus is insufficient to allow calcium deposition. Hypophosphatemia stimulates renal synthesis of calcitriol, which activates the intestinal absorption and skeletal resorption of calcium and phosphorus. Phosphorus supplementation and the use of human milk fortifiers can prevent hypophosphatemia and hypercalcemia. Similar situations have been reported in infants on parenteral nutrition, providing an unbalanced calcium-to-phosphorus ratio. Additionally, thiazide diuretics reduce renal calcium excretion and may represent a contributing factor.

CONGENITAL HYPERPARATHYROIDISM

Neonatal hyperparathyroidism is defined as symptomatic hypercalcemia with skeletal manifestations of hyperparathyroidism during the first 6 months of life. It may present in the first few days of life with PTH-dependent hypercalcemia, hypotonia, constipation, and respiratory distress.

Secondary Hyperparathyroidism

In many cases, a thorough investigation of the infant's mother will disclose previously known but poorly treated hypoparathyroidism, pseudohypoparathyroidism, or clinically unsuspected hypocalcemia, as seen in mothers with renal tubular acidosis that had induced severe secondary hyperparathyroidism in the developing fetus during pregnancy. The clinical presentation is variable and may depend on the severity of maternal hypocalcemia. Neonatal hypercalcemia is not a constant manifestation of this condition, whereas there is usually some radiologic evidence of metabolic bone disease. Secondary hyperparathyroidism is a transient condition with a good prognosis provided that supportive measures are instituted. Bone disease usually resolves by 6 months of age.

Primary Hyperparathyroidism

In other cases, heterozygous or homozygous loss-of-function mutations in the *CASR* gene cause neonatal hyperparathyroidism.[54,70,87]

The main forms of primary familial hyperparathyroidism presenting in infancy are autosomal dominant familial hypocalciuric hypercalcemia (FHH), resulting from an inactivating mutation of the *CASR* gene; neonatal severe hyperparathyroidism (NSHPT) in children with homozygous or double heterozygous mutations of the *CASR* gene; and sporadic neonatal hyperparathyroidism due to a de novo heterozygous *CASR* mutation. In many families, NSHPT and FHH are the homozygous and heterozygous manifestations, respectively, of the same genetic defect.

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA

FHH is characterized by lifelong and generally asymptomatic, modest elevations in serum calcium levels, with relative hypocalciuria and PTH levels that are not suppressed by hypercalcemia and are inappropriately normal. Hypercalcemia is accompanied by borderline hypermagnesemia and hypophosphatemia. The low urinary excretion of calcium is inappropriate considering the presence of hypercalcemia. Therefore, loss-of-function *CASR* mutations cause an increase in the set point for serum Ca^{2+}-responsive PTH release and elevate the renal calcium reabsorption at any given level of serum calcium, leading to hypercalcemia and hypocalciuria.

NEONATAL SEVERE HYPERPARATHYROIDISM

In contrast, individuals who are homozygous for *CASR* mutations have NSHPT, a disorder characterized by marked hypercalcemia, skeletal demineralization, and parathyroid hyperplasia, which can be fatal without parathyroidectomy.

NSHPT is generally manifested in the first few days of life with failure to thrive, hypotonia, constipation, and respiratory distress. Bony abnormalities are major and include undermineralization, subperiosteal erosion, metaphyseal destruction, and multiple fractures of both the long bones and ribs. It is often a life-threatening disorder, with a mortality rate of more than 25% in historical series. Children who survive NSHPT but remain hypercalcemic may feed poorly, with resulting failure to thrive; hypotonia; and developmental delay, and may be at risk for subsequent neurodevelopmental deficits. After the infant is rendered aparathyroid by surgical treatment, there is a dramatic fall in the serum calcium level, necessitating vitamin D and calcium therapy. Constitutional symptoms quickly reverse, with resolution of the bony abnormalities over about 6 months. Subtotal parathyroidectomy is often ineffective. Total parathyroidectomy with partial autotransplantation could be performed, leaving a minimal amount of parathyroid tissue necessary for normal calcium homeostasis. It has been suggested that the use of pamidronate may be helpful to stabilize life-threatening demineralization before parathyroidectomy in rescue situations.[123]

Williams Syndrome

Williams syndrome (also known as *Williams-Beuren syndrome*) is a multisystem disorder now recognized to be caused by a microdeletion of chromosome 7.[4] It is present at birth and affects boys and girls equally. Williams syndrome is characterized by dysmorphic, elfin facies (100%); cardiovascular disease (most commonly supravalvar aortic stenosis 80%); mental retardation (75%); a consistent cognitive profile (90%); and idiopathic hypercalcemia (15%). The microdeletion codes for the structural protein elastin explain some of the characteristics of Williams syndrome. The pathogenesis of other characteristics, such as hypercalcemia, mental retardation, and unique personality traits, remains unexplained.

Idiopathic infantile hypercalcemia (IIH) is an intriguing feature of Williams syndrome that can contribute to the presence of extreme irritability, vomiting, constipation, and muscle cramps associated with this condition. IIH usually occurs during the first year of life, with a peak between 5 and 8 months. Hypercalciuria in some infants may lead to nephrocalcinosis.[73,90] Symptomatic hypercalcemia usually resolves during childhood, but lifelong abnormalities of calcium and vitamin D metabolism may persist. The mechanisms responsible for hypercalcemia are not uniform. Some of these infants have elevated vitamin D metabolites, suggesting vitamin D intoxication or subtle renal dysregulation of vitamin D metabolism, both of which would account for the increased intestinal calcium absorption. In others, the vitamin D levels are normal, suggesting an increased sensitivity to vitamin D, again accounting for increased gut absorption. Recently, some infants have been found to have elevated PTHrP levels at the time of the onset of hypercalcemia. Its inheritance pattern is still questioned. The pedigree is consistent with autosomal recessive inheritance, but the presence of hypercalciuria among other family members suggests more complex inheritance.

Subcutaneous Fat Necrosis

See Chapter 28.

Subcutaneous fat necrosis is common in full- or late-term newborns who experience a traumatic or difficult delivery. Fat necrosis occurs in tissues that sustain direct trauma, such as those on which forceps or vacuum extraction is used. It is characterized by multiple indurated plaques or nodules with or without erythema on the cheeks, buttocks, posterior trunk, or extremities. Many lesions become calcified or fluctuant with liquefied fat. The cause of this disorder is unknown, but it may be initiated by ischemic injury, hypoxia, or hypothermia. Subcutaneous fat necrosis may be clinically occult, with spontaneous resolution over several weeks to as long as 6 months.[35,122] Hypercalcemia is uncommon, but it is the most frequently reported and serious complication of subcutaneous fat necrosis. Hypercalcemia usually appears when the subcutaneous fat necrosis begins to resolve, but it has been associated with long-term intellectual impairment and may be fatal if unrecognized, requiring the need for long-term monitoring of total and ionized calcium levels after the onset of skin lesions.

The pathogenesis of hypercalcemia is not fully understood. Three hypotheses have been proposed. In the first, the calcium is released from the resolving subcutaneous plaques, but most individuals do not develop hypercalcemia or have calcium deposition in the subcutaneous fat necrosis lesions. In the second, the elevated levels of PTH and prostaglandin E_2 stimulate bone resorption, but most patients have levels within the normal range. Elevated prostaglandin levels may be the result of emesis and therapy with furosemide. The third, the most widely accepted theory, proposes that the elevated $1,25(OH)_2D_3$ secreted from the granulomas of subcutaneous fat necrosis lesions stimulates intestinal calcium uptake. PTH normally stimulates the production of $1,25(OH)_2D_3$ from $25(OH)D_3$ by the kidney. The findings of low-normal PTH concentrations and elevated $1,25(OH)_2D_3$ support the hypothesis of the extrarenal production of $1,25(OH)_2D_3$.

Other Causes of Hypercalcemia

Congenital carbohydrate malabsorption can cause hypercalcemia during the first few months of life. Case reports have been provided for congenital lactase, glucose-galactose, or sucrase-isomaltase deficiency with hypercalcemia and nephrocalcinosis.[17,85] The etiology of hypercalcemia is unclear, but it is thought to be related to an increase in intestinal calcium absorption secondary to increased gut lactose or galactose or to metabolic acidosis, or both.

Distal renal tubular acidosis is another disorder associated with hypercalcemia and nephrocalcinosis. Metabolic acidosis also has a significant effect on calcium homeostasis. In chronic metabolic acidosis, the buffering of acidosis by bone salts is markedly enhanced. Bone demineralization results from the release of calcium carbonate from the bone to neutralize excess hydrogen ions. In addition to its other effects, metabolic acidosis reduces the urinary citrate concentration and increases the risk for the formation of insoluble calcium oxalate or phosphate crystals.

Severe infantile hypophosphatasia is an autosomal recessive disorder associated with a marked deficiency in serum and tissue alkaline phosphatase, skeletal demineralization and bone deformity, and hypercalcemia.[119] This disorder presents with a spectrum of clinical manifestations. The most severe form presents with polyhydramnios; extreme skeletal hypomineralization; short, deformed limbs; and fetal death. Less severe forms are carried to term, but the infant has hypercalcemia, severe rachitic changes, and undermineralized bone on radiograph. These less severe forms are generally lethal early in life. An additional clinical form, transmitted as an autosomal dominant trait characterized by perinatal symptoms but a better clinical course, has been described.[79]

Jansen metaphyseal chondrodysplasia arises from a heterozygous mutation in the PTH/PTHrP receptor. The receptor is found in the kidney, bone, and growth plate. The constitutive activity in bone causes hypercalcemia due to increased bone resorption and is lifelong. The aberrant receptor in the growth plate alters its function, resulting in postnatal-onset, short-limbed dwarfism. As infants, they are of normal length and appearance. However, in childhood, the phenotype becomes more apparent, with prominent hypertelorism, mandibular hypoplasia, and a progressive and disproportionately short stature. At birth, these infants have obvious bony lesions on radiograph, consisting of rachitic changes, radiolucencies, and irregularities of the metaphyses of the long bones.

Blue diaper syndrome is a rare familial disease in which hypercalcemia and nephrocalcinosis are associated with a defect in the intestinal transport of tryptophan. The mechanism of hypercalcemia is uncertain, although oral tryptophan loading in humans and experimental animals produces an increase in the serum calcium level. The bacterial degradation of tryptophan in the intestine leads to excessive indole production, which is converted to indican in the liver and causes indicanuria. The oxidative conjugation of two molecules of indican forms the water-insoluble dye indigo blue (indigotin), which causes a peculiar bluish discoloration of the diaper. The clinical course is characterized by failure to thrive, recurrent unexplained fever, infections, marked irritability, and constipation. Treatment consists of glucocorticoid administration and low calcium and low vitamin D diets.

Tumor-related hypercalcemia has been found in infants with increased levels of PTHrP, which is thought to be the causative agent of hypercalcemia.

Congenital hypothyroidism has also been associated with hypercalcemia, but the mechanism for its action has yet to be thoroughly clarified.

CLINICAL MANIFESTATIONS

Most infants are asymptomatic when diagnosed. Those with mildly elevated levels of calcium often fail to manifest specific symptoms of hypercalcemia. Infants with chronic hypercalcemia may present with failure to thrive as the principal source of physical distress. There are nonspecific signs and symptoms such as anorexia, vomiting, and constipation (but rarely diarrhea); polyuria may occur with moderate to severe hypercalcemia. In severe hypercalcemia, infants are often dehydrated, lethargic, and hypotonic. Alternatively, they may present with seizures. Clinically, these infants can have bradycardia, a short QT interval, and hypertension. However, renal complications such as nephrocalcinosis, nephrolithiasis, and hematuria may be the earliest clinical manifestations of hypercalcemia. Otherwise, the physical examination is usually normal except for the infants with subcutaneous fat necrosis, Williams syndrome, Jansen metaphyseal chondrodysplasia, and hypophosphatasia.

In clinical practice, the following approach may be useful. First, the possibility of iatrogenic hypercalcemia should be excluded. Second, a maternal history of calcium-phosphorus disease or excessive vitamin D intake during pregnancy should be investigated. Third, the signs of clinical syndromes associated with hypercalcemia, such as blue diapers, fat necrosis, and elfin facies, should be sought. Fourth, the initial laboratory evaluation should include serum calcium, phosphorus, alkaline phosphatase, PTH, the urinary calcium-to-creatinine ratio, and tubular reabsorption of phosphorus. In most cases, these tests allow the differentiation of hypercalcemia caused by parathyroid disorders from nonparathyroid conditions. In hyperparathyroidism, the serum phosphorus concentration is low; renal tubular phosphorus reabsorption is decreased, usually to less than 85%; and the serum PTH concentration is elevated. Finally, additional tests may be performed: A serum 25(OH)D_3 determination may be useful when an excess of vitamin D is suspected; long-bone radiographs identify demineralization, osteolytic lesions, or both (hyperparathyroidism), or osteosclerotic lesions (occasionally with vitamin D excess); measurements of serum and urinary calcium in parents allow a diagnosis of familial hypocalciuric hypercalcemia; and renal sonography detects nephrocalcinosis.

TREATMENT

The treatment of neonatal hypercalcemia depends on the severity of the presentation. Conservative management is appropriate in the case of mild hypercalcemia in a preterm infant resulting from an inappropriate mineral supply, hypoalbuminemia, or chronic acidosis, with special emphasis on the phosphorus supply when hypercalcemia is associated with hypophosphatemia. Hypercalcemia seen in newborns exposed to maternal hypocalcemia is usually mild and transient, and treatment consists of no more than supplying the appropriate amounts of calcium and phosphorus in the milk.

Infants with moderate to severe hypercalcemia need more aggressive treatment. The initial steps are not specific: (1) discontinue oral and intravenous calcium and vitamin D supplementation and dietary restriction; (2) increase the urinary excretion of calcium by maximizing glomerular filtration with the administration of intravenous fluids, which consist of standard saline at about twice the maintenance requirements; and (3) encourage calcium excretion with furosemide after rehydration but with particular attention to maintaining electrolyte homeostasis.

More specific therapy comprises the use of glucocorticoids, calcitonin, bisphosphonate, dialysis, and total parathyroidectomy. Glucocorticoids (2 mg/kg of prednisone) decrease intestinal calcium absorption, decrease bone resorption, and increase renal excretion. They may be useful during a short period, mainly in cases of an excess of vitamin D, but are relatively ineffective in cases of hyperparathyroidism. Calcitonin (4 to 8 IU/kg subcutaneously every 12 hours, up to a maximum of 8 IU/kg every 6 hours) reduces the serum calcium concentration, but its effectiveness declines after a few days. Bisphosphonate therapy is limited in newborn infants. However, pamidronate (0.5 to 2.0 mg/kg) has been used in the treatment of subcutaneous fat necrosis and could be an ideal agent to stabilize cases of NSHPT, as recently suggested. A calcimimetic drug that reduces PTH secretion, approved by the U.S. Food and Drug Administration for chronic secondary hyperparathyroidism in dialyzed patients, could be of major interest in primary hyperparathyroidism but needs to be evaluated during infancy.[120] Dialysis could be prescribed with a low-calcium dialysate (1.25 mmol/L) in the face of severe and unremitting hypercalcemia. Total parathyroidectomy with partial autotransplantation could be a rescue treatment in the severe form of NSHPT.

In the chronic phase, dietary restriction with the use of a special formula without vitamin D supplementation is the mainstay of treatment. If the dietary regimen is insufficient, corticosteroids can be used with caution. Cellulose phosphate binders have been occasionally used in children, but there is limited experience in neonates, and they may contain unwanted free phosphate.

Nephrocalcinosis in Preterm Infants

Nephrocalcinosis refers to deposits of calcium crystals diffusely located in the parenchyma of the kidney. The incidence is particularly high in infants with VLBW and ELBW. However, it varies widely between 1.7% and 64% depending on different study populations, ultrasonographic criteria, and equipment.[53,110] Ultrasonography has been found to be a sensitive and reliable method for the detection of nephrocalcinosis. It shows either bright reflections of 1 ± 2 mm without acoustic shadowing, defined as white flecks, or bright reflections larger than 2 mm with or without acoustic shadowing, defined as white dots. The etiology of nephrocalcinosis in preterm neonates has not been fully clarified. It develops as the result of an imbalance between stone-inhibiting and stone-promoting factors. Because of its hypercalciuric effect, furosemide therapy is most frequently mentioned as a provocative factor. Treatment with aminoglycosides, corticosteroids, and xanthines may also contribute to stone formation, and neonates with lower birthweight, shorter gestational age, and transient renal failure appear to run a higher risk. Moreover, preterm neonates receive a high intake of calcium, phosphorus, and vitamin D during the first months of life to prevent rickets of prematurity, with frequent calcium-phosphorus imbalance owing to poor solubility in parenteral nutrition and broad variability of intestinal absorption rates in enteral nutrition. Immature kidneys have relatively better developed deep nephrons, with a long Henle loop and probably a low urinary flow velocity. Therefore, conditions are favorable for the formation of crystals, which then stick to the surface and grow. Preterm neonates who develop nephrocalcinosis have a high urinary calcium-to-creatinine ratio, and an accompanying high intake of ascorbic acid might contribute to the high urinary oxalate-to-creatinine ratio, which is a potent lithogenic factor. In contrast, a low urinary citrate-to-calcium ratio, considered a lithoprotective factor, has been reported in infants with ELBW, suggesting that supplementation with alkaline citrate may have a beneficial effect in the prevention of nephrocalcinosis.[116]

The short- and long-term evolution of nephrocalcinosis has not been clearly defined. Ultrasonographic abnormalities that develop during the first months of life disappear in most patients within months to years. A study showed persistent nephrocalcinosis at 30 months of age in former preterm infants diagnosed with neonatal nephrocalcinosis.[111] Although proximal tubular function is unaffected in children with neonatal nephrocalcinosis, high blood pressure and impaired glomerular and distal tubular function might occur more frequently than in healthy term children.[111]

The long-term outcome of nephrocalcinosis in preterm neonates has not been defined, but small-scale studies suggest a decrease in renal function.[57] In contrast, nephrocalcinosis was not a prognosis factor for long-term (3 to 18 years) renal disease in infants with ELBW who had neonatal renal failure.[1]

CLINICAL CONDITIONS ASSOCIATED WITH MAGNESIUM DISTURBANCES

Hypomagnesemia

Hypomagnesemia occurs when serum magnesium concentrations fall below 0.66 mmol/L (1.6 mg/dL), although clinical signs often do not develop until they fall below 0.49 mmol/L (1.2 mg/dL). The signs of hypomagnesemia are the same as those of hypocalcemia: irritability, tremors, and seizures. Because serum magnesium does not reflect total-body magnesium, there is no strict correlation between the clinical signs and serum magnesium concentrations. Hypomagnesemia and hypocalcemia frequently coexist.

ETIOLOGY

Refer to Box 49-9.

Maternal Diabetes

In diabetes, glycosuria causes polyuria and increased urinary magnesium losses. The severity and prevalence of hypomagnesemia in the infants of insulin-dependent diabetic mothers are directly related to the severity of maternal diabetes, which is thought to reflect the severity of maternal magnesium deficiency. The incidence of hypomagnesemia is also increased in infants of gestational diabetic mothers.[14] Hypomagnesemia in IDMs (and infants of gestational diabetic mothers) is associated with neonatal hypocalcemia and decreased parathyroid

BOX 49–9 Neonatal Hypomagnesemia and Hypermagnesemia

NEONATAL HYPOMAGNESEMIA

Decreased magnesium supply

- Maternal magnesium deficiency
- Intrauterine growth restriction
- Maternal diabetes, insulin-dependent and gestational
- Malabsorption syndrome
- Extensive small intestine resection
- Intestinal fistula or diarrhea
- Hepatobiliary disorders
- Defect of intestinal magnesium transport: primary hypomagnesemia with hypocalcemia

Magnesium loss

- Exchange transfusion with citrated blood
- Decreased renal tubular reabsorption
- Primary:
  - Infantile isolated renal magnesium washing (dominant and recessive)
  - Hypomagnesemia with hypercalciuria and nephrocalcinosis
- Secondary:
  - Extracellular fluid compartment expansion, osmotic diuresis
- Drugs (e.g., loop diuretics, aminoglycosides)
- Other causes
- Increased phosphate intake
- Maternal hyperparathyroidism

NEONATAL HYPERMAGNESEMIA

Increased magnesium supply

- Maternal treatment with magnesium sulfate
- Neonatal magnesium therapy: asphyxia, pulmonary hypertension
- Parenteral nutrition
- Antacids, enema

function. Cord serum magnesium concentrations and its stores are decreased. Magnesium supplementation improves both serum calcium and PTH.

Intrauterine Growth Restriction

Some infants with IUGR manifest hypomagnesemia at birth. This manifestation may represent conditions in which maternal supply, placental transfer of magnesium, or both are deficient. Hypomagnesemia is seen especially in infants with IUGR born from young, primiparous, toxemic mothers.

Neonatal Hypoparathyroidism

PTH and serum magnesium concentrations are interrelated, so it may not be clear whether hypomagnesemia is the cause or the effect of hypoparathyroidism. A magnesium infusion test may help resolve the issue. If PTH increases after the magnesium load, magnesium deficiency with secondary functional hypoparathyroidism is likely. If PTH does not increase, hypoparathyroidism is probably unrelated to the deficiency.

Inherited Disorders of Renal Magnesium Handling

The genetic basis and cellular defects of a number of primary magnesium wasting diseases have been elucidated during the past decade.[30,31]

PRIMARY HYPOMAGNESEMIA WITH SECONDARY HYPOCALCEMIA

This is a rare autosomal recessive disorder resulting from primary defects in the intestinal transport of magnesium, with the responsible gene mapping to the long arm of chromosome 9. It presents in early infancy with persistent hypocalcemia and seizures that cannot be controlled with anticonvulsants, calcium gluconate, or both. Serum magnesium is frequently less than 0.8 mg/dL (normal, 1.6 to 2.8 mg/dL), and circulating levels of PTH are low despite the presence of hypocalcemia. In older children with inadequate magnesium control, clouded sensorium, disturbed speech, and choreoathetoid movements have been observed. The administration of magnesium to these infants leads to spontaneous parallel increases in serum PTH levels, serum calcium levels, and renal phosphate clearance. The prognosis is favorable if a diagnosis is made early enough.

INFANTILE ISOLATED RENAL MAGNESIUM WASTING (DOMINANT)

Hypomagnesemia as the result of isolated renal magnesium loss is an autosomal dominant condition associated with few symptoms other than chondrocalcinosis. Patients always have hypocalciuria and variable but usually mild hypomagnesemic symptoms.

INFANTILE ISOLATED RENAL MAGNESIUM WASTING (RECESSIVE)

There is evidence of a variant form of hypomagnesemia that is more consistent with isolated renal magnesium loss with autosomal recessive inheritance. Patients also have variable symptoms, but they usually have normal urinary calcium excretion.

HYPOMAGNESEMIA WITH HYPERCALCIURIA AND NEPHROCALCINOSIS

A distinct syndrome of hypomagnesemia with hypercalciuria and nephrocalcinosis (HHN) has been described. The HHN syndrome is an autosomal recessive disorder that is characterized by renal magnesium wasting and results in persistent hypomagnesemia and marked hypercalciuria, leading to early nephrocalcinosis. It is distinguished from other conditions by the absence of infantile hypocalcemic tetany and normal plasma potassium.

Other Causes of Hypomagnesemia

Secondary defects in the renal tubular reabsorption of magnesium may result from extracellular fluid expansion caused by excessive glucose, sodium, or fluid intake or by osmotic diuresis. Loop diuretics such as furosemide and high doses of aminoglycosides such as gentamicin may cause magnesuria. Any severe malabsorption syndrome can cause magnesium deficiency. In the neonatal period, multiple exchange blood transfusions, with citrate as an anticoagulant, result in the complexing of citrate with magnesium, which leads to hypomagnesemia.

CLINICAL MANIFESTATIONS

Hypomagnesemia in the neonatal period is usually transient (except for malabsorption syndromes) and asymptomatic, but it can cause hyperexcitability and occasionally severe, intractable hypocalcemic seizures that are unresponsive to calcium infusion and anticonvulsants. Hypomagnesemia should be considered in any patient with hypocalcemia that does not respond clinically or biochemically to calcium or vitamin D therapy.

TREATMENT

Hypomagnesemia should not be treated with calcium or vitamin D, which may cause a further decrease in serum magnesium. The administration of magnesium salts is the treatment of choice. The average amount of magnesium sulfate required in the neonate is a 50% solution of magnesium sulfate, 0.05 to 0.1 mL/kg (0.1 to 0.2 mmol/kg, or 2.5 to 5.0 mg/kg of elemental magnesium), given intramuscularly or by slow intravenous infusion over 15 to 20 minutes. Repeated doses may be required every 8 to 12 hours. Possible complications of intravenous infusion include systemic hypotension and prolongation or even blockade of sinoauricular or atrioventricular conduction.

Concomitant oral magnesium supplements can be started if oral fluids are tolerated. A 50% solution of magnesium sulfate can be given at a dose of 0.2 mL/kg per day. In specific magnesium malabsorption, daily oral doses of 1 mL/kg per day may be required. Daily serum magnesium concentrations should be measured until the values are stable to evaluate efficacy and safety. Oral magnesium salts are not well absorbed, and large doses may cause diarrhea. The maintenance magnesium supplement should be diluted fivefold to sixfold to allow for more frequent administration, maximizing gut absorption and minimizing side effects.

Neonatal seizures due to hypocalcemia and hypomagnesemia do not have a uniformly favorable outcome. Neurologic abnormalities at follow-up have been found in about 22% of patients.

Hypermagnesemia

Hypermagnesemia is defined as a serum magnesium concentration of greater than 1.15 mmol/L (2.8 mg/dL). Hypermagnesemia is invariably an iatrogenic event caused by excessive magnesium administration. Because magnesium balance is regulated mainly by the kidneys, decreased renal function can be a contributing factor.

ETIOLOGY

Refer to Box 49-9.

Maternal Treatment with Magnesium Sulfate

Magnesium sulfate is used to prevent seizures in preeclampsia and as a tocolytic agent (see Chapters 15 and 17). Maternal hypermagnesemia results in fetal and neonatal hypermagnesemia. Concomitant maternal hypocalcemia may also occur secondary to decreased serum PTH concentrations. With the current treatment of preeclampsia, the neonatal serum magnesium concentration usually does not rise to a potentially dangerous level and gradually returns to normal after a few days.

Excessive Magnesium Administration

Treatment with magnesium-containing antacids for the prevention and treatment of stress ulcers has been reported to cause hypermagnesemia. Excessive magnesium administration with total parenteral solution is a potential cause of hypermagnesemia, especially in sick neonates.

High doses of intravenous magnesium sulfate have been used in the treatment of persistent pulmonary hypertension in the newborn. At high doses, magnesium appears to reverse the hypoxia-induced increase in pulmonary arterial pressure.

CLINICAL MANIFESTATIONS

Hypermagnesemia should be suspected in depressed infants born to mothers who have been treated with magnesium sulfate. In most cases, hypermagnesemia is associated only with hypotonia. However, in extreme cases severe neuromuscular depression (a curare-like effect) and respiratory failure (CNS depression) may occur. In adults, the signs may include neuromuscular depression and hypotension (usually at magnesium concentrations of greater than 1.64 to 2.46 mmol/L, or 4 to 6 mg/dL), difficult urination (greater than 2.05 mmol/L, or 5 mg/dL), CNS depression (greater than 2.46 to 3.28 mmol/L, or 6 to 8 mg/dL), and respiratory depression and coma (greater than 4.92 to 8.33 mmol/L, or 12 to 17 mg/dL).

Serum calcium concentrations may be normal, decreased, or increased in hypermagnesemic neonates. Hypermagnesemia may suppress PTH and 1,25$(OH)_2D_3$ production and may result in lower serum calcium concentrations. Rickets has been reported when maternal magnesium therapy is prolonged (e.g., in tocolysis to prevent preterm delivery).

TREATMENT

In most cases of neonatal hypermagnesemia, supportive treatment is sufficient because an excess of magnesium is gradually removed through urinary excretion. Calcium is a direct antagonist of magnesium, and intravenous calcium given at the same dosage as that given for the treatment of hypocalcemia may be useful for acute therapy. Optimal hydration is important to ensure adequate urinary flow. Loop diuretic therapy may increase magnesium excretion. In cases of severe CNS depression, exchange blood transfusions may be used to lower the increased serum magnesium concentration. Citrated donor blood is particularly useful because the complexing action of citrate expedites the removal of magnesium from the infant. Peritoneal dialysis and hemodialysis may be considered in refractory patients. Supportive measures such as cardiorespiratory assistance and adequate hydration may be needed.

OSTEOPENIA OF PREMATURITY

Premature babies are at increased risk for developing bone disease by reduced bone mineral content. Increased survival of infants with VLBW has been associated with an increased incidence of osteopenia of prematurity, which is also called *metabolic bone disease* or *rickets of prematurity*. The incidence is inversely proportional to gestational age and birthweight, and two decades ago, it was estimated to be 50% in infants weighting less than 1000 g and 23% to 32% in infants weighting less than 1500 g; however, the current incidence is difficult to estimate because the nutritional strategy has changed. Maximizing calcium and phosphorus intake from parenteral and enteral nutrition, early initiation of feeding, and decreased use of paralysis during mechanical ventilation probably have decreased the incidence of the disease.

Etiology

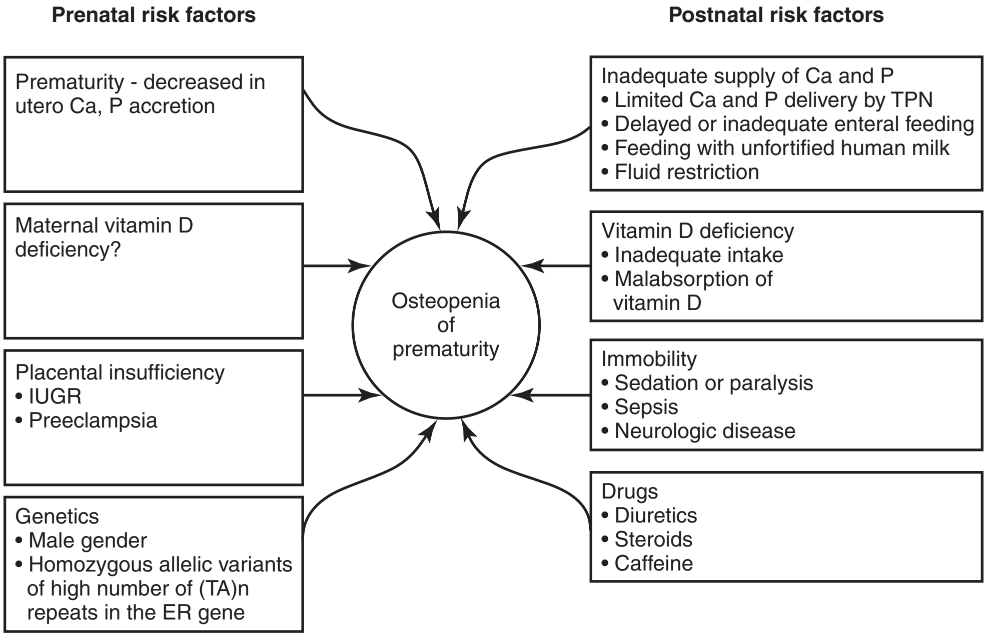
From birth, premature babies begin the process of physiologic postnatal adaptation, which is characterized by an increase in bone remodeling, with a progressive increase in marrow cavity size and a concomitant reduction in physical density. The reasons for the postnatal adaptation of the skeleton are not entirely clear, but it is obvious that the skeleton is exposed to different conditions before and after birth. First, in utero mechanical stimulation is likely to be higher. In utero movement offers more resistance against the uterine wall than spontaneous movements occurring after birth in infants with VLBW.[94] Second, the hormonal situation is different postnatally because the placental supply of estrogen and many other hormones has been cut off. Third, mineral supplies differ greatly from those provided during fetal life, while length and skeletal growth rates remain relatively high during the last trimester of gestation.[98] During the last trimester of gestation, the daily accretion rate per kilogram of body weight represents around 120 mg of calcium and 70 mg of phosphorus, which contrasts with the 40 to 90 mg of calcium and 30 to 60 mg of phosphorus retention obtained by metabolic balance studies in preterm infants fed fortified human milk or preterm formula.

Although vitamin D deficiency can cause rickets, it is not the primary cause of osteopenia of prematurity; vitamin D supplementation alone does not reduce the incidence of rickets. Adequate serum concentrations of 25(OH)D_3 and 1,25$(OH)_2D_3$ can be achieved with supplementation of 400 to 1000 IU/day of vitamin D. The role of maternal vitamin D status in the development of osteopenia of prematurity is not clear, although low maternal vitamin D status is associated with reduced bone mineralization of offspring in term infants.

Additional risk factors for bone disease in preterm infants include prolonged parenteral nutrition, feeding with unsupplemented human milk, fluid restriction, chronic illness, and the use of hypercalciuric drugs such as furosemide for the treatment of bronchopulmonary dysplasia and methylxanthines for the treatment of apnea and bradycardia, both of which increase calcium loss. The use of postnatal steroids can decrease bone formation. In addition, immobility, especially for prolonged periods of sedation during mechanical ventilation, could enhance calcium loss and demineralization. There is evidence that placental insufficiency has a role in the development of osteopenia of prematurity. There is an increased incidence of osteopenia of prematurity in infants with IUGR[51] or born to mothers with preeclampsia.[22] Severe demineralization has also been reported in infants born to a mother with severe chorioamnionitis.[106]

Development of osteopenia of prematurity in preterm infants may be associated with genetic polymorphisms. Candidate genes associated with adult osteoporosis have been evaluated for bone disease in infants in VLBW. A correlation between osteopenia of prematurity and thymine-adenine repeat [(TA)n] allelic variant in the estrogen receptor gene has been described.[21] A summary of the risk factors that contribute to the development of osteopenia of prematurity is illustrated in Figure 49-21.

The rate of rickets is inversely related to birthweight. Despite the differences in incidence according to reference criteria, significant bone demineralization was diagnosed by DEXA at term in more than 50% of infants with a birthweight of less than 1500 g and close to 100% of those with a birthweight of less than 1000 g.



Prenatal risk factors
Postnatal risk factors
Prematurity - decreased in utero Ca, P accretion
Maternal vitamin D deficiency?
Placental insufficiency
• IUGR
• Preeclampsia
Genetics
• Male gender
• Homozygous allelic variants of high number of (TA)n repeats in the ER gene
Osteopenia of prematurity
Inadequate supply of Ca and P
• Limited Ca and P delivery by TPN
• Delayed or inadequate enteral feeding
• Feeding with unfortified human milk
• Fluid restriction
Vitamin D deficiency
• Inadequate intake
• Malabsorption of vitamin D
Immobility
• Sedation or paralysis
• Sepsis
• Neurologic disease
Drugs
• Diuretics
• Steroids
• Caffeine

Figure 49–21. Prenatal and postnatal risk factors for development of osteopenia of prematurity. Ca, calcium; IUGR, intrauterine growth restriction; P, phosphorus; (TA)n, thymine-adenine repeat; TPN, total parenteral nutrition; VDR, vitamin D receptor; COLIA1, collagen I-α1.

Diagnosis

CLINICAL SYMPTOMS

Clinical symptoms of osteopenia are rare in infants with VLBW because of the widespread use of well-balanced parenteral solutions, human milk fortifiers, and preterm formulas. Fractures, which represent the major symptom and were detected in up to 24% of infants with VLBW in the late 1980s, have diminished.[61]

BIOCHEMICAL FEATURES

Biochemical features are relatively nonspecific. Usually serum calcium concentrations are within the normal range and serum phosphorus concentrations are normal or low at the time of diagnosis. The occurrence of a prolonged reduction of serum phosphorus during the early weeks of life could be predictive of the occurrence of osteopenia because infants with ELBW are at risk for low renal phosphate reabsorption (tryptophan and GFR values), leading to urinary phosphate excretion even in the presence of low serum phosphate levels. Therefore, the absence of or very low urinary phosphate excretion also needs to be considered as an indicator of phosphate depletion. Alkaline phosphatase is frequently used to screen for osteopenia of prematurity despite conflicting evidence about its sensitivity and specificity.[47] Alkaline phosphatase of more than five times the upper adult limit of normal has been suggested as indicator of rickets. Radiologic changes of osteopenia were detected in one study when the alkaline phosphatase was greater than 750 IU/L.[43] The peak alkaline phosphatase level is inversely related to the serum phosphorus concentration.[78] Therefore, the combination of alkaline phosphatase and serum phosphorus concentration could be more useful to screen for osteopenia of prematurity than alkaline phosphatase alone. Alkaline phosphatase level higher than 900 lU/L has predicted radiographic osteopenia by DEXA scan with 88% sensitivity and 71% specificity, but the sensitivity is much higher with concomitant lower serum phosphorus concentrations ($<$1.8 mmol/L).[13] Other studies have found that neither alkaline phosphatase nor serum phosphorus can predict bone mineralization outcome in premature infants.[40] Therefore, following sequential levels of alkaline phosphatase rather than a single level could be more useful to screen and to monitor treatment of osteopenia of prematurity.

HORMONAL FEATURES

In preterm infants, the serum PTH, serum 25(OH)D_3, and serum 1,25$(OH)_2D_3$ concentrations increase during the first month of life. Both 25- and 1,25-hydroxylation mechanisms are functionally active in preterm infants. Both the 25(OH)D_3 and 1,25$(OH)_2D_3$ levels are related to the mother's vitamin D status at birth as well as to the vitamin D supply to the newborn during the first weeks of life. In infants with VLBW supplemented with vitamin D, osteopenia does not appear to be related to the hormonal status.

RADIOLOGIC FEATURES

Standard radiographs do not allow an accurate assessment of bone demineralization. Bone mineral density must decrease by 30% or more to be diagnosed by this method, and interobserver variability is considerable. However, standard radiographs can detect fractures, and a wrist radiograph at 6 to 8 weeks of age remains a practical assessment of the presence of overt rickets. Radiographs must be carefully examined because fractures, especially line fractures, are easily missed. DEXA is the current standard in whole-body mineral measurement, and normative data are available. DEXA equipment is not portable, so performing a scan involves transportation of the infant, which may not be feasible for very small and sick infants who are at the greatest risk for metabolic bone disease. Ultrasound quantification by the measurement of SOS is presently under evaluation,[83,105] as discussed earlier.

Prevention and Treatment

Calcium and phosphorus requirements in preterm infants are usually based on demands for matching intrauterine bone mineral accretion rates and the maintenance of serum calcium and phosphorus concentrations comparable to those of normal term infants. However, more recent consideration of bone physiology suggests that the process of postnatal adaptation could modify the requirement, considering that the remodeling stimulation by itself provides part of the mineral requirement necessary for postnatal bone turnover. Under extrauterine conditions, the care of premature infants should not necessarily aim to achieve intrauterine calcium accretion rates. Subsequently, the skeletons of these infants will adapt to the mechanical requirements whether intrauterine calcium accretion rates are achieved or not.[2]

PARENTERAL NUTRITION

See Chapter 35.

Inadequate calcium and phosphorus intake has been associated with diminished bone mineralization in parenterally fed premature infants. This deficiency occurs when protein and energy are adequate for growth but calcium and phosphorus are insufficient to sustain appropriate skeletal mineralization. Calcium and phosphorus cannot be provided through parenteral solutions at the concentrations needed to support in utero accretion because of precipitation. The solubility of calcium and phosphorus in parenteral solutions depends on the temperature, type, and concentration of amino acids; dextrose concentrations; pH of the calcium salt; sequence of the addition of calcium and phosphorus to the solution; calcium-to-phosphorus ratio; and presence of lipids. More acidic pediatric amino acid solutions improve calcium and phosphorus solubility. With a range of fluid intake of 120 to 150 mL/kg per day, it is advisable to supply a calcium content of 50 to 60 mg/dL (1.25 to 1.5 mmol/dL) and a phosphorus content of 40 to 45 mg/dL (1.25 to 1.5 mmol/dL), corresponding to a calcium-to-phosphorus ratio of 1.3:1 by weight and 1:1 by molar ratio in the total hyperalimentation solution. This quantity of calcium provided by the parenteral route is about 60% to 75% of that deposited by the fetus during the last trimester of gestation (100 to 120 mg/kg per day) but similar to or higher than that obtained in enteral nutrition with presently available preterm formulas. Administering sufficient amounts of calcium and phosphorus in hyperalimentation solutions is no longer a problem in countries in which organic phosphate preparations are available. The use of calcium glycerophosphate has the additional benefit of a much lower content of aluminum. However, information on bone mineralization in infants with ELBW receiving what appears to be adequate calcium and phosphate intake is still limited.[99]

ENTERAL NUTRITION

See Chapter 35.

The exclusive use of human milk without phosphorus and mineral fortification promotes the occurrence of osteopenia and rickets in infants with VLBW. Both liquid and powdered human milk fortifiers are commercially available. Their use has dramatically reduced the incidence of fractures and radiologically diagnosed osteopenia. A similar reduction has also been observed in preterm infants fed preterm formulas. In contrast, a significant reduction in BMC related to gestational age, body weight, and bone area as well as BMAD is still observed in most infants with VLBW at the time of discharge.[32,98]

Although both the absorption and retention rates of calcium and phosphorus are higher in infants than adults, intestinal absorption of minerals remains a limiting factor of mineral accretion. The range of calcium and phosphorus contents is wide in preterm formulas (70 to 140 mg/100 kcal and 50 to 108 mg/100 kcal, respectively). However, standard balance studies have reported that absorption rates are about 60% for calcium in human milk but tend to decrease up to 35% in formulas containing the highest calcium content (see Table 49-3). In contrast, phosphorus is generally well absorbed (80% to 90%), but phosphorus retention is related to calcium and protein accretion. These figures are similar to those obtained with stable-isotope techniques, taking into consideration the endogenous intestinal calcium secretion. The high fecal calcium excretion observed in preterm infants fed high-calcium preterm formulas is not necessarily beneficial because it has been related to impaired fat absorption, stool hardness, and prolonged gastrointestinal transit time.

MONITORING MINERAL SUPPLEMENTATION

As stated previously, there are very few markers of adequate bone mineralization during the early weeks of life in newborn infants. BMC can be measured accurately by DEXA, but in clinical practice, it is performed in very few centers.

An ideal approach to assess the adequacy of mineral intake may involve the following recommendations:

1. Calcium and phosphorus need to be provided together from the first hours of life in a well-balanced parenteral solution when necessary.
2. Vitamin D supplementation (400 to 1000 IU orally or 160 to 320 IU parenterally) according to maternal status and seasonal variation may be provided from the first day of life.
3. Serum phosphorus concentrations should be regularly determined and maintained above 6 mg/dL (2 mmol/L). Serum phosphorus is much more loosely regulated than serum calcium and may be an effective indicator of the adequacy of mineral intake.
4. Urinary calcium and phosphorus should be measured. Because phosphorus excretion is inversely related to calcium excretion, the simultaneous presence of both calcium and phosphorus in spot urine samples in a ratio of less than 0.5 indicates that both are provided in sufficient amounts. Conversely, the absence of either calcium or phosphorus from urine samples indicates a deficiency of one of these minerals and that maximal tubular reabsorption is in effect.
5. Serum alkaline phosphatase should be measured. It is of limited absolute value given its wide fluctuation, but marked elevations (more than five times the normal rate, or more than 1200 IU) may indicate the presence of rickets and the risk for subsequently reduced linear growth.

MECHANICAL STIMULATION PROGRAM

Reduced mechanical stimulation against resistance and reduction of spontaneous movements occurring after birth in infants with VLBW frequently sedated for prolonged periods enhances calcium losses and demineralization. It has been reported that a gentle program of physiotherapy, including passive mobilization and the stimulation of active mobilization against resistance, improves bone mineral density in VLBW infants.[2] However, available data are inadequate to justify the standard use of physical activity programs in preterm infants or to predict the long-term effect of such interventions.[112]

Outcome

Catch-up mineralization is rapidly observed after discharge in infants with VLBW.[11] At 6 months of corrected age, spine and total bone mineral density, corrected for anthropometric values, are in the range of normal term newborn infants. In fact, the catch-up mineralization observed after discharge is quite similar to that observed after the initial acceleration of growth during adolescence. Nevertheless, peak bone mass may be less during adulthood.[125] Therefore, Fewtrell and coworkers found that at 8 to 12 years of age, formerly preterm infants were shorter, were lighter, and had lower BMCs than controls. However, BMC was appropriate for the body size achieved and was not affected by early dieting or human milk feeding.[41]

Osteopenia or rickets of prematurity appears to be a self-resolving disease, although the potential long-term consequences on the attainment of peak bone mass are not clearly known. Even if BMC improves spontaneously in most infants, this discovery does not imply that a period of demineralization is acceptable. Although the long-term consequences are unclear, the benefits of prevention and treatment include avoidance of fractures and possibly improved linear growth and peak bone mass.

PART 3

Thyroid Disorders

Susan R. Rose

Many physiologic factors influence fetal and neonatal thyroid function. They include embryogenesis of the thyroid, fetal-maternal relationships and the dynamic alteration of thyroid function with birth, the action of thyroid hormones, the synthesis and transport of these hormones, and mechanisms regulating thyroid function. Thyroid hormone abbreviations are defined in Table 49-5. To provide the background necessary to

TABLE 49–5 Abbreviations Related to Thyroid Hormones

ACTH, adrenocorticotropic hormone
CH, congenital hypothyroidism
DIT, diiodothyronine (diiodotyrosine)
FT_4, free T_4
FT_3, free T_3
GH, growth hormone
IQ, intelligence quotient
KI, potassium iodide
MIT, monoiodothyronine (monoiodotyrosine)
MTZ, methimazole
PTU, propylthiouracil
rT_3, reverse T_3 (3,3′,5′-L-triiodothyronine)
SGA, birth small for gestational age
T_4, thyroxine (tetraiodothyronine)
T_3, triiodothyronine (3,5,3′-L-triiodothyronine)
T_3U (T_3RU), T_3 resin uptake to estimate thyroid binding
TBG, thyroid (thyroxine)-binding globulin
TBII, TSH-binding/inhibiting immunoglobulins
TG, thyroglobulin
TGAb, thyroglobulin antibodies
TH, thyroid hormone
TPOAb, thyroid peroxidase (formerly microsomal) antibodies
TRAb, TSH-receptor antibodies
TRH, thyrotropin-releasing hormone, TSH-releasing hormone (L-pyroglutamyl-L-histidyl-L-prolineamide)
TSH, thyrotropin
TSI, TSH receptor-stimulating immunoglobulins
TTR, transthyretin (formerly T_4-binding prealbumin)

understand thyroid disorders in infants, this chapter begins with sections on thyroid physiology and laboratory tests. Embryology and fetal development of thyroid function are then described. Finally, clinical conditions of altered thyroid function are discussed.

PHYSIOLOGIC ACTION OF THYROID HORMONES

Functions of the Thyroid Gland

The principal functions of the thyroid gland are to synthesize, store, and release the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) into the circulation. The major secretory product of the thyroid is T_4. Thyroidal secretion of T_3 accounts for only about 20% of its production. The remaining 80% is derived from peripheral deiodination of T_4. Therefore, T_4 acts as a prohormone for T_3 because T_4 has negligible intrinsic metabolic activity in most tissues. Most of the physiologic effects of thyroid hormone are mediated by T_3 through its interaction with the thyroid response element on DNA.[3]

Neurologic Effects

Congenital thyroid hormone deficiency results in cretinism (severe mental retardation) if not treated. This effect is prevented by thyroid hormone replacement early in life. Newborn screening for thyroid deficiency was initiated in Quebec in 1974. Intellectual development is normal in children with congenital hypothyroidism who are treated early and aggressively and is significantly better in those treated early (by 7 days of age) and with higher thyroid hormone doses (12 μg/kg per day) than in those started on therapy later or treated with lower doses.[9]

Prenatal and postnatal maturation of the brain, retina, and cochlea is thyroid hormone dependent.[23] Thyroid hormone modulates expression of thyroid hormone–responsive target genes at precise times during development, controlled by an interplay of deiodinases, thyroid receptor expression, transporters, cofactors, and transcription factors.[3,7] T_3 promotes the neural differentiation of embryonic stem cells. Genes involved in neural migration are also regulated by thyroid hormone.[4,7]

Thyroidectomy in neonatal monkeys results in defective growth and development of the brain. The degree of mental retardation in cretinism is related to the severity and duration of the hypothyroid state of the infant. The brain is susceptible to a lack of thyroid hormone during its rapid growth and maturation. Defective growth and permanent damage do not occur if hypothyroidism begins after morphologic maturation of the brain is completed (i.e., after a postnatal age of 2 to 3 years).

Thyroid hormone also affects peripheral nerves. In hypothyroidism, relaxation phase of the ankle and knee-jerk reflexes is prolonged; in hyperthyroidism, sympathetic and autonomic responses may be exaggerated.

Cellular Metabolism

One of the principal actions of thyroid hormone is to stimulate rate of cellular oxidation in a large variety of tissues, leading to increased oxygen consumption, liberation of carbon dioxide, and production of heat. In hypothyroidism, the basal metabolic rate is reduced, but in hyperthyroidism, it is increased. The action of thyroid hormone may be mediated through increased protein synthesis. T_3 binds to the thyroid response element in the cell nucleus, leading to enhancement of polymerase activity, which in turn leads to increased cellular messenger RNA (mRNA) and corresponding proteins.[3] Synthesis of membranous sodium-potassium adenosine triphosphatase (ATPase) is enhanced by this mechanism. A large portion of oxygen consumption depends on sodium pump activity. T_3 has direct effects on the mitochondria in vitro and probably in vivo.[53] T_4 in cell culture induces phosphorylation of mitogen-activated protein kinase. Thyroid hormone enhances response of β-receptors to catecholamines without increasing the number of receptors.

Clinically, the calorigenic action of thyroid hormone affects circulation by increasing heart rate, stroke volume, and cardiac output. The pulse pressure is widened mainly by a decrease in the diastolic pressure and by some elevation in the systolic pressure. Circulation time is shortened. In hypothyroidism, the electrocardiogram (EKG) may show decreased voltage for all complexes, prolongation of the PR interval, and depression or inversion of the T wave. However, effects on the EKG may be secondary to myxedema of the myocardium.

Protein and Lipid Metabolism

Negative nitrogen balance occurs in hyperthyroidism unless the patient is protected by adequate caloric intake to provide for the increased energy requirements. In severe hypothyroidism, there is deposition of a mucoprotein containing hyaluronic acid in extracellular myxedematous fluid. Thyroid hormone influences the incorporation of creatinine into the phosphocreatine cycle. In hypothyroidism, there is an excessive storage of creatine, whereas in hyperthyroidism, the urinary excretion of creatine is increased. However, the total excretion of creatine and creatinine is not affected by thyroid hormone. Therefore, thyroid hormone changes the urinary creatine-creatinine balance; creatine accounts for 10% to 30% in the normal child, 0% to 10% in those with hypothyroidism, and 25% to 65% in those with hyperthyroidism.

Effects of thyroid hormone on lipid metabolism are seen in the increased serum total cholesterol and low-density lipoprotein (LDL) cholesterol concentrations in hypothyroidism. The total neutral fats, fatty acids, apolipoprotein B, and phospholipids of the serum are also increased in hypothyroidism.[26]

Carbohydrates, Calcium, Vitamin D, Water Balance, and Liver Function

The rate of glucose absorption and use is increased by thyroid hormone. In hypothyroidism, hypercalcemia may occur, the serum carotene level may be high, and the glucuronic acid conjugation mechanism of the liver may be impaired. In infants, hyperbilirubinemia associated with primary hypothyroidism is almost entirely indirect; in hypothalamic-pituitary hypothyroidism, it is both direct and indirect. Retention of water in the extracellular compartment occurs in hypothyroidism, producing the myxedematous fluid.

In hyperthyroidism, calcium balance tends to be negative; urinary and fecal calcium excretion is enhanced. Demineralization of bone occurs, and efflux of calcium from the bones leads to higher plasma ionized calcium and phosphate and lower circulating 1,25$(OH)_2D_3$, which in turn results in decreased calcium absorption from the intestine.

Growth and Development

A principal action of thyroid hormone is its effect on growth and development. These effects may be tissue specific and synergistic with other hormones. Prenatal growth is highly dependent on nutrition and insulin secretion. Postnatal linear growth is dependent on thyroid hormone and growth hormone (GH), which are mediated through insulin-like growth factor type 1 and its receptor. Similar synergistic effects between thyroid hormone and growth hormone can be observed in skeletal maturation. Thyroid hormone exerts its effects together with multiple hormones and growth factors. When primary hypothyroidism occurs, dental eruption, linear growth, and skeletal maturation are retarded. Retardation of skeletal maturation may be severe and is associated with immature skeletal proportions and facial contours, which contribute to the characteristic body configuration of hypothyroidism (long torso compared to short length of arms and legs) that is different from that seen in stunted growth caused by isolated GH deficiency. Ossification of cartilage is also disturbed in hypothyroidism, leading to epiphyseal dysgenesis in radiographs of the ossifying epiphyseal centers (Fig. 49-22). Growth rate and adult height are normal in children with congenital hypothyroidism in whom thyroid hormone therapy is consistently maintained.[34]

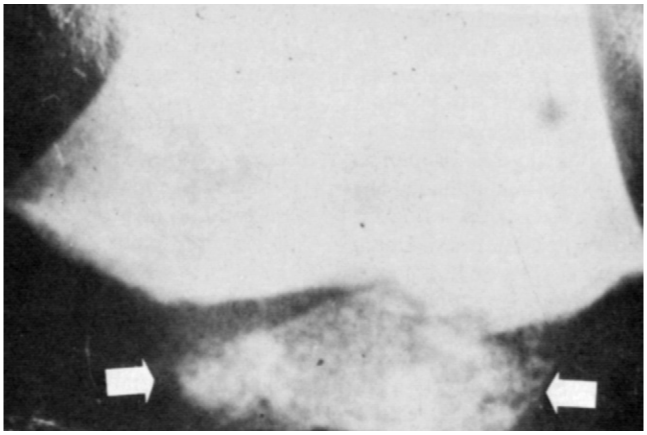

Figure 49–22. Epiphyseal dysgenesis of the distal femoral center.

Calcitonin

In addition to the classic thyroid hormones (T_4 and T_3), a calcium-lowering hormone, thyrocalcitonin (i.e., calcitonin), is secreted by the parafollicular cells of the thyroid. Although calcitonin has hypocalcemic and hypophosphatemic actions when administered to humans, its physiologic role is not yet clearly understood. In normal newborn infants, a physiologic nadir in serum calcium concentration occurs at 24 to 48 hours of age, potentially related to delayed responsiveness of calcitonin. Thyroidectomy does not lead to hypercalcemia because there is secretion of calcitonin from extrathyroidal organs such as the brain, thymus, lung, gastrointestinal tract, and bladder.

SYNTHESIS, RELEASE, TRANSPORT, AND USE OF THYROID HORMONES

The biologically active thyroid hormones T_4 (also known as L-thyroxine) and T_3 are iodinated amino acids. Their synthesis starts within the follicular cells.

Iodine Metabolism

Iodine is supplied to the body mainly through dietary intake, but it can be absorbed readily from the skin, lungs, and mucous membranes. Application of iodine-containing ointment or lotion to the skin, common during procedures with premature or sick infants, causes very high levels of iodide in circulation and promptly blocks thyroid hormone release from the thyroid gland. Although some organic iodine compounds, including T_4 and T_3, can be absorbed unchanged from the gastrointestinal tract, most are reduced and absorbed as inorganic iodide. One fourth to one third of ingested iodide is taken up by the thyroid; this is the basis for radioiodine uptake studies.

This iodide-trapping mechanism involves an active transport process (an iodide pump [iodide symporter]) that requires oxidative phosphorylation. The iodide pump is a major rate-limiting step in thyroid hormone biosynthesis and, when it is defective, is a rare cause of congenital goitrous hypothyroidism.[15] The iodide pump is present at both the basal and apical surfaces of follicular cells. At the basal cell surface, the pump concentrates iodide in the cells by transporting them from the extracellular space. At the apical cell surface, the pump pushes iodide into the follicular lumen as a secondary reservoir. The mechanism is capable of maintaining intrathyroidal iodide concentration at a 20-fold to 100-fold higher level than that of serum. Some anions—bromide (Br^{2-}), nitrate ($NO_2{}^{2-}$), thiocyanate (SCN^{2-}), perchlorate ($ClO_4{}^{2-}$), and technetium pertechnetate ($TcO_4{}^{2-}$)—are capable of competitively inhibiting iodide transport.

Iodide is immediately oxidized to an active form for iodination of thyroglobulin (TG) by a peroxidase enzyme system.[15] TG, a glycoprotein, is synthesized by the ribosomes of the follicular cells. Iodination of TG (organification) appears to occur at the cell colloid-lumen interface. Almost all the iodine taken up by the thyroid is rapidly incorporated into the 3 and the 5 positions of the many tyrosyl residues of TG to form monoiodothyronine (MIT) and diiodothyronine (DIT). Once it is organically bound to tyrosyl residues, iodine can no longer be readily released from the thyroid. Defects in iodide oxidation or organification can be seen in several types of goitrous cretinism.

Synthesis of Triiodothyronine and Thyroxine

The synthesis of T_3 requires the coupling of an MIT and a DIT molecule, accompanied by elimination of an alanine residue. T_4 is formed by the coupling of two DIT molecules. These reactions occur within the structure of TG and involve oxidative processes, probably catalyzed by thyroid peroxidase as well.

Secretion of Triiodothyronine and Thyroxine

Secretion of T_4 and T_3 into the circulation requires the liberation of these moieties from TG.[45] TG molecules pass from the lumen of the follicles into the follicular cells (endocytosis), where colloid droplets are ingested by lysosomes and undergo proteolysis. Congenital hypothyroidism may result from abnormal TG synthesis or metabolism. Of the about 125 tyrosyl residues in TG, only about 10 form iodothyronines, and another 20 consist of MIT and DIT. After proteolysis of TG, the freed MIT and DIT are deiodinated by iodotyrosine deiodinase, and the liberated iodide is recycled by the thyroid for reiodination of new TG. A defect in the deiodination mechanism of freed iodotyrosines results in depletion of iodine by release from the thyroid gland into the circulation and then excretion into the urine, resulting in goitrous cretinism.

Serum Protein Binding or Transport

The thyroid is the only source of T_4, and its blood concentration is 50 to 100 times greater than that of T_3. T_4 and T_3 secreted into the circulation are transported by loose attachment, through noncovalent bonds, to the plasma proteins. Three proteins play a role in the transport system. More than 75% of T_4 is normally bound to thyroxine-binding globulin (TBG). A second carrier protein is TTR (formerly called T_4-binding prealbumin); about 15% of T_4 is bound to TTR. A third protein is serum albumin, a high-capacity, low-affinity, iodothyronine-binding protein that usually transports less than 10% of the circulating T_4. While T_4 binds with all three proteins, T_3 binds only with TBG and albumin, and its binding affinity is much less than that of T_4. The free T_4 (FT_4) concentration more accurately indicates the metabolic status of the individual than total T_4 or T_3 does because only the free hormones can enter the cells to exert their effects. If the capacity of TBG is increased, a rise in the concentration of total hormones will follow, and the concentration of free hormones will be maintained without significant change.

Monodeiodination of Thyroxine

Monodeiodination of T_4 occurs in many tissues through the action of three distinct deiodinase enzymes. Type I deiodinase, or 5′-monodeiodinase, is found in peripheral tissues such as the liver and kidney. Deiodination at the 5′ position of T_4 in peripheral tissues generates T_3, the iodothyronine that mediates the metabolic effects of thyroid hormone. Eighty percent of circulating T_3 is produced by the monodeiodination of T_4. However, the relative serum levels of T_4 and T_3 do not reflect the intracellular proportions of the hormones. The tissue distribution of T_3 may differ greatly from that of T_4 from tissue to tissue. The plasma half-life of T_3 is one day, compared with 6.9 days for T_4. However, the plasma half-life of T_4 is much shorter (3.6 days) in neonates. Most T_3 is localized in cells, whereas T_4 is found mainly in the extracellular space. The metabolic effects of T_3 are mediated through binding to specific receptors in the DNA response element that regulates transcription. It also interacts with membranous, mitochondrial, and cytosolic binding sites. The direct binding of T_4 in fetal neural tissue may be important in early neural development in order to permit intracellular deiodination to T_3.

Neural tissue requires FT_4 (and does not bind T_3). Intracellularly, the FT_4 is converted to FT_3 by type II deiodinase. Type II deiodinase regulates T_3 production from T_4 in the pituitary, neuroglial cells, and astrocytes and is involved in the control of TSH secretion.[44]

Type III deiodinase, or 5-deiodinase, regulates peripheral deiodination of T_4 at the 5 position on the thyronine molecule instead of 5′ and generates reverse T_3 (rT_3). Serum rT_3

concentration parallels that of T_3 in normal circumstances but not in fetal life, starvation, or patients with severe nonthyroidal illnesses (e.g., euthyroid sick syndrome, nonthyroidal illness syndrome). rT_3 is generally metabolically inactive, although weak nuclear binding activity has been reported.

REGULATION OF THYROID FUNCTION

Control of thyroid hormone secretion is centered in the hypothalamic-pituitary-thyroid axis. Basophilic cells of the anterior pituitary gland synthesize and store thyrotropin (TSH), a glycoprotein capable of rapidly increasing intrathyroidal cyclic adenosine monophosphate (cAMP). TSH release from the pituitary causes an increased uptake of iodine by the thyroid, accelerates virtually all steps of iodothyronine synthesis and release, and increases the size and vascularity of the thyroid. These changes are mediated by activation of adenylate cyclase and tyrosine kinase. Human chorionic gonadotropin (hCG) weakly competes with TSH for receptors on thyroid follicular cells. Hyperthyroidism seen in patients with choriocarcinoma can be explained by this mechanism. Similarly, certain immunoglobulins—among them TSH-binding inhibiting immunoglobulins and TSI (discussed later)—found in autoimmune thyroid diseases, compete with TSH for binding to TSH receptors. Graves disease can be explained by this mechanism.

Secretion and plasma levels of TSH are inversely related to circulating levels of FT_3 and FT_4. The inhibitory feedback action of FT_3 and FT_4 involves a direct action of these hormones on the pituitary gland without involving the hypothalamus. Therefore, secretion of TSH is regulated directly by the ambient intrapituitary T_3 concentration and intrapituitary deiodination of T_4 to T_3 by type II monodeiodinase activity.[44] A progressive decline in the T_4 secretion rate with increasing age partially reflects maturational changes in thyrotropin-releasing hormone (TRH) and TSH secretion.[16,17]

The hypothalamus secretes TRH, a tripeptide that stimulates release of TSH by the pituitary gland. Although precise anatomic locations of TRH biosynthesis are not known, TRH synthetase is found in the median eminence and ventral and dorsal hypothalamus. When TRH is infused, it rapidly stimulates release of TSH into the circulation, and plasma TSH reaches a peak value in 20 to 30 minutes. Plasma half-life of TRH is extremely short, probably not exceeding 4 minutes. Production of TRH is modulated by both peripheral and hypothalamic thermal receptors. Exposure to a cold environment increases TRH synthetase activity. This activity is reduced in hypothyroid animals and increased in hyperthyroid animals. The hypothalamus may regulate the setpoint of feedback control as a thermostat through TRH, with iodothyronines playing a positive-feedback role in TRH synthesis. This control probably operates in neonates whose circulating TSH becomes rapidly elevated after parturition. After administration of TRH, there is an increase in the secretion of TSH, prolactin, and GH in normal neonates and older patients with pituitary tumors.

A circadian variation of circulating TSH has been found in normal children and adults.[44] A peak TSH concentration (about 3 to 4 mU/L) develops between 10:00 PM and 4:00 AM and is about twofold higher (50% to 300% higher) than the afternoon (2:00 PM to 6:00 PM) nadir values. This nocturnal TSH surge is not directly related to sleep; it is blunted or absent in central (secondary or tertiary) hypothyroidism but maintained in primary hypothyroidism. The circadian pattern of TSH is not yet present in neonates but has been noted to be present in infants as young as 4 months of age.

In most children with idiopathic hypopituitarism, TSH release after TRH administration is normal, indicating impaired TRH secretion rather than a primary TSH deficiency.[55] TRH-mediated TSH release can be augmented by administration of theophylline or estradiol and may be blunted by the administration of L-dopa, somatostatin, or glucocorticoids. However, clinically significant hypothyroidism rarely occurs after prolonged administration of glucocorticoids or adrenocorticotropic hormone (ACTH).

In addition to hypothalamic-pituitary regulation, the thyroid is responsive to an intrinsic autoregulatory mechanism, intrathyroidal iodide, which compensates for fluctuation in dietary iodine intake. However, iodide trapping by the follicular cells is modulated by variations in dietary iodine intake within the physiologic range.

LABORATORY TESTS USED IN THE DIAGNOSIS OF THYROID DISEASE IN INFANCY AND CHILDHOOD

Concentration of Circulating Thyroid Hormones

With the development of sensitive methods, more tests to determine thyroid function and disease have become available in hospitals and reference laboratories (Table 49-6). Concomitantly, many previously used thyroid function tests are now obsolete, such as the protein-bound iodine test.

Total plasma or serum TSH, T_4, T_3, and rT_3 can be determined by specific competitive assays. These procedures require a very small quantity of blood ($<50\ \mu L$), an advantage exploited for screening neonates for hypothyroidism. Determination of TSH is the most sensitive test to detect primary hypothyroidism, or thyroid gland failure.[5]

Thyroxine

The plasma pool of T_4 constitutes a large protein-bound reservoir; this pool turns over slowly. Therefore, T_4 measurement usually reflects the adequacy of the hormonal supply. The normal level of T_4 is age dependent in infancy and childhood, particularly during the neonatal period. T_4 reaches a peak concentration shortly after birth and declines slowly, gradually approaching the adult normal range in puberty.[16] The range of normal levels for each age group is also wide. Normal adult values of serum T_4 by radioimmunoassay are about $8.3 \pm 2.4\ \mu g/dL$ (see Appendix B). However, it should be kept in mind that more than 99% of circulating T_4 is bound to serum thyroid hormone–binding proteins. Any change or abnormality in the concentration of these proteins, particularly TBG, can affect the T_4 level. Several clinical situations and pharmacologic agents can alter the levels of TBG or transthyretin (TTR).

TABLE 49–6 Laboratory Tests Used for the Diagnosis of Thyroid Disorders and Assessment of Thyroid Function in Infancy and Childhood

Serum Tests
Thyrotropin (TSH)
Thyroid hormones: thyroxine (T_4), free T_4 by analogue methods (initial screen) and direct dialysis (definitive method), triiodothyronine (T_3)
Thyroid hormone-binding protein: thyroid-binding globulin (TBG)
Thyroid autoantibodies: thyroglobulin antibodies (TGAb), thyroperoxidase (microsomal) antibodies (TPOAb), TSH-receptor antibodies (TRAb) by TBII or TSI methods
Thyroglobulin (TG)
Imaging Tests
Thyroid scan with ^{99m}Tc-pertechnetate or ^{123}I-iodide
Thyroid ultrasound
Miscellaneous Tests
Assessment of skeletal maturation
In vivo isotopic tests: ^{123}I-iodide uptake test; perchlorate discharge test at 2 hours after isotope ingestion
Thyrotropin-releasing hormone (TRH) stimulation test
TSH surge test
Urinary iodine excretion

Drug Effects on Thyroid Concentrations

Certain anticonvulsants not only bind competitively to TBG but also interfere with T_4 assays, without greatly influencing the TSH level in a person with an otherwise normal thyroid reserve. These drugs include phenytoin, valproate, primidone, and carbamazepine. As much as twice the dose of drugs such as carbamazepine may be required in a patient receiving T_4 therapy. In addition, T_4 dose requirement may double in a patient receiving carbamazepine. Other drugs, such as furosemide, salicylate, and L-asparaginase, compete with thyroid hormone for binding with plasma proteins and can alter the levels of T_4, T_3, FT_4, and FT_3. Phenobarbital increases hepatic binding of T_4 and its disposal without altering circulating levels of thyroid hormone. Propylthiouracil (PTU), propranolol, dexamethasone, and some cholecystographic dyes inhibit peripheral conversion of T_4 to T_3. This effect of PTU is separate from its action on thyroid hormone biosynthesis by the thyroid gland. Administration of T_3 results in a decrease in T_4 because it suppresses endogenous T_4 secretion.

Amiodarone, an antiarrhythmic drug, contains covalently bound iodine and can alter thyroid test results.[6] It inhibits the hepatic conversion of T_4 to T_3 and decreases the clearance of T_4. FT_4 and rT_3 are increased, and T_3 and FT_3 are decreased. Because of its high content of iodine, amiodarone can also result in either hypothyroidism or hyperthyroidism and may cause congenital goitrous hypothyroidism when it is administered to pregnant women. This effect is analogous to direct exposure of the fetus or infant to high doses of iodine.

Triiodothyronine

When TSH becomes elevated, the percentage of T_3 produced by the thyroid gland is increased. Serum concentration of T_3 can vary from day to day. Because of the overall small quantity of T_3 in serum, its level may not fall below the normal range until T_4 is critically low. Therefore, serum T_3 is not very useful in evaluation of patients for possible hypothyroidism. T_3 is physiologically low in the fetus and cord blood, but rises promptly after birth to levels greater than those in older children and adults. T_3 and FT_3 are also low during nonthyroidal illness. Normal serum T_3 concentrations vary among laboratories but generally range from about 100 to 220 ng/dL in children and 80 to 200 ng/dL in adults.[5]

Reverse Triiodothyronine

Most hormonally inactive rT_3 is derived from deiodination of T_4 and represents a deiodination rate similar to that of T_4-to-T_3 conversion in normal adults. Serum half-life is very short, less than one half that of T_3. Concentration of rT_3 usually parallels that of T_3. However, rT_3 is disproportionately high in the fetus, in the early neonatal period, and in severe nonthyroidal illness, probably reflecting altered tissue metabolism of T_4.[5] Normal adult serum level of rT_3 is 30 to 80 ng/dL.

Free Hormones

FT_4 in serum can be estimated by direct dialysis. This method depends on the FT_4 concentration being governed by equilibrium in levels of binding proteins, protein-bound T_4, and FT_4, following the law of mass action. In clinical settings, FT_4 does not depend on the T_4-binding capacity as such because a change in such a capacity is soon compensated for by a change in the amount of T_4 released from the thyroid. To estimate FT_4, serum is placed in a dialysis cell on one side of a semipermeable dialysis membrane, with a buffer solution on the other side. T_4 equilibrates across the membrane. Bound T_4 remains with serum, and free T_4 crosses the membrane and enters the buffer solution. T_4 is measured in the buffer solution, and the amount corresponds to the level of endogenous FT_4. FT_3 levels in the serum can be measured in the same dialysate as that used for FT_4. Other analogue methods for determining FT_4 have been introduced.

The principle of analogue methods is that the rate of binding of labeled hormones to antibodies depends on the FT_4 concentration during a timed incubation. Analogue methods are less expensive, can be performed more rapidly than the direct dialysis method, and are acceptable for routine testing in children. However, FT_4 analogue methods may not provide an accurate assessment of FT_4 in some neonates, patients receiving medications that interfere with T_4 binding, chronically or critically ill neonates or children, or patients with very low levels of TBG.[51]

When hypothalamic or pituitary hypothyroidism is suspected, the definitive test to measure the FT_4 is by direct dialysis. This test is readily available in specialized commercial laboratories. Because there is a delay in obtaining results, the specimen should be collected and T_4 therapy started. If there is an associated ACTH or cortisol deficiency, hydrocortisone therapy should be started at least 6 to 8 hours before T_4 therapy is initiated.[19]

Measurement of FT_3 is not currently part of standard care. In the future, FT_3 measurements may be shown to be useful in assessing hypothyroidism. Currently, FT_3 may be useful when the diagnosis of thyrotoxicosis is suspected and TSH is suppressed but values for T_4, T_3, or both are normal. The approximate serum values for normal adults are 1.0 to 2.4 ng/dL for FT_4 and 240 to 620 pg/dL for FT_3. The range of normal values for infants and young children is probably higher than that for adults, but exact ranges have not been established.

Proteins That Bind to Thyroid Hormones

Because concentrations of T_4 and T_3 are affected by those of thyroid hormone–binding proteins and by the degree of their saturation at the binding site, T_4 must be interpreted with a simultaneous evaluation of these proteins. The simplest approach is to measure TSH and FT_4 (by dialysis or analogue methods) and not measure T_4 at all, avoiding the issue of changes in levels of thyroid hormone–binding proteins.

The alternative approach is to determine T_3U, which is a rapid, indirect assessment of the binding proteins. However, it may not be accurate in the same clinical conditions as those described previously for the FT_4 analogue methods. The T_3U value is then multiplied by the total T_4 value to give the FT_4 index, which is essentially a mathematically corrected T_4 value for the degree of saturation of the thyroid hormone–binding proteins. Direct dialysis is the best FT_4 method, especially in infants. Analogue methods are very cost-effective in measuring FT_4 and will probably replace methods that measure the FT_4 index.

In general, when TBG is increased in a euthyroid individual, T_4 is elevated and T_3U is low, but FT_4 is about normal. The reverse situation is observed in individuals with low TBG, but again FT_4 is normal. The administration of a drug that competes with T_4 for TBG-binding sites results in low T_4 and high T_3U but normal FT_4.

Serum TBG is determined by radioimmunoassay in commercial laboratories, and its measurement is useful in the quantitation of abnormal levels of TBG. Because most T_4 is bound to TBG, these measurements give a good approximation of the T_4-binding protein capacity. The binding capacity of TBG is increased in many clinical situations, including those during pregnancy and in neonates. It may also be increased in patients with hypothyroidism, liver disease, porphyria, or AIDS.

Pharmacologic agents that increase TBG levels include estrogens, methadone, and heroin. The concentration of TBG may be decreased in preterm infants and in hyperthyroidism, hypercortisolism, acromegaly, diabetic ketoacidosis, chronic hepatic diseases, alcoholism, nephrotic syndrome, other chronic renal diseases, and protein-calorie malnutrition. Drugs that decrease TBG levels include androgens, anabolic steroids, danazol, glucocorticoids, and L-asparaginase. Pharmacologic agents that compete with T_4 for TBG-binding sites include salicylates, phenytoin, and possibly other anticonvulsants, hypolipemic agents, sulfonylureas, diazepam, heparin, and fenclofenac. These agents give falsely low T_4 and falsely high T_3U values. TSH and FT_4 determinations by direct dialysis method are usually normal. The normal value for TBG in adults is about 1.2 to 2.8 mg/dL.

Thyrotropin

Measurements of TSH and FT_4 are the most important tools for screening thyroid function. Serum TSH is measured by specific competitive-binding isotopic and nonisotopic methods, and values are expressed in milliunits per liter (mU/L) of an international reference standard. TSH is the most sensitive test for primary hypothyroidism at any age and is used in many neonatal thyroid screening programs. Serum TSH is also an indicator of the adequacy of thyroid hormone replacement therapy and is used in assessment of the hypothalamic-pituitary-thyroid axis by the TSH surge test and the TRH test (see later discussions). The normal adult value is 0.2 to 3.0 mU/L.[5] TSH is elevated in primary hypothyroidism. A surge of TSH release also occurs at parturition and reaches a peak within 2 hours after birth. TSH in the cord serum and the infant's serum after the first day of postnatal life is usually less than 20 mU/L. Therefore, TSH is the most important test to screen for primary congenital hypothyroidism. The target range for TSH during thyroid hormone therapy for primary hypothyroidism is 0.5 to 2 mU/L. The highly sensitive TSH assay can also be used in identifying individuals with thyrotoxicosis in whom TSH is suppressed to less than 0.01 mU/L.

Thyroid Autoantibodies

Numerous methods have been used for detection of a large variety of thyroid antibodies. Assays for thyroglobulin antibodies (TGAb) and thyroperoxidase (microsomal) antibodies (TPOAb) are widely available. These antibodies are found in Hashimoto thyroiditis and in about 2% of the adult population. TSH receptor stimulating and blocking antibodies may be detected in the sera of patients with autoimmune thyroid diseases and are known as TSH receptor antibodies (TRAb). TRAb that are stimulatory are found in the sera of patients with active Graves disease and are known as TSI. TRAb that are inhibitory are called TBII.

Mothers with primary hypothyroidism and Hashimoto thyroiditis may have circulating serum TBII or antibodies that block the TSH receptor. These mothers give birth to children with a transient form of congenital hypothyroidism as a result of the transplacental transfer of TBII. The disease may recur in infants of subsequent pregnancies if the high-affinity antibody persists in the mother's circulation. The half-life of immunoglobulins in the neonate is about 2 weeks, and TRAb usually disappear from the serum of affected infants by 6 to 8 weeks of age.

Mothers with Graves hyperthyroidism may have TBII but more commonly have TSI. These mothers give birth to children with a transient form of hyperthyroidism as a result of the transplacental transfer of TSI. This disease may also recur in infants of subsequent pregnancies if the high-affinity antibody persists in the maternal circulation. Hyperthyroidism in the affected infant may persist for 2 to 6 months.

Thyroglobulin

It was previously believed that TG was present only in the thyroid gland. With the development of radioimmunoassay for TG, it is now known that some of it appears in the circulation. The mean value of TG for normal adults is 5 ng/mL, with a range from less than 1 to about 30 ng/mL. The median value for preterm infants at birth is high (102 ng/mL), rapidly decreases during the first 30 days of life for reasons not yet understood, and further decreases during infancy and childhood to the adult mean value by 20 years of age.

In athyreotic cretinism, TG is not detectable. However, in the form of autoimmune congenital hypothyroidism caused by antibodies that block the TSH receptor, TG may be detectable even when the radioactive iodine scan suggests an absent thyroid gland. Ultrasound identifies the thyroid gland; TG levels may be elevated when the thyroid gland is hyperactive, as in endemic goiter, subacute thyroiditis, toxic nodular goiter, and Graves disease. TG cannot be reliably measured in Hashimoto thyroiditis because of the possible presence of TGAb. TG levels are often greatly increased in papillary-follicular carcinoma but not in medullary or anaplastic carcinoma of the thyroid. TG levels are useful not only in the differential diagnosis, but also in follow-up studies to monitor patients for recurrence of papillary-follicular carcinoma.

Thyroid Imaging

The development of sensitive and specific assays to quantitate thyroid hormone and TSH has largely obviated the need for radioiodine uptake studies in childhood. As a result, radioactive thyroid scans are rarely performed in infants and children. Measurement of TG concentration can identify the presence or absence of thyroid glandular tissue. Ultrasonography of the thyroid gland is useful for visualization of normal-sized glands and goiters. It is also used to distinguish solid and cystic nodules of the thyroid. Ultrasonography can identify dysgenetic thyroid glands.[37] Slower correction of TSH may be seen with dysgenetic glands than with eutopic glands. Ultrasonography should be used as the first imaging tool, with a scan performed to distinguish agenesis from ectopia. However, hypoplastic or ectopic glands may be missed by this technique. When a scan is necessary, ^{123}I or ^{99m}Tc should be used to reduce radiation exposure to the child. The half-life of ^{123}I is 13.3 hours, compared with 8 days for ^{131}I.

Radioiodine uptake studies are invaluable for diagnosing certain inborn errors of thyroid hormone synthesis, such as the iodide-trapping defect and the iodide oxidation or organification defect. ^{99m}Tc-pertechnetate can also be used for iodide-trapping studies because this anion is trapped by the thyroid in a manner similar to iodine, but is not organified and is therefore discharged early from the thyroid gland. In addition to the thyroid gland, the salivary glands, gastric mucosa, uterus, small intestine, mammary glands, and placenta are capable of concentrating iodine. In patients with goitrous cretinism caused by iodide-trapping defects, the ability of salivary glands to trap iodide can be exploited for diagnostic purposes. The trapping defect is shared by the thyroid and the salivary glands in these patients. The perchlorate discharge test is performed during the radioiodine uptake test to detect the presence of a defect in the oxidation of iodide to iodine (see "Congenital Hypothyroidism").

Thyrotropin-Releasing Hormone

In 2002, the TRH test became commercially unavailable in the United States. Historically, TRH was the first identified hypothalamic neuropeptide and had been used in clinical assessment since the 1960s. The following section regarding the TRH test is retained in this chapter for reference in the event that the TRH test again becomes a tool available to the clinician.

Given current ultrasensitive TSH assays, the TRH test is required only when TSH is mildly elevated (4.5 to 10 mU/L) to help determine whether the child has mild primary hypothyroidism (as opposed to central hypothyroidism) or for the assessment of possible thyroid hormone resistance. A suppressed basal TSH value is significant and sufficient for the diagnosis of hyperthyroidism, and a basal TSH concentration of higher than 10 mU/L (after the first week of age) is significant and sufficient for the diagnosis of primary hypothyroidism.

A bolus infusion of TRH (7 μg/kg of body weight) results in increased TSH that peaks at 20 to 30 minutes. A peak increment of 10 to 30 mU/L is seen in healthy children, with a decline to basal TSH levels by 2 to 3 hours. Serum T_3 levels peak at 3 to 4 hours and T_4 levels at 6 to 9 hours after TRH. Therefore, the TRH test can be used to examine responsiveness of both TSH to TRH and of thyroid gland to TSH, when necessary. Patients with primary hypothyroidism have an exaggerated TSH response. Patients with hyperthyroidism and those receiving T_4 replacement do not respond to TRH stimulation because of chronic suppression of TSH by thyroid hormone.[19]

The TRH test may be helpful in confirming central hypothyroidism (pituitary or hypothalamic) in some patients. Those with secondary (pituitary) hypothyroidism do not respond to TRH.[19] In some patients with tertiary hypothyroidism (hypothalamic TRH deficiency), a delayed response of TSH to TRH stimulation is seen, so TSH at 60 minutes is higher than that present at 20 to 30 minutes. However, many patients with tertiary hypothyroidism have a normal response to TRH.

Thyroid-Stimulating Hormone Surge Test

Central hypothyroidism is diagnosed in infants who have low or low-normal FT_4, no TSH elevation, and other common features of hypopituitarism (e.g., hypoglycemia, microphallus). More subtle central hypothyroidism (FT_4 in the lowest third of the normal range) can be confirmed in children older than 1 year by the TSH surge test.[44] This test is not useful in infants younger than 6 months, before development of the circadian pattern of TSH secretion.

The TSH surge test is performed by obtaining blood for TSH assay at the usual time of the nadir of the circadian variation of TSH (the mean of two or three samples between 10:00 AM and 6:00 PM) and again at the usual time of peak TSH secretion (the mean of the three highest sequential samples between 10:00 PM and 4:00 AM). The mean nadir and peak TSH values are calculated. Normal night-time (peak) TSH values are 50% to 300% higher than those (nadir) obtained during the day. Blunting or absence of this rise confirms central hypothyroidism.[44] At age over 2y, with FT4 below 1.2 mg/dL, 8 AM to 4 PM TSH ratio below 1.3 also confirms central hypothyroidism.[44a]

EMBRYOGENESIS

The major portion of the human thyroid originates from the median anlage, the tissue that arises from the pharyngeal floor (toward the back of the future tongue) and is identifiable in the 17-day-old embryo.[40] The median anlage is initially in close contact with the endothelial tubes of the embryonic heart. With the descent of the heart, the rapidly growing median thyroid is progressively pulled caudally until it reaches its final position in front of the second to sixth tracheal ring by 45 to 50 days of gestation. The pharyngeal region contracts to become a narrow stalk called the *thyroglossal duct*, which subsequently atrophies. The descent of the heart may influence the downward movement of the thyroid because of topographic contact. The median anlage usually grows caudally so that no lumen is left in the tract of its descent. An ectopic thyroid gland or persistent thyroglossal duct or cyst results from abnormalities of thyroid descent. Lateral parts of the descending median anlage expand to form the thyroid lobes and the isthmus.[40]

The second source of thyroid tissue is composed of a pair of ultimobranchial bodies arising from the caudal extension of the fourth pharyngeal pouch. These bodies are initially connected to the pharynx by the pharyngobranchial duct (late seventh week). The pharyngeal connection is subsequently lost, and the ductal lumen becomes obliterated. The ultimobranchial bodies are incorporated into the expanding lateral lobes of the median anlage. They contribute little to the future size of the thyroid, and their differentiation appears to require the influence of the median anlage. Parafollicular or C cells arise from the ultimobranchial bodies in mammals and are the source of calcitonin.

By the latter part of the 10th week of gestation, the histogenesis of the thyroid is virtually complete, although the follicles do not contain colloid.[40] A single layer of endothelial cells surrounds the follicular lumen. T_4 has been detected in the serum of a 78-day-old fetus. At this age, the fetal thyroid is capable of trapping and oxidizing iodide.[19] Therefore, the fetal thyroid begins to secrete thyroid hormone and contributes to the fetal circulation of thyroid hormone by the beginning of the second trimester.

At the same time as the development of the thyroid gland, the fetal pituitary and hypothalamus are also forming and beginning to function. The anterior pituitary gland is derived from the Rathke pouch, which originates at the roof of the pharynx. Histologic differentiation of pituitary cells can be observed by 7 to 10 weeks of gestation, and TSH can be detected in fetal blood by 10 to 12 weeks.[28] The hypothalamus develops from the ventral portion of the diencephalon. TRH has been found in fetal whole-brain extracts by 30 days and in the hypothalamus by 9 weeks of gestation.

Knowledge regarding the genetic basis of normal thyroid physiology and disease has been rapidly developing and will continue to advance (Table 49-7).[27] For additional updates, the reader can consult the following websites: www.ncbi.nlm.nih.gov/PubMed, www.ncbi.nlm.nih.gov/Omim, and www.uwcm.ac.uk/uwcm/mg/hgmd0.html.

THYROID FUNCTION: FETAL-MATERNAL RELATIONSHIP

In considering the fetal-maternal relationship, the placenta is of major importance. TSH does not cross the placental barrier, whereas TRH does. Although there is some maternal-to-fetal transport of T_4 during the third trimester, transfer during the first trimester from the mother to the fetus may be greater because fetal brain development appears to depend on maternally derived T_4. Maternal hypothyroidism during early gestation can lead to neurologic damage of the fetus.[30] Because the placenta rapidly deiodinates T_4 into biologically inactive rT_3 and DIT, transplacental transfer of maternal T_4 during later stages of pregnancy is limited. However, this T_4 transfer in a fetus with a total inability to synthesize T_4 results in a fetal T_4 concentration that is 25% to 50% of that found in normal neonates. Therefore, in a mother with normal thyroid function, the hypothyroid fetus is somewhat protected. The mother with hypothyroidism and a normal fetus may have a relative thyroid deficit in the first trimester of gestation, whereas the mother with hypothyroidism and a hypothyroid fetus may experience a more significant deficit.[20]

Iodine deficiency may be a factor contributing to concurrent maternal and fetal hypothyroidism. The ideal allowance of iodine for pregnant women is 250 to 300 μg daily.[14,21] Iodides cross the placenta readily. Iodine in excess can also cause problems in the fetus. Iodides and iodine, when given in large quantities, produce a transient inhibition of T_4 synthesis by diminishing iodination, probably through effects on thyroidal autoregulation. Therefore, iodine given to the mother in large amounts causes goiter in the offspring (Fig. 49-23). Even iodine applied topically to the mother, such as the vaginal application of povidone-iodine, can adversely affect thyroid function of the newborn and may cause transient primary hypothyroidism.

Other clinically important compounds that can affect fetal thyroid function by crossing the placenta from the mother to the fetus are antithyroid drugs, environmental goitrogens, endocrine disruptors, and thyroid antibodies.[19,32] Antithyroid drugs include perchlorates and thionamide compounds such as thiourea, thiouracil, PTU, methimazole, and carbimazole. Transplacental transfer of these drugs can result in fetal goiter with or without hypothyroidism. Transfer of TSI across the placenta to the fetus can cause transient neonatal thyrotoxicosis (see "Thyrotoxicosis," later); the placental transfer of TBII can cause transient neonatal hypothyroidism.

Thyroid hormone can be detected in the amniotic fluid. However, T_4, FT_4, T_3, and TSH levels in the amniotic fluids correlate poorly with maternal or fetal serum levels. Although more invasive, cordocentesis provides levels that more accurately represent the fetal thyroid hormone status.[47] More than 20 case reports of highly elevated amniotic or fetal blood TSH concentrations (samples obtained between 24 and 38 weeks of gestation) in fetuses found to have large goiters

TABLE 49–7 Inherited Disorders of Thyroid Metabolism

Hypothalamic-Pituitary Development	Gene	Inheritance
Combined pituitary hormone deficiency	Mutations of *LHX3, HESX1, PROP1, POU1F1*	AR or AD
TRHR	Loss-of-function TRHR mutation	AR
TSH deficiency	TSH β-subunit mutation	AR
TSHR	Loss-of-function TSHR mutation Resistance to TSH with normal TSHR Gain-of-function TSHR mutation *GNAS1* mutations	AR or AD AD AD
Thyroid Gland Development	*TITF1* (haploinsufficiency) Mutations of *FOXE1, PAX8* *TTF2, NKX2-1, HHEX, BCL2*	AR or AD

Iodide transport	Iodide symporter NIS *SLC5A5*	AR
TPO	TPO mutations *THOX2*	AR
Pendred syndrome	Pendred syndrome mutations	AR
Thyroid NADPH oxidase	*DUOX1* and *DUOX2* mutations	
TG	TG mutations	AR or AD
Iodide cycling	Defect not known	?AR
Thyroid Hormone Transport		
TBG	TBG deficiency, partial or complete X-linked recessive TBG excess	X-linked recessive X-linked recessive
TTR	TTR mutations	AD
Albumin	Albumin mutations	AD
Generalized Thyroid Hormone Resistance	THR mutations THR-β	AD

AD, autosomal dominant; AR, autosomal recessive; GNAS, gene encoding G_s-protein α subunit; NADPH, reduced nicotinamide-adenine dinucleotide phosphate; TBG, thyroxine-binding globulin; TG, thyroglobulin; THR, thyroid hormone receptor; TPO, thyroid peroxidase; TRHR, thyrotropin-releasing hormone receptor; TSH, thyrotropin; TSHR, TSH receptor; TTR, transthyretin.

Adapted from Knobel M, Medeiros-Neto G: An outline of inherited disorders of the thyroid hormone generating system, *Thyroid* 13:771, 2003.

by ultrasonography have led to prenatal therapy by means of the intra-amniotic injection of thyroid hormone (T_4 or T_3). Treatment effects have included reduction of fetal goiter, reduction of polyhydramnios, and reduction or normalization of TSH.

T_4 is detectable in fetal serum by the 12th week of gestation.[47] Thereafter, both T_4 and FT_4 increase linearly in relation to gestational age. Mean cord concentration of T_4 between 20 and 30 weeks of gestation is 5.5 ± 1.6 μg/dL. Normal ranges have been published for thyroid hormone concentrations in third-trimester amniotic fluid.[47] At term, the T_4 reaches 12.6 ± 4.0 μg/dL in umbilical cord serum, which is 10% to 20% lower than the corresponding value in maternal serum. FT_4 in cord blood is equal to or higher than that in maternal blood. Fetal T_4 metabolism differs markedly from that of postnatal life. In the fetus, T_4 is metabolized predominantly to rT_3 rather than T_3.

The concentration of rT_3 in the fetus exceeds 250 ng/dL early in the third trimester and progressively decreases to 150 to 200 ng/dL at term.[28] By the third to fifth day after birth, a rapid decrease occurs in rT_3, which reaches adult levels by 1 to 2 months of age. Compared with T_3, rT_3 has minimum metabolic activity. Therefore, serum concentrations and production rates of rT_3 are much higher in the fetus, whereas both T_3 and FT_3 in the fetal circulation are lower than those in the adult. T_3 and FT_3 in cord blood have been shown to be 30% to 50% of the maternal concentrations at term.

TSH is also present in the 12-week-old fetus and rapidly rises thereafter, in parallel with the increasing FT_4. TSH does not correlate with fetal T_4 or maternal FT_4. TSH is higher in the fetus than in the mother. At term, the fetal value of TSH is more than twice that found in the mother. These findings suggest that fetal TSH regulates fetal thyroid function.

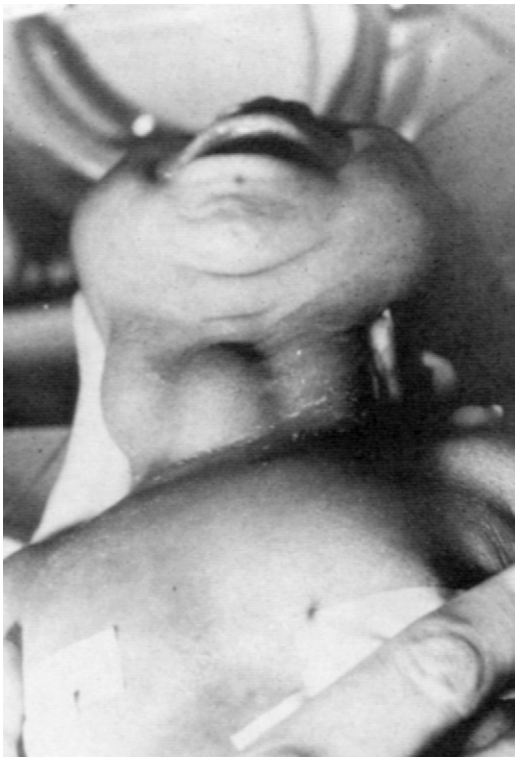

Figure 49–23. Iodine-induced goiter in a neonate. The lateral bulging of the neck is caused by enlarged lateral lobes of the thyroid.

T_4-binding proteins can also be detected in the 12-week-old fetus. During early fetal life, T_4 appears to be bound mainly to TTR and albumin. Fetal TBG increases rapidly and by midgestation reaches a level approaching that in a full-term infant. During early gestation, the rise in fetal TBG parallels the increase in T_4 bound to TBG. The binding capacity of TBG in premature and full-term infants is about 1.5 times that in the normal adult but lower than that in the mother. The high TBG in the neonate is caused by transplacental transfer of estrogens from the mother and to a large extent accounts for the high T_4 in infants. TBG remains essentially unchanged during the first 5 days of life. TTR is low in both newborn and maternal sera and plays a minor role after midgestation.

Shortly after birth, transient but marked hyperactivity occurs in the thyroid function of neonates (Tables 49-8 and 49-9). Within the first minutes of life, there is a dramatic release of TSH, reaching a peak level of about 100 mU/L at 30 minutes of age. This hypersecretion of TSH persists during the next 6 to 24 hours. Evidence shows that this acute rise in TSH may be stimulated at least partially by a drop in the body temperature of the fetus with birth. In response to the postnatal TSH surge, T_4, FT_4, and T_3 increase progressively during the first hours of extrauterine life, reaching a peak at about 48 hours of age. The increases in T_3 and FT_3 are more marked than those of T_4 and FT_4 during this period because of increased peripheral conversion of T_4 to T_3. Therefore, neonates experience a physiologic hyperthyroid state during the first few days of life. The absence of this chemically hyperthyroid state constitutes strong evidence of congenital hypothyroidism. Concentrations of thyroid hormone remain elevated during the first 2 weeks of life and fall gradually thereafter, with FT_4 reaching high-normal adult values by 4 to 6 weeks of age. True adult levels of T_4 and T_3 are not reached until puberty probably because TBG levels in children remain elevated compared with adults until mid-puberty (Table 49-8 and 49-9).

The postnatal TSH surge occurs even in preterm infants and those who are small for gestational age (SGA), although the changes in TSH and iodothyronines are less than those in healthy full-term infants. In preterm infants, T_4 concentrations may decline for a week and then gradually rise, remaining lower than those of full-term infants during the first weeks of life.[18] FT_4 is usually in the normal range for adults, although it is low compared with that in healthy full-term infants. T_4 varies in relation to TBG values. TSH returns to normal adult values after 3 to 10 days of postnatal life regardless of gestational age (see Tables 49-8 and 49-9) (see later section, “Transient Disorders of Thyroid Function”).

In human milk, T_4 is present in very small amounts. The concentrations of T_3 and rT_3 in human milk vary from specimen to specimen. The T_3 concentration in breast milk is insufficient to prevent the detrimental effects of hypothyroidism, although it may alleviate the symptoms in certain cases.

The iodine kinetics in infants and children are different from those in adults. The thyroid weighs about 2 g at birth, which is about one tenth of its adult weight. The 24-hour ^{123}I uptake by the thyroid in the infant after 1 month of age is similar to that in the adult. Therefore, the concentration of ^{123}I per gram of thyroid tissue in the infant is greater than that in the adult. The thyroid of the infant is more susceptible than that of the adult to damage by radiation and to the blocking effects of iodine and other goitrogens. T_4 turnover rate is also higher in infants and children than that in adults, which accounts for their greater thyroid hormone requirements per unit of body weight.

CONGENITAL HYPOTHYROIDISM

Congenital hypothyroidism is a deficiency in thyroid hormone present at or before birth.[29] Prompt diagnosis is critical because a delay in treatment can lead to irreversible brain damage or cretinism. However, overt signs of hypothyroidism are rarely present at birth, and 95% of affected babies are asymptomatic. Dynamic changes in thyroid function after birth, limited dependence of peripheral tissues on thyroid hormone until late in fetal life, and deprivation of maternal hormones and factors acquired by transplacental transfer contribute to the difficulty in establishing a diagnosis. Newborn screening for hypothyroidism was first performed and consequently established in 1972 in Quebec, Canada, to permit early identification of infants at risk and allow prompt institution of thyroid hormone replacement therapy (see “Neonatal Screening for Hypothyroidism,” later).[1,29]

Etiology and Pathogenesis

The etiologic classification of congenital hypothyroidism:

I. Primary hypothyroidism
  A. Defective embryogenesis of thyroid
    1. Agenesis (athyreosis)
    2. Dysgenesis
      a. Thyroid remnant in normal location (hypoplasia)
      b. Maldescent or ectopic thyroid gland (ectopia)
  B. Inborn error of hormone synthesis or metabolism (familial dyshormonogenesis)
    1. Iodide-trapping defect
    2. Iodide organification (oxidation) defect
      a. Without deafness
      b. With deafness (Pendred syndrome)
    3. Coupling defect of iodotyrosines
    4. Deiodination defect
      a. Generalized
      b. Limited to thyroid gland
      c. Limited to peripheral tissues
    5. TG synthetic defects
    6. Goiter with calcification
    7. Peripheral tissue resistance to thyroid hormone
    8. Unresponsiveness of thyroid to TSH
  C. Goitrous cretinism caused by maternal ingestion of goitrogens
  D. Iodine deficiency (endemic goiter)
II. Central hypothyroidism
  A. Genetic mutation or deletion (see Table 49-7)
    1. Isolated deficiency of TSH β-subunit
    2. Abnormality of hypothalamic-pituitary development, with multiple pituitary hormone deficiencies
  B. Midline congenital defect (septo-optic dysplasia, holoprosencephaly, cleft lip, single central incisor)
  C. Acquired birth injury (usually hypothalamic TRH deficiency) (birth injury, hemorrhage, hydrocephalus, meningitis, trauma, nonaccidental injury)

DEFECTIVE EMBRYOGENESIS OF THE THYROID

In contrast to the clear preponderance of thyroid disorders in females compared with males during childhood and adult life, the gender difference in incidence of congenital hypothyroidism is much less obvious. In North America, the female-to-male ratio is about 2:1, as detected by neonatal screening programs.[1] The relative incidences of each type of congenital hypothyroidism vary widely in different geographic locations.

In nongoitrous regions, defective embryogenesis of the thyroid accounts for 80% to 90% of nonendemic congenital hypothyroidism. Loss-of-function mutations of the TSH receptor gene lead to hypoplasia of the thyroid gland and TSH elevation (see Table 49-7).[27] Mutations in transcription factors (such as *PAX8* and *TTF2*) may be responsible for some cases of congenital hypothyroidism. Failure in the anatomic development of the thyroid gland may be complete or partial. Residual thyroid tissue in the normal position or in ectopic location is detected in 60% to 80% of infants and children with hypothyroidism. An ectopic thyroid is usually composed of a remnant of undescended thyroid tissue that is usually situated in the midline. Undescended thyroid is located at the base of the tongue in about half of the cases, between the tongue and the hyoid bone in about one fourth, and between the hyoid bone and the normal location in the remaining one fourth. Ectopic tissue is often capable of undergoing compensatory hypertrophy when hormone production becomes inadequate, and thus may be found as a midline mass. Etiology of defective embryogenesis of the thyroid is unknown. Dysgenesis of the thyroid can be a familial condition. The ectopic or dysgenetic tissue may show a transient iodine organification defect.

Neonates with congenital hypothyroidism do not have an increased incidence of TGAb or TPOAb, nor do mothers with these autoimmune antibodies appear to have a higher risk for giving birth to children with congenital hypothyroidism.

However, these antibodies, as well as inhibiting TRAb, are associated with transient neonatal hypothyroidism.[19] Some types of maternal autoimmune antibodies against the thyroid may play a role in pathogenesis of the thyroid gland. One mother with both TSI and TBII was reported to have given birth to euthyroid, hyperthyroid, and hypothyroid children in three successive pregnancies.

FAMILIAL DYSHORMONOGENESIS

Genetically determined errors of T_4 synthesis or metabolism involve a deficiency of one or more enzymes necessary at various stages of the biosynthetic and metabolic pathways. Impaired secretion of T_4 and T_3 results in hypersecretion of TSH, usually leading to compensatory hyperplasia of the thyroid. The familial forms of congenital hypothyroidism are usually referred to as *familial dyshormonogenesis*. Hypothyroidism, goiter, or both may be present in the newborn and infant, depending on the degree and time of onset of the hormonal deficiency. Family members of children with familial dyshormonogenesis often have less severe defects manifested by goiter without associated hypothyroidism. Genetic defects in TG and thyroperoxidase synthesis have been reported in a few patients with familial dyshormonogenesis.

Hypothyroidism caused by a defect in the trapping of iodide can be confused with athyreosis because of the failure of administered radioiodine to be concentrated in the neck (point mutation in *SLC5A5*, sodium-iodide symporter). However, a goiter is clearly present in these patients, and salivary glands fail to concentrate radioiodine. A partial defect in iodine trapping results in decreased but not absent radioiodine uptake by the thyroid and salivary glands. The iodine-trapping defect is an autosomal recessive trait.[15]

There are specific types of defects in the oxidation or organification of iodide. Among them, the thyroperoxidase enzyme is deficient or defective, or cofactors that are required for activation of the enzyme or for the hydrogen peroxide generating system are defective (mutations in thyroperoxidase or *THOX2*).[15,33] These defects are usually associated with more severe hypothyroidism. In Pendred syndrome, patients have goiter with mild hypothyroidism or euthyroidism and congenital deafness. Many have an abnormal radioiodide discharge from the thyroid after perchlorate administration, indicative of defective iodide oxidation. However, peroxidase activity and hydrogen peroxide generation have been reported to be normal. TG is normal in quantity and low in iodine and hormone content. The mRNA encoding the 3′ region of TG may be abnormal, reducing efficiency of iodination and iodotyrosyl coupling. Chromosomal location reported for Pendred syndrome is 7q31. The sensorineural hearing defect is caused by a Mondini malformation of the cochlea. Incidence of this disorder is estimated to be about 1.5 to 3 per 100,000 schoolchildren. The defects are transmitted as autosomal recessive traits.

Mode of transmission of other inborn errors of thyroid hormone synthesis or metabolism has not been clearly established, although autosomal recessive inheritance and single gene mutations have been reported for most entities. In the coupling defect of iodotyrosines, T_4 and T_3 are decreased and MIT and DIT are increased in both serum and the thyroid gland (gene mutation not yet identified). In patients with iodothyronine deiodinase defects, there is a rapid turnover of thyroid iodine and wasting of iodotyrosines into the urine. The defect may be generalized, or it may be limited to intrathyroidal or peripheral deiodination. Defects in TG synthesis are suspected in patients with abnormal iodoproteins in their sera. Absent serum TG in neonates and mutations in the TG gene (8q24, stopping synthesis or causing conformational changes in the molecule) have been reported in these patients. Other rare types of familial dyshormonogenesis include a large kindred with goiter characterized by extensive intrathyroidal calcification. Transmission pattern suggests an autosomal dominant trait.

Generalized resistance to thyroid hormone by peripheral tissues (without resistance by the pituitary) has been reported (3q24, thyroid hormone receptor-β). Affected members of a family had deaf-mutism, goiter, delayed skeletal maturation with stippled epiphyses, and increased levels of thyroid hormone. Patients were reported to be clinically hypothyroid and required frequent thyroid hormone replacement therapy. However, the TSH response to TRH stimulation was normal.

Unresponsiveness of the thyroid gland to TSH has been reported in some children with congenital hypothyroidism without goiter. Serum TSH was elevated, and exogenous TSH stimulation caused no thyroid response (no increased radioiodine uptake or serum iodothyronine levels). Loss-of-function germline mutations of both alleles of the gene for the TSH receptor have been reported to cause resistance to the action of TSH and hypothyroidism.[35] The mutations were located in the extracellular, TSH-binding domain of the TSH receptor. The TSH receptor is coupled to the protein that binds to guanine nucleotide, or G protein. In these mutations, the TSH receptor does not activate G protein, and the effector adenylate cyclase (cAMP) signaling pathway remains inactive (*GNAS* mutations).[42] Some patients with these mutations may also have resistance to other hormones mediated by G protein (parathyroid hormone, growth hormone–releasing hormone, luteinizing hormone, follicle-stimulating hormone), as in pseudohypoparathyroidism type Ia.

MATERNAL INGESTION OF GOITROGENS

Maternal ingestion of antithyroid drugs, especially iodides, thiocarbamides, and potassium perchlorate, can cause neonatal goitrous hypothyroidism. Expectorants are an example of over-the-counter drugs containing iodides. Although correlation between dosages of these drugs and incidence of neonatal goiter is poor, prolonged administration of large doses of these drugs increases the risk for goitrous congenital hypothyroidism. Administration of large quantities of an inorganic iodide to the mother, usually as a perinatal or neonatal antiseptic, also causes neonatal goiter filled with colloid (see Fig. 49-23). Administration of amiodarone, an antiarrhythmic drug that contains two atoms of iodine, has resulted in goitrous congenital hypothyroidism in 11 of 64 (17%) treated pregnancies.[6] Radioiodine treatment given to pregnant women after 11 to 12 weeks of gestation has resulted in congenital hypothyroidism in the offspring. It is worthy of note that the hypothyroidism was not obvious at birth in most instances.

IODINE DEFICIENCY

Endemic goiter and cretinism are still prevalent in large geographic areas where dietary iodine is deficient. In iodide-sufficient regions, no more than 3% of newborns have transient TSH elevation. There are two severe types of endemic cretinism: myxedematous cretinism with metabolic symptoms of hypothyroidism and neurologic cretinism with dominant neurologic disorders. Despite the prevalence of intellectual impairment in endemic iodine-deficient regions, incidence of goiter in neonates is relatively low in these areas. Many individuals living in the same environment do not develop goiter. These observations suggest that other environmental factors may be superimposed on iodine deficiency. For instance, selenium deficiency leads to the inadequate use of iodine.[25] Iodine deficiency results in altered iodine metabolism, and the production of T_3 is increased relative to T_4. Reduced maternal T_4 levels early in gestation may deprive the developing fetal brain of T_4, which may be the essential iodothyronine for early brain maturation.

Many countries have initiated salt iodination. However, there is some concern that maternal iodine deficiency may be reappearing in developed countries despite salt iodination because diet-conscious young women may avoid iodine-supplemented salt and breads.[21] Iodine supplementation before or during pregnancy may normalize thyroid function in the mother and newborn. The recommended iodine intake for pregnant women is 200 μg daily, and in infants, the recommended intake is 40 μg daily.[21] Urinary iodine assay can be used to assess the adequacy of iodine uptake. Cochrane review indicated that there are insufficient data to support routine supplemental iodine in preterm infants.[24]

CENTRAL HYPOTHYROIDISM

Secondary (pituitary) and tertiary (hypothalamic) hypothyroidism are not commonly recognized in neonates. Central hypothyroidism can be confirmed in children and adults by the TSH surge test.[44,55] However, circadian variation of TSH secretion does not mature until about 4 to 6 months of age. Infants with central hypothyroidism can be detected through neonatal thyroid screening programs when T_4 measurements are included with TSH as the neonatal screening test (see Appendix Fig. B-6). Most of these patients have TRH deficiency, causing low-normal T_4 and low or normal TSH levels. They respond to TRH infusion with a sharp rise in serum TSH.

Secondary hypothyroidism may be suspected in infants with low T_4 and FT_4 and low TSH.[19] However, many infants with central hypothyroidism have normal TSH and are missed until they are older than one year.[35a] A low FT_4 by direct dialysis is the confirmatory test that determines the need for continued treatment when the diagnosis is suspected on the basis of initial tests. When available, the TRH infusion test may be used to distinguish hypothalamic TRH deficiency from pituitary TSH deficiency.

Pituitary TSH deficiency is rare in neonates (1 in 100,000).[4] However, autosomal recessive disorders that cause severe hypothyroidism as a result of congenital TSH deficiency have been reported. Mutations have been identified in the β-subunit of TSH, the TRH gene, and the TRH receptor gene.[41] Congenital TSH and growth hormone deficiencies may occur as the result of a difficult birth or anoxia.[39] Multiple pituitary hormone deficiencies suggest a genetic defect in the cascade leading to fetal pituitary formation, such as *PROP1*, *LHX3*, or *POU1F1*. When present, pituitary aplasia may be associated with anencephaly or other severe malformations of the brain. These patients rarely survive beyond the neonatal period.

Other midline facial, cranial, or intracranial defects should suggest the possibility of hypopituitarism, including altered functioning of the hypothalamic-pituitary-thyroid axis. Septo-optic dysplasia, often associated with pituitary hormone deficiencies, can be manifested as secondary or (more commonly) tertiary hypothyroidism. A genetic mutation in *HESX1* has been described in septo-optic dysplasia. Clinical symptoms of hypopituitarism, such as neonatal hypoglycemia (from growth hormone and ACTH deficiencies), polyuria (from antidiuretic hormone deficiency), or a small phallus in boys (from gonadotropin deficiency), whether or not accompanied by the presence of blindness, congenital nystagmus, or midline defects of the brain, should alert the physician to suspect septo-optic dysplasia.

Neonatal Screening for Hypothyroidism

Every state in the United States and every province in Canada have legislatively mandated the screening of newborns for congenital hypothyroidism.[1] Screening programs have also been established in Western Europe, parts of Eastern Europe, Japan, Australia, and parts of Asia, South America, and Central America. However, many countries still do not have a nationwide program for neonatal thyroid screening (see Table 49-10).

Most programs currently use the filter paper spot technique.[1] Capillary blood specimens from a heel stick are obtained at 24 hours to 5 days of age. The filter paper designed for this purpose bears printed circles. Blood samples are placed in these circular areas to fill and saturate the areas. Most programs throughout the world screen for primary hypothyroidism with the measurement of TSH only.[19] In some U.S. states and some Canadian provinces, initial screening measures T_4. Those samples with T_4 values that fall within the lowest 10th percentile of that day's T_4 determinations are tested for TSH. These methods effectively screen for congenital hypothyroidism for the following reasons: (1) they are easily incorporated into the existing metabolic-genetic screening programs (e.g., phenylketonuria screening); (2) primary T_4 with confirmatory TSH screening (T_4 + TSH) also rapidly identifies those infants with central hypothyroidism or TBG deficiency; (3) selectivity is high because TSH measurements discriminate between affected and nonaffected infants, with a low recall rate (0.3% to 1%); (4) cases of mild congenital hypothyroidism are identified by primary TSH screening, and most cases are also identified by T_4 + TSH screening.

Both methods of screening (primary TSH and primary T_4 + TSH) appear to be capable of detecting almost all infants with primary congenital hypothyroidism, the only form of congenital hypothyroidism that carries a high risk for mental retardation if not detected early and treated adequately. Although a TSH level of greater than 50 mU/L is highly suggestive of congenital hypothyroidism, some affected infants have TSH values between 25 and 50 mU/L. These infants require prompt serum confirmation testing because many will be shown to have primary congenital hypothyroidism. The practice of early hospital discharge (before 48 hours of age) has led to a higher rate of indeterminate results. Infants screened before 48 hours of age require recheck of the newborn screen by the primary care physician at 2 weeks. Preterm infants screened prior to 48 hours of age have an elevated false positive rate.[47a] From mass screening programs in North America, overall incidence of congenital hypothyroidism appears to be about 1 in 3500 to 4000 births.

CH, congenital hypothyroidism; FT_4, free T_4; IQ, intelligence quotient; NA, not applicable; T_4, thyroxine; TSH, thyrotropin.

Incidence of congenital hypothyroidism (including dyshormonogenesis) is greatly increased in Down syndrome, as are acquired autoimmune diseases of the thyroid gland, pancreas, stomach, and adrenal gland.[22] Obvious congenital hypothyroidism occurs in 1 of about 140 subjects with Down syndrome. T_4 concentrations in 284 newborns with Down syndrome were significantly decreased compared with those in controls.[50] Many additional children with Down syndrome have mildly elevated TSH (5 to 15 mU/L) and low-normal FT_4 values. TSH bioactivity appears to be normal, suggesting that these children with Down syndrome and mild TSH elevation have mild tissue hypothyroidism. If TSH elevation persists up to 4 weeks of age, the child's mental development may be best protected by initiating thyroid hormone replacement, as in transient hypothyroidism.[1]

There is a female preponderance of 2:1 in the incidence of congenital hypothyroidism in North America, with aplastic or hypoplastic thyroid gland in about one third of the cases. The prevalence of nonendemic, goitrous congenital hypothyroidism depends on frequency of the defective gene in the population but usually occurs in 10% to 20% of infants with primary hypothyroidism. Ectopic thyroid tissue occurs in 33% to 50% of congenital hypothyroidism cases. Ascertainment depends on sophistication of imaging methods. Infants with central hypothyroidism constitute less than 5% of the detected cases. In the United States, combined incidence of secondary and tertiary hypothyroidism is about 1 in 80,000 to 100,000 births, and that of goitrous hypothyroidism is about 1 in 30,000 births. There are geographic differences in prevalence of transient hypothyroidism that may be related to iodine intake. In areas with an adequate iodine supply, most infants with transient hypothyroidism were born to mothers who received goitrogens during pregnancy. Some cases result from placental transmission of maternal antibodies.

Screening programs that measure T_4 also identify infants with TBG deficiency. This predominantly X-linked trait (Xq22.2) occurs as frequently as 1 in 5000 to 10,000 births. TBG deficiency has no clinical importance but leads to abnormal laboratory tests. T_4 and TSH concentrations are low, T_3U is elevated, and FT_4 is normal. Diagnosis can be confirmed by low TBG concentration on specific radioimmunoassay. Infants with normal FT_4 and TSH levels should not be treated with thyroid hormone.[19]

Clinical Manifestations

Even in athyreotic infants, classic clinical features of congenital hypothyroidism are usually absent at birth and appear only gradually over about 6 weeks. In patients with a functional remnant of thyroid tissue and in those with familial dyshormonogenesis, clinical manifestations may be delayed several months or years, depending on the functional state of the thyroid.[19] Early manifestations include lethargy, inactivity, hypotonia, periorbital edema, large anterior and posterior fontanelles, feeding difficulty, respiratory distress, pallor, prolonged icterus, perioral cyanosis, mottled skin, poor or hoarse crying, constipation, and hypothermia.[19]

Feeding difficulty is often first noted by the mother or a nurse; the infant readily falls asleep after sucking for a short period, necessitating repeated stimulation and a prolonged period to complete the feeding. Respiratory distress associated with myxedema of the airway is characterized by noisy breathing, nasal stuffiness, and intermittent cyanosis, especially in the perioral area. Respiratory symptoms may lead to suspicion of congenital anomalies of the airway or congenital heart disease. After the first week of life, prolonged physiologic jaundice may be an indication of hypothyroidism. Jaundice may appear to be further prolonged when carotenemia is superimposed after feeding the infant a diet high in carotene. In primary hypothyroidism, indirect hyperbilirubinemia predominates, whereas in central hypothyroidism, there is a mixture of indirect and direct hyperbilirubinemia. Serum creatinine may be elevated.

Classic features of congenital hypothyroidism in the infant usually become apparent after about 6 weeks of age (Fig. 49-24). They include typical facies, characterized by a depressed nasal bridge, a relatively narrow forehead, puffy eyelids; thick, dry, cold skin; long and abundant coarse hair; large tongue, abdominal distention, umbilical hernia, hyporeflexia, bradycardia, hypotension with narrow pulse pressure, anemia, and widely patent cranial sutures.[19]

Lingual thyroid tissue can occasionally be seen in infants and children as a discrete round mass at the base of the tongue (Fig. 49-25). The base of the tongue must be firmly depressed to visualize the lingual thyroid. Because ectopic

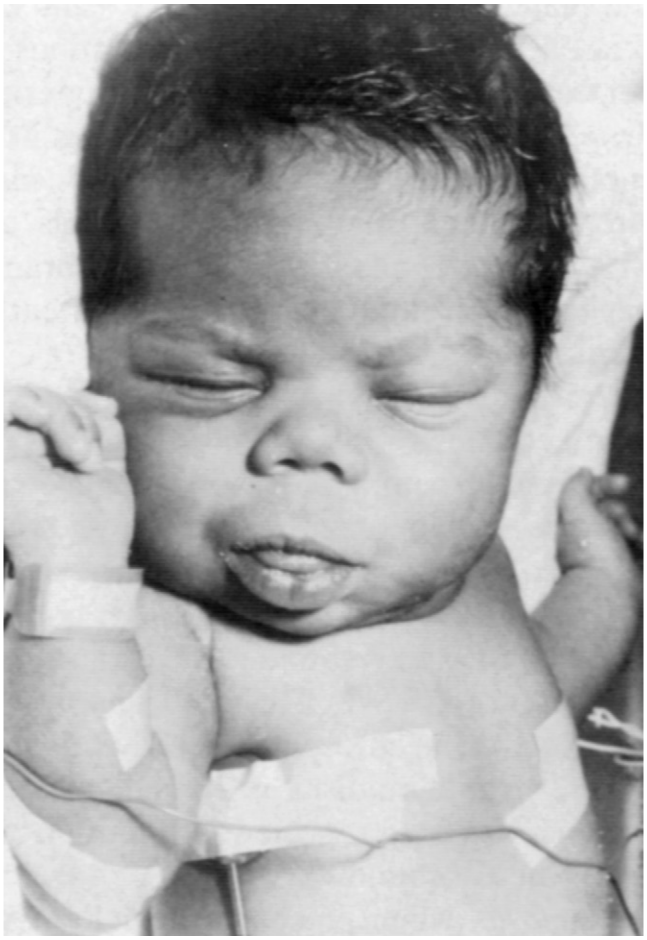

Figure 49–24. Typical facial features of cretinism.

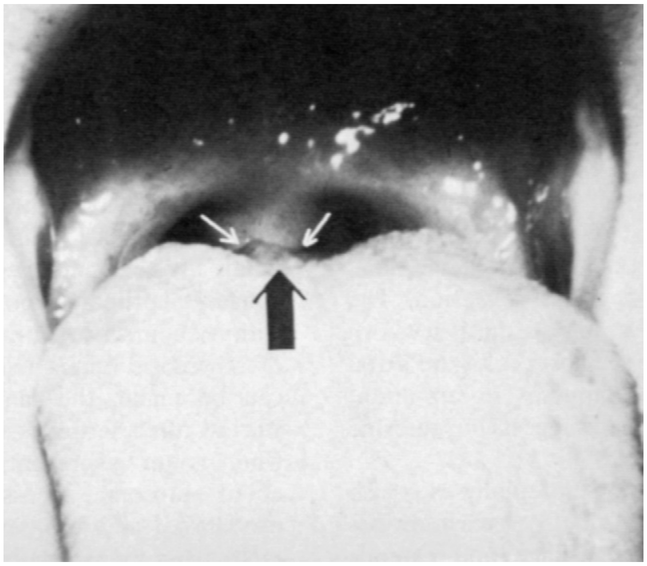

Figure 49–25. Visualization of a lingual thyroid.

thyroid tissue may function normally at birth, the ectopic gland of a child may not be detected by newborn screening and may present during childhood or adolescence with a lingual mass associated with speech and feeding problems. In some instances, the sublingual thyroid is palpable as a round midline mass deep under the mandible or is visualized by ultrasonography.

Neonatal goiters may be extremely large, asymmetric, and confused with hygroma or other cervical masses (see Fig. 49-23). Alternatively, the goiter may be quite small and escape notice. The thyroid can be palpated in infants by placing them in the prone position, gently extending the neck, identifying the thyroid cartilage, and palpating inferiorly and laterally for the thyroid isthmus and lobes. The normal size of each thyroid lobe is about equal to the volume of the distal segment of the patient's thumb.

In infants with central hypothyroidism, there is no thyroid enlargement. Onset of symptoms tends to be gradual because some T_4 production continues. As a result, prognosis for mental development remains good. However, signs of other pituitary hormone deficiencies, congenital midbrain defects, or both are typically present. These signs may include neonatal hypoglycemia, a small penis, hypospadias, undescended testes, wandering nystagmus, cleft lip or palate, and combined direct and indirect hyperbilirubinemia. Growth failure gradually becomes evident in these patients.[35a,44]

Laboratory Manifestations

When the diagnosis of congenital hypothyroidism is suspected, thyroid function tests should be performed. It is advisable to assess FT_4, TSH, and TG levels.[1] Measurements of T_3, rT_3, FT_3, and T_3U are not currently indicated. Elevated serum TSH value is the most sensitive and specific test to confirm the diagnosis of primary hypothyroidism. The normal value for TSH in cord blood is higher than that at any other age (see Tables 49-8 and 49-9). The physiologic TSH surge occurs during the first 6 hours of life, as noted earlier, and concentration of TSH may remain higher than 10 mU/L during the first 24 to 48 hours of life. Infants whose specimens were collected before 24 hours of life and who have mildly elevated TSH values very likely will have normal thyroid function tests on repeated testing.[47a]

The typical laboratory findings for primary hypothyroidism are an elevated TSH, with T_4 and FT_4 values in the low or low-normal range. A low or undetectable TG concentration with TSH elevation confirms a dysgenetic or absent thyroid gland, whereas a high TG with TSH elevation suggests an organification defect. In central hypothyroidism, TSH is usually normal, T_4 is low-normal, and FT_4 is in the lowest third of normal. In the latter, further investigation should include assessment of FT_4 by direct dialysis and measurement of TBG to confirm the diagnosis.

In infants with acute or chronic illness including respiratory distress syndrome, the euthyroid sick syndrome or nonthyroidal illness syndrome may be present and affects thyroid function test results but does not produce hypothyroidism.[18] Typical laboratory findings in nonthyroidal illness are low or normal serum T_4, normal FT_4 by direct dialysis, and normal TSH. Total T_3 can be very low, and rT_3 is elevated. In certain types of hypothyroidism, such as iodine-deficient cretinism, the preferential synthesis of T_3 may occur. Therefore, a normal or high T_3 concentration alone does not exclude hypothyroidism any more than does a normal T_4 concentration.

When a confusing situation arises, such as borderline values in screening tests, a repeated measurement of TSH and FT_4 determination by direct dialysis may be helpful. The TRH stimulation test may be helpful if available.

Retardation of bone maturation is present in about half of the newborns with primary hypothyroidism and may suggest the fetal age at which a deficiency developed in the delivery of thyroid hormone to responsive tissues. Therefore, assessment of bone age is useful in the newborn.[1] However, radiographic examination of the hand and wrist (most often used in estimating bone age in children older than 2 years) is not helpful during the neonatal period because the first wrist ossification center, the hamate, does not appear in the normal infant until 3 to 4 months of age. Retardation of bone maturation in neonates is best assessed by radiographs of the knee and foot. The ossification centers of the calcaneus and talus appear at about 26 to 28 weeks of gestation, and those of the distal femur at about 34 to 36 weeks. The proximal tibial epiphyses appear at about 35 weeks of gestation. Absence of the distal femoral epiphyses in a newborn weighing 3000 g or more or absence of the distal femoral and proximal tibial epiphyses in an infant weighing 2500 to 3000 g at birth suggests an intrauterine thyroid hormone deficiency.

Ossification of the cartilage of the epiphyses is also disturbed in hypothyroidism. Ossification normally begins from the center of the cartilage and extends peripherally in an orderly manner. In hypothyroidism, calcification of epiphyseal centers starts from multiple irregular foci scattered within the developing cartilage. The irregular calcification pattern appears on the radiograph as stippled or fragmented ossification centers and is referred to as *epiphyseal dysgenesis* (see Fig. 49-22). This finding is highly characteristic of hypothyroidism and provides a strong clue for the diagnosis. Abnormal changes occur in the epiphyseal cartilage secondary to thyroid hormone deficiency before calcification, so even after hypothyroidism is treated, the characteristic pattern of calcification appears in all the centers that normally would have calcified during the period of deficiency. Stippled epiphyses may also occur in thyroid hormone resistance. The only other disorder with stippled epiphyses is multiple epiphyseal dysplasia, and thyroid function is normal in this familial disease.

In severe myxedema, low voltage of all complexes in the EKG and electroencephalogram may be seen, and cardiomegaly, reflecting myxedema of the heart, may be identified on a radiograph of the chest. Measurements of serum cholesterol levels and basal metabolic rates are not reliable diagnostic aids in the assessment of thyroid function during the neonatal period.

Interpretation of Scanning Results

An enlarged, lingual, or dysgenetic thyroid may be identifiable by ultrasound.[37] The use of ^{123}I or ^{99m}Tc-pertechnetate is recommended when practical to distinguish dysgenesis from ectopia. Within 2 hours, a definitive diagnosis of ectopic dysgenesis or athyreosis compared with antibody-induced hypothyroidism (TRAb) can be made, the family counseled, and treatment started after serum is collected for thyroid tests. Furthermore, when goiter is present, the family can be counseled about autosomal recessive disease and its probability of recurrence, and additional tests can be performed on DNA from the patient and family without a delay in initiating therapy.[29] However, initiation of thyroid hormone replacement therapy should not be delayed so that a scan may be obtained. Ultrasound may be performed and the scan can be delayed until after the age of 2 or 3 years, a time when thyroid hormone therapy can be safely withheld for 4 to 6 weeks.

^{99m}Tc can be intravenously administered by means of the same venous access used to collect blood for confirmatory thyroid function tests. Radioiodine should be administered through a nasogastric tube and the tube flushed with water to prevent any loss of the tracer. The presence of a defective iodine-trapping mechanism can be suspected in infants with goiter when there is a failure of radioiodine to be concentrated in the thyroid within 2 to 4 hours after oral administration of the tracer. The defect can be demonstrated by comparing radioiodine concentrations in simultaneously obtained samples of saliva and plasma 1 to 2 hours after the administration of the tracer. In the normal infant, salivary level is at least 10-fold and usually 20-fold greater than that in plasma. Radioiodine fails to be concentrated in the salivary glands of patients with defective iodine trapping.

In patients with one of the iodide oxidation defects, iodide taken up by the thyroid is readily released from the gland because it cannot be rapidly oxidized to iodine, especially in the presence of a competitive inhibitor. When thyroid uptake of radioiodine is measured 2, 4, 6, and 24 hours after oral administration of radioiodine in these patients, uptake may be normal or elevated during the early hours but rapidly declines within 24 hours. In normal infants, thyroid uptake of radioiodine gradually increases during the first 4 to 6 hours and plateaus at a level equal to 15% to 30% of the administered dose at the end of 24 hours.

When rapid oxidation of inorganic iodide to iodine fails to take place in the thyroid, an anion such as perchlorate can competitively inhibit the iodide accumulation, leading to a net loss of iodide from the gland. The perchlorate discharge test involves measurement of ^{123}I-iodide uptake at 2 hours, after which sodium or potassium perchlorate is given orally in doses of 10 mg/kg of body weight. Thyroid uptake is measured every 15 to 30 minutes for 2 hours. If the uptake decreases by more than 20% of the initial value, a defect in iodide oxidation is confirmed.

Immaturity of the oxidation system is suggested by reports of infants with transient thyroid dyshormonogenesis. They had positive perchlorate discharge tests at birth but normal thyroid function and uptake when tests were repeated after 2 years of age once thyroid hormone replacement therapy was discontinued. The defect may be temporary in ectopic thyroid tissue. These factors may constitute additional reasons to wait until the age of 2 or 3 years to perform the perchlorate discharge test.

Differentiation among other types of familial dyshormonogenesis is more difficult and often technically impossible to achieve during infancy. Studies required for the differential diagnosis usually involve the administration of radioactive substances in doses greater than those considered safe for infants. Studies of iodine kinetics in blood specimens obtained after the administration of radioiodine, in tissue culture specimens obtained by biopsy, or in both may be necessary for differential diagnosis. Therefore, in most instances, patients should be treated for a few years, with a definitive study undertaken at a later date. In the future, additional specific mutations will be known, and diagnosis may be confirmed by DNA analysis.

Diagnosis of hypothyroidism caused by maternal ingestion of goitrogens or neonatal exposure to iodine is usually established from the history and confirmed by its self-limited course. Thyroid hormone therapy should be administered in standard doses (see “Treatment” section, later). Therapy may be withdrawn at 3 years of age and thyroid function reevaluated off therapy.[1] Perchlorate discharge test may be positive both in iodine-induced goiter and after administration of antithyroid drugs. Urinary iodine concentration is elevated in infants with transient hypothyroidism caused by iodine excess.

In iodine deficiency, there is a decreased ratio of T_4 to T_3. When goiter is present, there should be an elevation of serum TSH and a decrease in serum T_4 levels after birth. Urinary concentration of iodine is low ($<$12 mg/dL) in these infants, and radioiodine uptake is increased.

TRANSIENT DISORDERS OF THYROID FUNCTION

Several causes of transient neonatal thyroid dysfunction must be distinguished from permanent disorders of thyroid function. The results of neonatal screening tests from these patients may mimic those found in permanent hypothyroidism and may lead to an erroneous diagnosis.

Transient Primary Neonatal Hypothyroidism

Transient hypothyroidism may occur in apparently healthy full-term infants. Thyroid function in patients with transient primary hypothyroidism reverts to normal either very promptly and spontaneously or after several months of T_4 therapy. If FT_4 is low or steadily decreases or TSH remains higher than 5 mU/L on serial testing within the first month of life, the infant should be treated with T_4 until 3 years of age to protect brain development. Persistent TSH elevation (beyond 4 weeks of age) is undesirable for brain development. Of course, one cannot know whether the case of hypothyroidism was transient until later.[10]

The incidence of transient primary hypothyroidism is higher in geographic areas where the dietary supply of iodine is insufficient. Premature infants are more susceptible, and incidence increases with decreasing gestational age.[18] The T_4 levels are low and TSH levels usually increased, but these test results may overlap with the normal range. FT_4 levels fall into the range seen in neonates with congenital hypothyroidism during the first 1 to 2 weeks of life. In many cases, the T_4, T_3, and TSH levels in the cord blood of affected infants have been found to be normal, suggesting that hypothyroidism developed only after birth. The condition is frequently associated with transient hypothyroxinemia of prematurity, which confounds the diagnosis. Transient hypothyroidism may develop after low Apgar scores are observed. Low urinary iodine concentration suggests inadequate dietary iodine availability as the causative factor. Iodine supplementation of the diet may successfully correct hypothyroidism and goiter in these infants.

The transplacental passage of antithyroid drugs from the mother may cause transient hypothyroidism with goiter in the neonate. Excessive supply of iodine may also cause transient hypothyroidism. Premature infants appear to be more susceptible to iodine-induced transient hypothyroidism. The excessive application of iodine-containing antiseptics to mucous membranes (e.g., omphalocele) or intact skin has also caused transient hypothyroidism in infants. Yet another cause of transient neonatal hypothyroidism may be the transplacental transfer of maternal inhibiting TRAb. These antibodies may persist in the infant's circulation for 2 to 3 months until they are metabolized. No goiter is present, and no image is seen on the thyroid scan, although thyroid tissue can be seen on an ultrasonogram.

Transient Hyperthyrotropinemia

Transient hyperthyrotropinemia is characterized by elevated serum TSH concentrations during the neonatal period despite normal T_4 and FT_4 levels. This condition probably represents mild transient or permanent primary hypothyroidism.[10] The basis for this statement is the sensitivity of modern TSH assays. TSH concentrations are the most sensitive indicators that the hypothalamic-pituitary axis is experiencing less T_4 than the body perceives to be optimal. The hypothalamic-pituitary-thyroid axis is finely tuned to maintain a fairly stable level of FT_4 within any individual. Divergence from this individual optimal setpoint because of illness or malfunctioning of the thyroid gland results in TSH elevation except when the hypothalamus or pituitary is unable to respond (in central hypothyroidism or rare pituitary resistance to FT_4 feedback). There may be a delayed rise in TSH, particularly in infants with very low birthweight.[1]

If left untreated, the high TSH levels may persist for a few days to several months or years.[1,2] The infants appear to be asymptomatic, and the cause of the condition is unknown. This disorder is very likely to be missed because, until recently, newborn screening programs in the United States initially used T_4, with TSH not measured unless initial T_4 fell into the lowest 10% level of each assay.[19] Transient TSH elevation has been reported in infants born to mothers who received antithyroid medications or iodine and in neonates with iodine deficiency. The incidence of transient neonatal TSH elevation appears to be higher in infants with Down syndrome.

In the case of persistence of TSH elevation above 5 mU/L, these patients may have permanent congenital hypothyroidism, transient neonatal hypothyroidism, or acquired autoimmune thyroid disorders.[10] Because untreated hypothyroidism can result in developmental loss, it will benefit the infant's brain development to initiate thyroid hormone replacement therapy by 4 to 6 weeks of age in cases of continued mild TSH elevation, rather than continue to monitor the levels without treatment while waiting for the resolution of TSH elevation. Treatment should be continued until the age of 3 years, when thyroid function can be reevaluated. If increased TSH persists at this older age, a thyroid scan or ultrasound examination should be performed to exclude ectopic thyroid dysgenesis or goiter from mild familial dyshormonogenesis.[19]

Transient Hypothyroxinemia

Transient hypothyroxinemia is seen in many preterm infants,[18] related to immaturity of the hypothalamic-pituitary axis. Serum T_4 and FT_4 levels are low in comparison with those of full-term infants, but TSH levels are normal. Serum TBG levels are only slightly low in preterm infants and do not account for the degree of hypothyroxinemia. When dietary supply of iodine is slightly deficient, low T_4 and FT_4 levels in preterm infants may be accompanied by high TSH levels and exaggerated TSH responses to TRH stimulation. Therefore, preterm infants living in iodine-deficient areas are exposed to the combined risk for transient tertiary and primary hypothyroidism. Prevalence of transient hypothyroxinemia may be as high as 1 in 6000 births in certain regions.

Low T_4 has been associated with a higher risk for intraventricular hemorrhage or death in premature infants. Serious illness is also a cause of low T_4 values.[18] With gestational ages of less than 30 weeks, there may be low TBG. After 30 weeks of gestation, TBG reaches the concentration present at term and does not account for the serum concentrations of T_4.

In preterm infants, the T_4 levels usually increase on repeated evaluations and become normal by 3 to 4 months of age.[18] By 6 months of age, all infants had T_4 levels in the normal range, thus documenting the transient nature of the defect. Developmental attainment at 1 year of age was equal to that in a matched control group who did not have low T_4 levels. No clear effect of T_4 administration on developmental outcome was found. It is recommended that thyroid screening in preterm infants be performed at 5 days of age and repeated at 2, 4, and 6 weeks of age.[18] Therapy for hypothyroxinemia in preterm infants born at less than 28 weeks of gestation led to improvement in mental outcome and less adverse medical outcome than those not treated. However, those preterm infants born at greater than 28 weeks of gestation had increased morbidity with thyroid hormone therapy. A placebo-controlled study in infants born at less than 30 weeks of gestation did not show beneficial effects of T_3 therapy plus hydrocortisone compared with placebo on risk for death or ventilator dependence at 1 or 2 weeks of age.[8]

Therefore, in the absence of TSH elevation, pragmatic treatment with thyroid hormone is not currently indicated in full-term or preterm infants with transient hypothyroxinemia or respiratory distress.[18] A Cochrane review has recommended controlled trials to further assess thyroid hormone therapy in very preterm infants with hypothyroxinemia.[38]

EUTHYROID SICK SYNDROME

In acutely ill patients, serum T_3 is decreased. Current hypothesis is that alterations in thyroid hormone occur as an adaptive response to decreased basal metabolic rates in severely ill patients. The syndrome has been recognized in sick infants and children.[11,12] These patients may have severe nonthyroidal illnesses that are either acute or chronic.

The consistent finding is an abnormally low serum T_3 level, accompanied by an increase in the rT_3 level. T_4 may be low or normal and FT_4 may be normal, depending on metabolic clearance rate of T_4. Serum TBG may be low or normal, and TSH is normal. In preterm infants, T_4, FT_4, and T_3 levels are naturally lower than those in term infants, and rT_3 is high.[18] Therefore, thyroid tests in preterm infants may present a confusing situation when the infants are ill from nonthyroidal diseases.

In the neonatal period, preterm infants with respiratory distress syndrome are the most frequently encountered patients with euthyroid sick syndrome.[18,49] In children, a variety of nonthyroidal illnesses have been associated with this syndrome, including severe gastroenteritis, acute leukemia, anorexia nervosa, renal disease, burns, and surgical stress. An alteration in T_4 metabolism to favor production of rT_3 over T_3 appears to occur rapidly. Euthyroid sick syndrome is found in patients with acute metabolic stress (e.g., diabetic ketoacidosis) and occurs in all pediatric patients who undergo cardiac surgery. There is a sharp rise in rT_3 and a less dramatic fall in T_3 by 2 hours after cardiac surgery. Reverse T_3 returns to normal before T_3, and there is an inverse relationship between the severity of illness and the T_3 level.

In euthyroid sick syndrome, abnormal thyroid function gradually reverts to normal function as the patient's primary illness improves.[19] During recovery, TSH may be transiently elevated (up to 15 mU/L). Treatment with thyroid hormone is not indicated in these patients. However, preterm infants at risk should be monitored by serial determinations of FT_4 and TSH, and T_4 treatment should be initiated if there is a progressive increase in serum TSH and decrease in FT_4.[28] T_4 treatment should probably be initiated if the illness state is expected to be persistent and TSH remains elevated for a month or longer.

Differential Diagnosis

Errors in diagnosis of congenital hypothyroidism usually result from a failure of the newborn screening program (no specimen collected or a laboratory error), from a clinical failure to suspect the condition, or from the misdiagnosis of other disorders as hypothyroidism.[1] These errors typically arise when the diagnosis is based on a few suggestive clinical features, and laboratory data are incorrectly interpreted. It is necessary to perform newborn screening even in sick newborns so that clear-cut abnormalities cannot be missed. Repeated screening is then indicated as the illness resolves.[18]

During the early neonatal period, respiratory difficulty, pallor, and cyanosis in hypothyroid infants must be differentiated from other common causes of respiratory distress and from congenital heart disease. Lethargy, inactivity, hypotonia, and feeding difficulty may be mistaken for manifestations of sepsis or brain damage from a variety of causes. The prolonged jaundice in hypothyroidism must not be confused with icterus caused by hemolytic anemia, septicemia, or hepatic disease. The coarse facial features, macroglossia, and dry skin of hypothyroidism can mislead one to suspect Hurler syndrome, chondrodystrophy, or Down syndrome. A large goiter must not be confused with a hygroma, cyst, or tumor of the neck. A lingual thyroid, when visible or obstructing the airway, may be mistaken for a tumor of the pharyngeal area. Although epiphyseal dysgenesis may resemble osteochondritis deformans in its radiographic appearance, the latter does not occur during the neonatal period.

Treatment

All hypothyroid infants, with or without goiter, should be rendered euthyroid as promptly as possible by thyroid hormone replacement therapy.[46] When there is low T_4 and elevated TSH on screening tests, thyroid hormone replacement therapy for neonatal congenital hypothyroidism must be started as soon as blood is collected for serum confirmation tests.[1] A delay of 8 days in the initiation of thyroid hormone therapy can be detected later as a lower score on IQ testing.[9] The half-life of serum T_4, including T_4 acquired from the mother, is short in infants (3 to 4 days) compared with adults (about 6 days). Neonates with a euthyroid goiter should be regarded as having mild congenital hypothyroidism (elevated TSH with normal FT_4). For example, those with mild TSH elevation and normal FT_4 may be monitored with serial TSH and FT_4 tests and not treated for up to 4 weeks. However, if TSH remains elevated, thyroid hormone therapy should be started. An infant with an ectopic thyroid gland should be treated without delay because overt hypothyroidism is virtually inevitable at a later age. In rare instances in which the diagnosis of congenital hypothyroidism cannot be established expeditiously because of confounding laboratory results, it is the safest course to fully treat the infant for the first 2 to 3 years of life and then reevaluate. Breast feeding can continue. Specifically, human breast milk does not contain enough T_4 to alter thyroid hormone levels in the infant. At 3 years of age, after the brain has substantially completed its growth, treatment can be withdrawn or decreased by 50% and the patient studied 4 to 6 weeks later.

Although most infants with congenital hypothyroidism are asymptomatic and identified on neonatal screening tests, they must be treated vigorously at the youngest possible age.[9] There is increasing evidence that the previously recommended doses of thyroid hormone replacement are inadequate for some infants. Inadequate thyroid hormone treatment, either by the physician's direction or because of poor compliance, appears to be a significant contributor to lower intelligence in older children who were treated from the first 2 months of life.

Asymptomatic infants and those with minimal clinical manifestations of congenital hypothyroidism can be given sodium-L-thyroxine, 12 to 15 μg/kg per day (administered orally once per day), beginning as soon as the diagnosis is established (optimally by 2 weeks of age).[1] The pill should be crushed or a brand used that dissolves easily in liquid and suspended in a small amount of formula, breast milk, or water (not the whole bottle). The suspension can be provided by way of a cross-cut nipple and followed later by the feeding. The initial dose of T_4 does not need to exceed 50 μg/day. T_4 increases to more than 10 μg/dL and FT_4 to more than 2 ng/dL within 3 to 7 days. At 1 month of age, the thyroid hormone dose may need to be decreased to 37.5 μg/day or on rare occasions to 25 μg/day if FT_4 exceeds 2.5 ng/dL, TSH is below 0.05 mU/L, or clinical symptoms of thyrotoxicosis develop. The target for TSH concentrations should be between 0.5 and 2.0 mU/L during thyroid hormone replacement therapy for primary hypothyroidism.[5]

In preterm infants, the same starting dose of T_4 (12 to 15 μg/kg per day) is recommended to promptly increase T_4 to normal. The dose may need to be decreased, as described, once T_4 values reach the desired normal level.[1]

No adverse effects from this dose of T_4 replacement therapy were found in infants during their first year of life as long as they were frequently monitored, including FT_4 and TSH determinations. Sodium-L-thyroxine is the drug of choice because the cerebral cortex derives about 80% of the required T_3 directly from the monodeiodination of circulating T_4.[1] T_3 and desiccated thyroid are no longer recommended for the treatment of congenital hypothyroidism. No advantage is observed with a combined T_3 and T_4 preparation.

In treatment of infants with severe myxedema with fluid retention, possible complications should be kept in mind. Cardiac insufficiency caused by overtaxing the myxedematous heart through too rapid a mobilization of the myxedema fluid into the circulation is well known in the adult. This complication in older children and adults is prevented by administering a small dose of thyroid hormone at first and gradually increasing the dosage. However, infants generally tolerate a rapid restoration to the euthyroid state better than adults, and a prompt restoration of T_4 to a normal value is important for the recovery of brain development and maturation. Nevertheless, excessive thyroid hormone therapy must be avoided, and the dose must be adjusted judiciously if there is evidence of severe myxedema, particularly of the heart. Aspiration of food rarely occurs in otherwise normal infants after therapy has been started. There is aspiration only in cases of severe myxedema from an impairment in swallowing (caused by myxedema of the pharyngeal area), compounded by an increased appetite as the euthyroid state is restored. Therefore, when myxedema is severe, the infant should be fed carefully and slowly during the early phase of treatment.

After replacement therapy is initiated, the dose of T_4 should be adjusted so that T_4 and FT_4 levels are maintained at high-normal adult values (>10 μg/dL and >2 ng/dL, respectively).[1] Thereafter, thyroid function test values should be kept at age-appropriate levels, which differ in children from those in adults (see Tables 49-8 and 49-9). With thyroid hormone replacement therapy, TSH is maintained between 0.5 and 2.0 mU/L during the first 2 years of life.[5] Sodium-L-thyroxine is less well absorbed in adults during food intake and when an infant is fed a soy formula (compared with cow's milk). For these reasons, the optimal time at which T_4 should be given is at least one-half hour before a feeding. However, from a practical point of view, infants can be given their thyroid medicine in a small amount of formula, with dosing adjusted on this regimen.

During the first years of life, patients should be monitored frequently—at least every 2 months during the first 6 months of life, every 3 months during the next 2 years, and then twice a year—to assess clinical progress, FT_4, and TSH.[1] Because poor compliance and noncompliance have major sequelae, the initial and ongoing counseling of parents is of great importance.

Between 2 and 6 years of age, the average dose of sodium-L-thyroxine required to initiate treatment is about 5 μg/kg per day; from 6 to 12 years of age, it is 4 μg/kg per day. Thereafter, an initial dose of 2 to 3 μg/kg per day should be adequate. In adults, the average thyroid hormone dose is 1.6 μg/kg per day (the average adult dose is 112 μg daily). These doses approximate 100 μg/m^2 per day. The treatment of each patient must be individualized. The dosage should be adjusted so that a clinically euthyroid state—TSH between 0.5 and 2.0 mU/L and FT_4 levels in the upper part of the normal range—can be maintained.

Clinical observation should be supplemented by monitoring of the growth curve, FT_4, and TSH. Patients with permanent congenital hypothyroidism (e.g., dysgenesis, dyshormonogenesis) require lifetime substitution therapy. Therapy should be continued consistently until formally re-evaluated under physician supervision at 3y of age.[26a] After 3 years, if there is uncertainty about whether the disease is permanent or transient, or if the dose of T_4 has not required increase because TSH has remained in the target range of 0.5 to 2.0 mU/L, discontinuation of T_4 therapy for 4 to 6 weeks, with monitoring of the TSH, should distinguish transient from permanent congenital hypothyroidism.

Goitrous cretinism caused by the maternal ingestion of goitrogens is a self-limited condition.[19] The blocking effect of antithyroid drugs usually disappears several days after birth. Therefore, if the goiter is small, TSH is not elevated, and the patient is euthyroid, no treatment is required. However, if the patient is hypothyroid and TSH is elevated or if the goiter is large, it is safer to treat the infant until the age of 3 years, as described previously. Shrinkage of the goiter may be hastened by substitution therapy, and treatment can be withdrawn after the thyroid returns to a normal size. Occasionally, the goiter is huge, and asphyxia may occur in the neonate from a goiter that encircles the trachea. This complication is most often seen in iodide-induced goiter and constitutes a medical emergency.

Although PTU is secreted in breast milk, the amount is so small that there should be no effects resulting from the transmission of PTU to the breast-feeding infant. If there is concern, serum TSH should be monitored initially each week for about 4 weeks. Methimazole (MTZ) therapy for mothers is not widely used because its biopotency in the fetus is about four times that of PTU. Nursing mothers are usually not treated with MTZ after delivery. Iodides are secreted into breast milk and could cause iodide-induced hypothyroidism in the breast-fed infant. Those with endemic goiter and hypothyroidism should be given substitution therapy for an indefinite period unless iodine prophylaxis can be ensured in the specific geographic location.

Prenatal diagnosis and intrauterine treatment of congenital hypothyroidism have been successful in only a few instances. Measurements of iodothyronines in amniotic fluid are unreliable. Determination of TSH in amniotic fluid or fetal blood collected by cordocentesis offers better hope for the diagnosis of congenital hypothyroidism at present (see "Thyroid Function: Fetal-Maternal Relationship," earlier). Maternal administration of TRH results in increased fetal TSH and T_3 and does not inhibit the postnatal surge of TSH. The maternal administration of oral T_4 has not yet proved effective in treating the fetus. Prenatal diagnosis and treatment of congenital hypothyroidism await further developments.

Prognosis

Shortly after adequate substitution therapy is instituted, all clinical manifestations of hypothyroidism disappear. If growth restriction was present before treatment, accelerated linear growth occurs. After a period of catch-up growth, an optimal rate of growth is maintained. Goiter or a hypertrophied ectopic thyroid gradually shrinks in size when the patient is properly treated. Coarse hair is gradually lost and replaced by finer, normal hair over several months. If there was a delay in skeletal maturation at diagnosis, treatment is associated with an acceleration in bone maturation after a latent period of a few months. Thereafter, osseous development parallels the chronologic and height ages. When hypothyroidism is treated with a slightly excessive dose of thyroid hormone for a prolonged period, bone maturation may gradually exceed the chronologic age even though the patient fails to show overt signs of hyperthyroidism or has clearly elevated T_4. With substitution therapy, epiphyseal dysgenesis (see Fig. 49-22) appears in ossification centers that failed to calcify while the patient was hypothyroid, and then the calcification coalesces to form a normal epiphysis.

Although the prognosis for physical recovery is good, including stature,[34] the prognosis for normal mental and neurologic performance is less certain for infants whose disorders were not detected early by newborn screening. There have been some reports in which a low to normal IQ score was correlated with severe hypothyroidism at birth and intrauterine hypothyroidism (evidenced by retarded bone maturation at birth) even when replacement therapy was begun within the first 2 months of life. More than 80% of infants given replacement therapy before 3 months of age had an IQ score of greater than 85. However, 77% of these infants showed some signs of minimal brain damage, including impairment of arithmetic ability, speech, or fine motor coordination in later life.[48]

Of course, the current goal for therapy is to start thyroid hormone treatment by 1 week of age to optimize long-term outcomes. Auditory brainstem evoked potentials were abnormal in 25% of 37 patients with congenital hypothyroidism treated early. The processing of visuospatial relationships remained affected in adolescents with congenital hypothyroidism.

Current follow-up studies of patients treated within the first few weeks of postnatal life after identification by neonatal screening indicated that neurologic function was normal, with a few minor exceptions. The best outcome occurs with thyroid hormone therapy started at 12 to 15 μg/kg per day by 1 week of age.[9] There are only minor differences in intelligence, school achievement, and neuropsychological test scores in affected congenital hypothyroidism adults treated early with thyroid hormone compared with control groups of classmates and siblings.[36] Residual defects may include visuospatial processing, sensorimotor defects, and selective memory. A threshold effect of congenital hypothyroidism severity interacts with the effects of dose and age at onset of thyroid hormone therapy. Otherwise, neurologic and intellectual outcomes do not correlate well with the degree of T_4 deficiency found in neonatal screening.

Prior observations and lack of clinical manifestations of hypothyroidism in most neonates led to the current concept that the transplacental transfer of maternal T_4 in the first trimester may protect the brain during early development. For the same reason, maternal hypothyroidism during fetal development can have persistent neurodevelopmental effects on the child.[30] Serum T_4 concentrations at term in athyreotic babies are 25% to 50% of those found in normal neonates. Although they are low, these levels may offer some protection for the fetal brain. It is thought that the low to normal intelligence of patients with congenital hypothyroidism treated early in life results most often from inadequate treatment or poor compliance. During thyroid hormone therapy, recurrent episodes of insufficiently suppressed TSH (>5 mU/L) four or more times after the age of 6 months constitute the most important variable associated with school delay.[31] Thyroid hormone treatment regimens used today are more aggressive in targeting the early correction of TSH than the regimens used 20 or even 10 years ago. Therefore, current newborns with congenital hypothyroidism may have an even better intellectual and neurologic prognosis than those adults with congenital hypothyroidism who are currently being studied.

GOITER

Most neonatal goiters result from maternal ingestion of goitrogens, maternal iodine deficiency, maternal antibodies, or maternal thyroid medications. Prominent goiter is only present at birth in infants with familial dyshormonogenesis. Most of the euthyroid goiters of newborns are caused by compensatory hypertrophy of the thyroid mediated by TSH stimulation and therefore are indicative of mild TSH elevation. These infants should be investigated etiologically and treated appropriately.

Congenital neoplasms of the thyroid rarely occur but may include a Hürthle cell tumor, adenocarcinoma, and teratoma of the thyroid. Teratoma may be suggested by calcification within the thyroid gland. Neoplasm can be suspected when a nodular goiter or hard mass is present in the thyroid. A radioiodine or technetium thyroid scan reveals a cold nodule in the area corresponding to the location of the neoplasm where the uptake of the radioisotope is lacking. A diagnosis of neoplasm should be confirmed by biopsy.

THYROTOXICOSIS

Etiology and Pathogenesis

Neonatal thyrotoxicosis is caused by transplacental transfer of TRAb and TSI from the mother. The disease occurs in the neonate of a mother known to have active Graves disease either before or during pregnancy, Graves disease previously treated with thyroidectomy or radioiodine ablation, or Hashimoto disease. However, mothers with detectable TSI may give birth to normal infants, especially when maternal TSI activity is low. Family studies, observation of twins, and age-specific incidence rates suggest that this disease occurs randomly in a genetically preselected population. Measurement of TSI in third-trimester serum or cord blood can be prognostic of risk for thyrotoxicosis in the newborn.

Neonatal thyrotoxicosis may also occur in infants without detectable TSI. In these infants, the pathogenesis may be familial syndrome of isolated pituitary resistance to thyroid hormone with mild thyrotoxicosis, autosomal dominant inherited germline mutations in the TSH receptor, mutations in the TSH receptor that cause constitutive activation of the receptor, or TSH-independent activation. Mutations in the transmembrane domains of the receptor keep it in the activated state so that G protein and adenylate cyclase can be continuously activated, causing hyperthyroidism. In these cases, TSI does not play a role.

Clinical Manifestations

When neonatal thyrotoxicosis occurs in the infant born to a mother with untreated, active Graves disease, clinical manifestations of hyperthyroidism may become apparent within the first 24 hours of life. Infants may be born prematurely from such a mother. Prenatal diagnosis may be possible in the event of fetal goiter, elevated maternal TSI titer, or elevated maternal DIT.[54] Irritability, excessive movement, tremor, flushing of the cheeks, sweating, increased appetite, weight loss or lack of weight gain, supraventricular tachycardia, goiter, and exophthalmos may be observed in the newborn.[19] Unique to the neonate with severe Graves disease is generalized enlargement of the reticuloendothelial system, causing generalized lymphadenopathy, hepatosplenomegaly, thrombocytopenia, and hypoprothrombinemia. Although a goiter is inevitably present in neonatal thyrotoxicosis, its size varies considerably; it may be small and escape notice on a cursory examination, or it may be large enough to cause tracheal compression. In addition, the goiter may increase in size during the early neonatal period. Exophthalmos is usually mild when present. In severe neonatal thyrotoxicosis, hyperthermia, arrhythmia, and high-output cardiac failure may occur. If the condition remains untreated, death may result.[19]

In most cases, the course of neonatal hyperthyroidism is self-limited because of the gradual depletion of transplacentally acquired TSI. The signs and symptoms subside spontaneously after 3 weeks to 6 months, depending on the severity of the disease. The severity of hyperthyroidism is probably related to the titer of TSI in the plasma of the neonate. However, goiter may persist for some time after all signs of hyperthyroidism disappear. The thyroid gradually returns to its normal size. In rare instances, neonatal thyrotoxicosis may not be a transient disorder and may persist for years.

In the infant born to a mother who received antithyroid medications for the treatment of Graves disease during the latter part of pregnancy, the onset of clinical manifestations may be modified by transplacental acquisition of the antithyroid agent as well as TSI. At birth, the infant may be euthyroid or even hypothyroid, and the presence of a goiter may be the only abnormal feature. Because the plasma half-life of antithyroid agents is short compared with the half-life of TSI, the typical manifestations of neonatal thyrotoxicosis may appear several days to 2 weeks after birth. If the infant is born in a hypothyroid state, a period of euthyroidism may follow within a few days, and thyrotoxicosis may not occur until 5 to 14 days after birth. Although neonatal Graves disease is a disease mediated by monoclonal antibodies, polyclonal antibodies are sometimes produced by the mother and cause atypical disease in the infant. Late-onset hyperthyroidism may not develop until 1 to 2 months of age if a high-affinity TBII in low concentrations initially predominates; once it is metabolized, a second population of TRAb prevails to cause late-onset hyperthyroidism.

Diagnosis and Differential Diagnosis

A maternal history of Graves disease before or during pregnancy is important in the diagnosis of neonatal thyrotoxicosis. Information concerning both prior and current treatment of maternal hyperthyroidism must also be obtained. The infant should be examined sequentially for signs of thyrotoxicosis, and the neck should be palpated carefully to detect a goiter. Determination should be obtained of TSI in infant serum or cord blood, in addition to that of TSH and FT_4; unmeasurable TSH supports the presence of thyrotoxicosis.[5,29] Data should be interpreted in relation to clinical features and age of the neonate. Determination of radioiodine uptake by the thyroid has little value during the neonatal period. A higher titer of TSI in cord blood or neonatal serum strongly supports the diagnosis of neonatal thyrotoxicosis. Serial determinations of TSI in the neonate also help monitor disease activity and contribute to the decision to decrease or terminate therapy.

In the euthyroid or hypothyroid neonate born to a mother who received antithyroid medication during the latter part of pregnancy, it is almost impossible to predict whether thyrotoxicosis will ensue. Therefore, serial examinations of the infant must be undertaken during the first 10 days of life. Although neonatal thyrotoxicosis can be confused with various neurologic disorders, narcotic withdrawal in the infant of an addicted mother, congenital heart disease, or sepsis, a positive maternal history of Graves disease and presence of goiter should readily alert the physician to the correct diagnosis. In normal neonates and infants, the thyroid gland is difficult to palpate. Therefore, an easily palpable thyroid in such an infant should generally be regarded as a goiter.

Persistent neonatal thyrotoxicosis may result from a TSH receptor activating mutation.[52] Rare cases of hyperthyroxinemia are characterized by the syndrome of total or partial loss of peripheral tissue sensitivity to thyroid hormone, called *generalized resistance to thyroid hormone*. Prenatal thyroid hormone resistance may present with growth retardation and goiter that may improve with maternal T_3 therapy. In these patients, FT_4 is elevated and TSH is measurable within the normal range (i.e., not suppressed as expected), but there is no clinical manifestation of hyperthyroidism.[29] Hyperthyroxinemia may also reflect elevated TBG production, in which case FT_4 is normal, and no therapy is needed.[29]

Treatment

The treatment of thyrotoxicosis in a neonate is similar to that in an older child and involves use of antithyroid drugs.[19,43a,43b] Care should be exercised not to induce hypothyroidism with excessive medication. Iodine (Lugol solution) and an antithyroid drug, MTZ, are typically used. Lugol solution can be given in KI doses of 8 mg three times daily. Although iodine rapidly inhibits the release of T_4 from the thyroid, its effects tend to disappear after several weeks. MTZ is given in doses of 0.3 to 1mg/kg per day in one or two divided doses. PTU is no longer recommended for use in children.[43a] Circulating T_4 has a half-life of 3 to 4 days in neonates and about 6 days in adults. Therefore, little or no clinical response to antithyroid drugs can be expected during the first few days of therapy. When FT_4 decreases, TSH increases (although this increase may be delayed despite low FT_4 values), and TRAb decreases over 1 to 4 months. When TSH increases, the dose of MTZ should be reduced or discontinued to determine whether the disease has a self-limited course.[19]

The TSH response to a hypothyroid state induced by the excessive treatment of thyrotoxicosis may be diminished for several months or longer in these infants. Therefore, lack of TSH elevation cannot be relied on to indicate the excessive treatment of thyrotoxicosis. The addition of T_4 therapy to maintain FT_4 just above the mean for the assay may be required to avoid the consequences of infantile hypothyroidism. Monitoring of TSI may facilitate decision making about when to discontinue antithyroid therapy with MTZ. Antithyroid therapy should be discontinued by 6 months of age.

Most signs and symptoms of hyperthyroidism, including the cardiovascular manifestations, are closely related to increased adrenergic response.[19] Therefore, β-adrenergic blocking drugs can alleviate many of the potentially life-threatening, serious manifestations of neonatal thyrotoxicosis. In contrast to antithyroid drugs, these agents can rapidly diminish the severity of thyrotoxicosis, and their effects are evident within a few hours. Propranolol hydrochloride, together with iodine and MTZ, may be used in the treatment of severe neonatal thyrotoxicosis. Propranolol hydrochloride is given orally in a dose of 2 mg/kg per day in two or more divided doses.

Digitalization may be necessary in neonates with cardiac failure. Under these circumstances, reserpine may be contraindicated or must be used with extreme caution. In life-threatening cases, addition of pharmacologic steroids (hydrocortisone, 100 mg/m^2) reduces the production of thyroid hormone. A large goiter compressing the trachea and resulting in asphyxia must be treated surgically by splitting the isthmus.

The euthyroid or hypothyroid infant born to a mother who received antithyroid medications during pregnancy should be managed as described in the section on congenital hypothyroidism. If the infant has already received thyroid hormone, such therapy should be decreased as soon as thyrotoxic manifestations occur, and the appropriate management of hyperthyroidism must be initiated.

In the future, pregnant women with Graves disease may be screened for fetal hyperthyroidism. Prenatal therapy may be possible with the use of oral maternal PTU and adjustment of the dose to normalize fetal TSH, cardiac function, and maternal serum compound W (DIT representing fetal thyroid hormone status). Serial ultrasound monitoring of the fetal thyroid size may be used to detect goiter, suggesting maternal overtreatment and the need for a reduction in PTU dosage.[13]

Prognosis

Before the use of β-adrenergic blocking drugs, neonatal thyrotoxicosis carried a mortality rate of more than 15% if it was not recognized and treated promptly. In most instances, the syndrome has a self-limited duration, and no sequelae have been recognized. A goiter may resolve slowly over several months. Premature closure of all cranial sutures may occur. It is advisable to obtain a radiograph of the skull at 6 to 12 months of age in infants with history of thyrotoxicosis to evaluate this possibility.

FAMILIAL ABNORMALITIES OF THYROXINE-BINDING PROTEINS

Genetic disorders resulting in either increased or decreased levels of T_4-binding proteins have been reported. Affected individuals are healthy and asymptomatic because a change in the level of T_4-binding proteins does not lead to an alteration of FT_4. The disorders are usually discovered fortuitously by the measurement of T_4, which reveals unexpectedly high or low values. Therefore, the only clinical significance of these conditions lies in the abnormal T_4 level, possibly leading to an erroneous diagnosis. The TSH levels are normal in these individuals.

Decreased Thyroxine-Binding Globulin

In several families, affected males had no detectable TBG. Moreover, there was no male-to-male transmission of the trait. The most common form of TBG deficiency is transmitted as an X-linked trait. A female member of one of these families had no detectable TBG and a sex chromosome constitution of XO (Turner syndrome).[43] A single TBG gene has been shown to be present on the long arm of the X chromosome. However, in another family, a deficiency of TBG was found in three males and three females from two generations. The mode of transmission in this family suggested an autosomal dominant trait. Therefore, the level of TBG may be controlled by more than one gene. Prevalence of this disorder is about 1 in 5000 to 10,000 births. In the X-linked form, the affected homozygous males may have a complete lack of TBG or may have partial deficiency, and their heterozygous mothers often have decreased levels of TBG.[43]

Increased Thyroxine-Binding Globulin

Studies in families with increased TBG suggest that the trait is inherited as an autosomal dominant gene. In another family, the affected males transmitted the trait to female but not male offspring, suggesting that the trait is X-linked.

Increased Transthyretin

Families with increased levels of TTR have been reported and specific gene mutations identified. Serum T_4 and FT_4 index (FT_4I) were elevated, but FT_4 and FT_3 were normal.

Familial Dysalbuminemic Hyperthyroxinemia

There have been several reports of individuals who had levels of circulating T_4 that fell into the thyrotoxic range. Despite their high T_4, these individuals are asymptomatic and euthyroid. T_4 and FT_4I are increased. FT_4 is normal when measured by direct dialysis method but increased when determined by analogue assay. T_3 and rT_3 are normal, as are basal TSH and TSH response to TRH. These individuals may be confused with those with hyperthyroidism. However, the TRH test and normal TSH can distinguish between these two conditions. Familial dysalbuminemic hyperthyroxinemia is caused by enhanced binding of T_4 by abnormal serum albumin. The albumin in affected individuals appears to bind T_4 with greater affinity than normal albumin and only slightly less so than TTR. The condition appears to be an autosomal dominant trait, and its prevalence is estimated to be about 1 in 10,000 births. No clinical consequences are observed, and no therapy is required.

PART 4

Disorders of Sex Development

Rayzel M. Shulman, Mark R. Palmert, and Diane K. Wherrett

Genetic sex is determined at the time of fertilization, but carrying out the encoded genetic directives that lead to sexual differentiation takes place over 14 weeks of embryonic and fetal development. An error or fault in this process may result in a disorder of sex development (DSD), defined as a discrepancy in the genetic, gonadal, or genital makeup of an individual. This part reviews (1) normal fetal sexual differentiation; (2) an approach to the recognition and diagnosis of neonates who may have a DSD; and (3) the classification, clinical features, and general management principles of DSDs, with the focus on perinatal issues.

FETAL SEXUAL DIFFERENTIATION AND DEVELOPMENT

Genetic Control of Fetal Gonadal Development and Differentiation

The embryo and early fetus, regardless of genetic sex (i.e., 46,XX or 46,XY), are bipotential (i.e., sex indifferent) with respect to their possible sexual differentiation, having the anatomic and biochemical apparatus necessary for both male and female development. For normal male differentiation to occur, a succession of genetic and hormonal signals must be intact and occur normally.[41] The classic teaching is that there is an innate tendency of the embryo and early fetus to differentiate along female lines; that is, female differentiation occurs if the signals for male differentiation are absent. However, evidence is growing that describes an active process involved in female differentiation.[75]

Y CHROMOSOME AND ROLE OF *SRY* GENE

The differentiation of the bipotential gonad is the event that determines the sexual differentiation of the fetus. The presence of the *SRY* gene on the Y chromosome causes the bipotential gonad to differentiate as a testis, and male phenotypic development follows. The presence of one, two, or more X chromosomes does not alter this process; however, the presence of more than one X chromosome (e.g., 47,XXY syndrome) results in eventual meiotic failure, loss of germ cells, and infertility. Candidate genes for an X-linked female determining factor are being investigated.[9]

Early ovarian differentiation does not require two X chromosomes and thus proceeds in 45,X fetuses. Later on, in ovarian differentiation, two X chromosomes are necessary for normal formation of primordial follicles. If part or all of the second X chromosome is missing, ovarian development fails, beginning from about 15 weeks on, because the abnormal primordial follicles and oocytes degenerate rapidly through the remainder of gestation (postfertilization). The resulting gonad appears as an elongated, whitish streak that microscopically shows whorls of fibrous tissue lacking in germ cells or epithelial elements. This "streak" gonad is characteristic of the gonadal dysgenesis syndromes.

Y chromosome fetuses that fail to undergo testicular differentiation are believed to experience the same gonadal changes to form streak gonads, but unlike gonadal dysgenesis in patients with X chromosome abnormalities, these structures carry a high risk for the development of gonadal tumors.[19] These tumors may result from the persistence of residual XY germ cells that did not degenerate or from tumorigenic loci on the Y chromosome.

AUTOSOMAL AND X-LINKED GENES

Although the presence or absence of the *SRY* gene determines the differentiation of the bipotential gonad, additional genes that are both autosomal and X-linked and located upstream and downstream from the *SRY* gene are involved in gonadal development and differentiation (Fig. 49-26).[20] Several of these genes have in common the encoding of a type of protein that functions as a transcription factor or transcription regulatory protein, which activates or represses the expression of other target genes, often in multiple tissues, thereby influencing or controlling a diverse program of cellular differentiation and proliferation during embryonic and fetal development. When gene mutation occurs, an alteration in the functional domain of the transcription factor can lead to abnormal or changed regulation (e.g., from a repressor to an activator) of downstream genes, resulting in abnormal cell differentiation or growth or neoplastic transformation. It is the occurrence of such mutations and the resulting pathologic conditions that have led to the identification and functional understanding of many of these genes.

Embryology and Endocrinology

The bipotential gonads and the anlagen for the genital ducts and external genitalia are derived from the mesodermal germ layer; the exception is the urogenital sinus epithelium, which is of endodermal origin. The bipotential gonadal and genital tissues undergo morphogenesis during the embryonic period, which extends from the end of the third week, or about age 20 days, through the seventh o eighth week of gestational age. Sexual differentiation occurs in the fetal period beginning in the seventh week, when the bipotential gonad begins to differentiate as either a testis or an ovary, and proceeding until 12 to 14 weeks of fetal age, when differentiation of the internal genital ducts and external genitalia along male or female lines is largely complete.

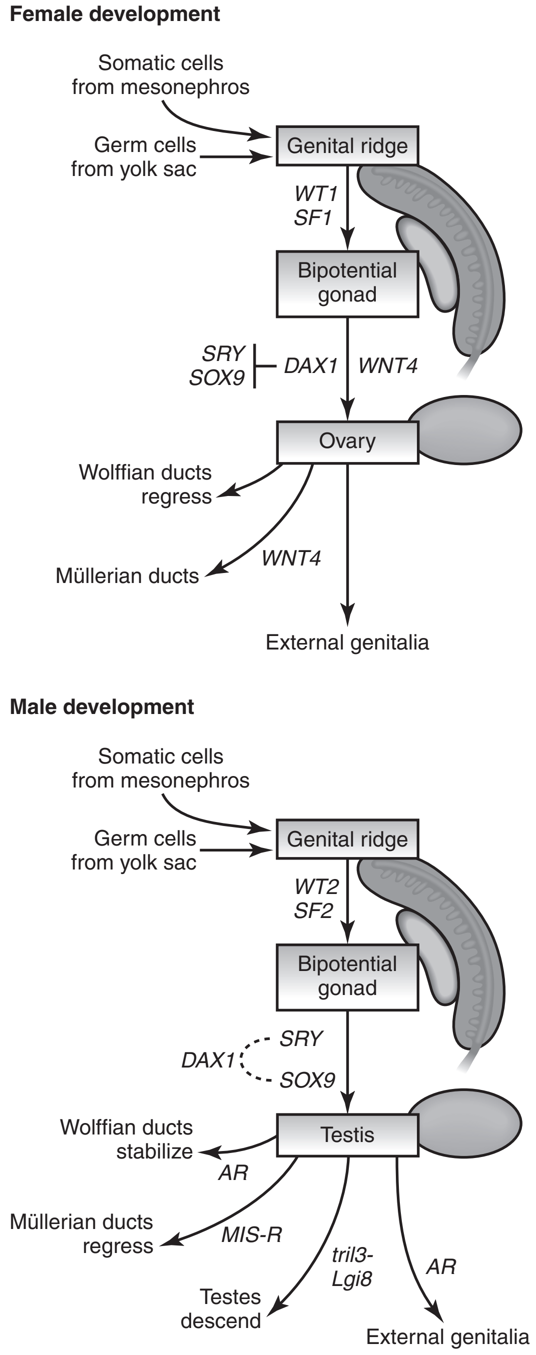

Figure 49–26. Possible roles of key genes in human fetal sexual development. The development of the genital ridge and bipotential gonad is under similar control in the two sexes. An ovary develops in the absence of *SRY* and *SOX9* action, possibly because of the antitestis effects of *DAX1* and *WNT4*. Steroidogenesis is delayed in the ovary by the action of *WNT4*, which is also needed for the development of the müllerian ducts. A testis develops as a result of *SRY* and *SOX9* action, complemented by *DAX1*. The regression of the müllerian ducts is mediated by müllerian inhibiting substance and its receptor (R), whereas the androgenic stabilization of the wolffian ducts and the differentiation of the external genitalia are mediated by the androgen receptor (AR). *(From Hughes IA: Female development—all by default?* N Engl J Med *351:748, 2004.)*

DEVELOPMENT OF THE GONADS

The gonadal blastema begins to form at 4 to 4½ weeks in the genital ridge, located bilaterally on the medial aspect of each mesonephros. The somatic component of the gonad is made up of cells from the coelomic epithelium and the underlying mesenchyme or adjacent mesonephros.[66] The germinal component comprises the primordial germ cells, which are mitotically active and migrate from the yolk sac endoderm at 24 days to reach the genital ridge at 4½ to 6 weeks, thereby forming the indifferent gonad (Fig. 49-27).[47]

Sex differentiation of the gonad begins at 7 weeks and denotes the onset of fetal sexual differentiation. The gonad differentiates as a testis if the *SRY* gene and its pathway are present and as an ovary if it is absent. The sex differences that appear in the developing gonad at this time include differentiation of cord somatic cells, changes in germ cell mitotic and meiotic activity, hormone production by the cord and interstitial (mesenchymal) cells, and development of the outer cortex. These differences are detailed in Table 49-11, and an overview is schematically represented in Figure 49-27.

TESTICULAR DIFFERENTIATION

Testicular differentiation begins at 7 to 8 weeks, when the sex cords form loops in the cortex and differentiate as the seminiferous cords; in the hilum, they anastomose to form the rete cords. From 8 weeks on, the seminiferous cords become coiled and thickened and contain 8 to 10 layers of Sertoli cells, whereas the spermatogonia remain located near the basement membrane of the cords. Leydig cells appear in the interstitium between the seminiferous cords at 7½ to 8 weeks. They increase strikingly in number during the third month, occupy half the volume of the testis at 13 to 14 weeks, and then show a significant fall in number. Some Leydig cells are present postnatally but histologically disappear after 3 to 6 months because of the physiologic lowering of gonadotropin stimulation.[27] As the fetus elongates, the testis descends and occupies a more caudal position. In the sixth and seventh months, the cremaster muscle differentiates in the caudal testicular ligament to form the testicular gubernaculum, which penetrates the inguinal canal and is anchored to the connective tissue of the scrotum. The testis descends behind the peritoneum and reaches the scrotum by the eighth or ninth month; the inguinal canal closes after testicular descent is complete.

OVARIAN DIFFERENTIATION

Ovarian differentiation begins at 7 weeks, as outlined previously and in Table 49-11. The sex cords in the ovary show germ cells (oogonia) undergoing repeated mitotic divisions from 7 weeks through about the fifth month. Most oogonia differentiate into oocytes between about 10 and 24 weeks; in so doing, they enter meiosis, proceeding through the first meiotic prophase. After reaching the meiotic prophase, many oocytes become surrounded by a single layer of granulosa cells to form the primordial follicles from about 15 weeks through term. Two X chromosomes are needed for differentiation of the primordial follicle. Oocytes that are not enclosed in a follicle degenerate. During ovarian differentiation, the number of germ cells greatly increases to several million oogonia and oocytes by the fifth month. Most germ cells degenerate thereafter either before or during the primordial follicle stage, leaving about 150,000 oocytes in each ovary at birth.

DEVELOPMENT OF THE GENITAL DUCTS

The internal genital ducts, unlike the gonads, develop from separate anlagen, from the mesonephric or wolffian ducts in the male and from the paramesonephric or müllerian ducts in the female. The wolffian ducts are formed in 26- to 32-day-old embryos; the müllerian ducts begin development at about 37 days in close association with the wolffian ducts, which serve as a guide to the caudal progression of the müllerian ducts. In the absence of the wolffian ducts, the müllerian ducts do not develop.

In the male fetus, the müllerian ducts begin to regress at 7 to 7½ weeks, shortly after the Sertoli cells have differentiated and begun to produce antimüllerian hormone (AMH), otherwise known as *müllerian-inhibiting substance*, and before the onset of local testosterone production by Leydig cells. Regression is complete by 9 weeks. Differentiation of the wolffian ducts is testosterone dependent and begins at about 8½ weeks. The wolffian ducts differentiate into the epididymis and vas deferens, and beginning at 10½ weeks, the seminal vesicles and their ejaculatory ducts develop at the caudal end from lateral outpouchings.

In the female fetus, müllerian duct differentiation occurs in the absence of AMH and does not require the presence of any ovarian hormone. The müllerian ducts form the fallopian tubes, uterus, and upper portion of the vagina beginning in the third month, stimulated in part by epidermal growth factor. The wolffian ducts degenerate in the absence of local testosterone and disappear by 13 weeks. The fallopian tubes later descend with the ovaries and are included in a fold of peritoneum called the *broad ligament*. At birth, the position of the uterus is vertical, and uterine development is disproportionate in that the uterine cervix is twice as large as the fundus; it remains so until puberty. Maternal estrogens stimulate uterine growth in utero, so its size at birth is larger than it is at several months of age; endometrial hyperplasia may occasionally result in transient neonatal uterine bleeding. The development of the vagina depends on the caudal müllerian ducts contacting the endodermal epithelium of the urogenital sinus. At this junction, a multilayered, solid epithelial cord known as the *vaginal plate* is formed; it disintegrates beyond 4 months to form the vaginal lumen. It is not clear whether the lower portion of the vagina is derived from the urogenital sinus, with the upper portion of müllerian origin, or the vagina originates entirely from the urogenital sinus.

DEVELOPMENT OF THE EXTERNAL GENITALIA

The external genitalia in both sexes, like the gonads, are derived from common anlagen (Fig. 49-28). Their inherent development is along female lines unless systemic androgens, specifically dihydrotestosterone (DHT), induce male differentiation. The genital tubercle forms early in the fourth week at the cranial end of the cloacal membrane, and on each side, the labioscrotal swellings and urogenital folds develop. Fusion of the urorectal septum with the cloacal membrane in the seventh week creates a dorsal anal membrane and a ventral urogenital membrane, which rupture in the eighth week to form the anus and urogenital orifice.

TABLE 49–11 Descriptive Features of Testicular and Ovarian Differentiation at 7 Weeks of Gestation

Gonadal Cells	Testicular Differentiation	Ovarian Differentiation
Cord somatic cells	Differentiate as Sertoli cells Synthesize antimüllerian hormone (AMH) at 7½ weeks Unable to aromatize androgens to estrogens	Differentiate as granulosa cells Do not synthesize AMH at this age Able to aromatize androgens to estrogens
Germ cells	Reduced mitotic activity results in small number of spermatogonia Meiosis is inhibited until puberty	High mitotic activity results in large number of oogonia Meiosis is promoted within several weeks
Interstitial cells	Differentiate as Leydig cells Synthesize testosterone de novo at 8 wk	Remain undifferentiated until 15 wk Lack steroidogenic capability at this age
Outer cortex	Sex cords lose connection with surface epithelium Mesenchymal tissue forms tunica albuginea that lacks germ cells	Sex cords retain connection with surface epithelium Thickened zone that contains germ cells

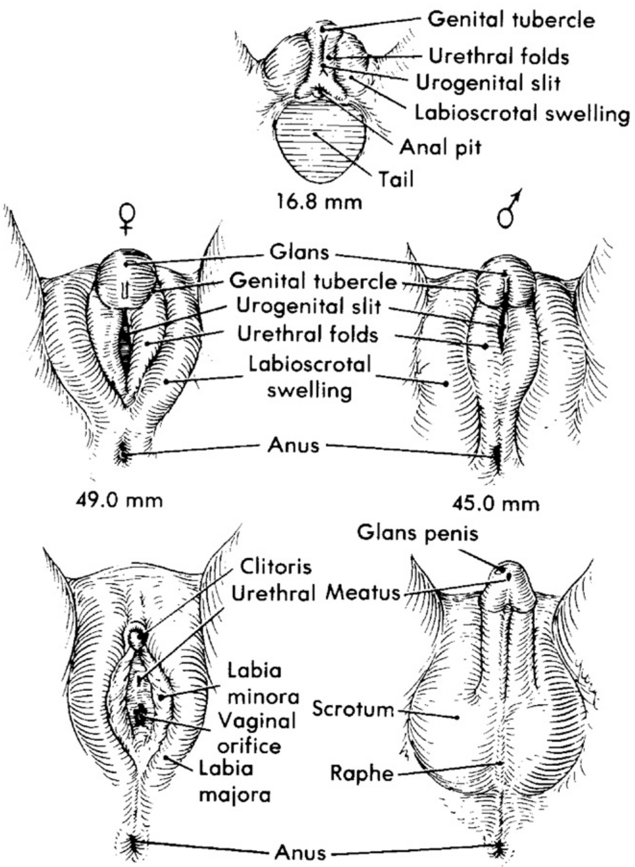

Figure 49–28. Differentiation of the external genitalia in the male and female fetus from the common primordia. *Top,* The indifferent genitalia are shown at about 48 days. The tail of the embryo has been cut away to uncover the genitalia. *Middle,* The genitalia at about 9½ weeks. In the male, anogenital lengthening and midline fusion have begun. *Bottom,* Newborn genitalia. Genitalia differentiation is complete by about 14 weeks of gestation. However, growth during the second and third trimesters accounts for the difference in phallic size. *(From Grumbach MM, et al: Disorders of sexual differentiation. In Wilson JD, et al:* Williams textbook of endocrinology, *10th ed, Philadelphia, 2003, Saunders, p 73.)*

Abnormal development of the urorectal septum results in anorectal malformations.

In the male fetus, the indifferent stage of the external genitalia lasts until the ninth week, when, in the presence of systemic androgens, masculinization begins with lengthening of the anogenital distance (see Fig. 49-28). The urogenital and labioscrotal folds fuse in the midline, beginning caudally and progressing anteriorly. The urethra develops with fusion of the urogenital folds, which forms both the membranous urethra in the perineum and the penile urethra along the ventral surface of the phallus. Midline fusion of the labioscrotal folds forms the scrotal raphe, whereas the penile raphe represents the fused portions of the urogenital folds. These processes are complete in the 14-week fetus.

In the 9-week female fetus, the anogenital distance does not increase, and the urogenital folds and labioscrotal swellings do not fuse (see Fig. 49-28). The labioscrotal swellings develop predominantly in their caudal portions but less so than in male fetuses, and they remain unfused as they are transformed into the labia majora. The urogenital folds develop into the labia minora. The epithelium of the vaginal vestibule between the labia minora and the hymen is endodermal, being derived from the urogenital sinus, whereas the epithelium between the labia minora and majora is ectodermal in origin.

Hormonal Control of Fetal Sex Differentiation

The fetal testes play a major role in male sex differentiation by producing two hormones, AMH and testosterone, which are major determinants of internal and external genital differentiation. On the other hand, the fetal ovaries play a negligible or no role in female sex differentiation, although they may have some steroidogenic capacity.

FETAL GONADAL ENDOCRINE FUNCTION

AMH is a large glycoprotein (molecular weight, 140,000 d) produced by the fetal Sertoli cells beginning at 7½ weeks that induces irreversible involution of the müllerian ducts. Regression of the müllerian ducts can be induced by AMH only during a fetal age of 44 to 70 days. The gene coding for AMH is located on chromosome 19p13.3, and for the AMH receptor on chromosome 12.

The other major hormone produced by the fetal testis is testosterone (Fig. 49-29). It is synthesized by the Leydig cells beginning at 8 weeks, and testicular production achieves peak serum testosterone levels at 10 to 15 weeks. In the second half of gestation, males show a gradual decline and females a rise in serum testosterone levels, so by the third trimester, males have similar or only slightly higher levels than females.[68]

The control of the fetal testicular synthesis of testosterone between 8 and 14 weeks is uncertain. The prime candidate has been human chorionic gonadotropin (hCG) of placental or fetal origin, which binds to fetal testes beginning at 8 weeks. From 14 weeks on, the fetal testes are able to respond to hCG with the production of testosterone. In the second and third trimesters, fetal serum luteinizing hormone (LH) levels correlate with the maintenance and subsequent decline of serum testosterone.[6] Follicle-stimulating hormone (FSH) receptors are present in fetal testes from 8 weeks on and may play a role in Sertoli cell or seminiferous tubule development.

The fetal ovary in the first trimester is hormonally quiescent, lacking hCG and FSH binding and the enzymes necessary for steroid synthesis. Starting at 8 weeks, the fetal ovary has aromatase activity and is capable of converting androstenedione or testosterone to estrone or estradiol, but actual production has not been demonstrated. Most estrogen that is present in the fetus is produced by placental aromatase. Amniotic fluid levels of estradiol at 12 to 16 weeks are slightly higher in females, raising the possibility of ovarian synthesis of estrogen. If it is synthesized, estradiol could play a local role in ovarian differentiation.[4]

CONTROL OF GENITAL DIFFERENTIATION: ROLES OF ANTIMÜLLERIAN HORMONE AND TESTOSTERONE

In the absence of testes, female sex differentiation occurs regardless of whether an ovary or no gonad is present; a male fetus castrated early also undergoes female sex differentiation. This activity is in keeping with the inherent tendency of the fetus to develop along female lines.

Male sex differentiation requires bilateral testes that produce AMH from the Sertoli cells and testosterone from the Leydig cells. AMH acts locally to cause regression of only the ipsilateral müllerian duct. If only one testis is present, müllerian duct development occurs on the contralateral side. Testosterone does not cause müllerian duct regression. A 46,XX female with müllerian duct regression due to a *WNT4* mutation suggests that müllerian duct regression can be controlled by proteins other than AMH.[26]

Testosterone produced by the fetal testes is secreted both locally, where it stimulates differentiation of the ipsilateral wolffian duct, and systemically, where it serves as a prohormone in the masculinization of the external genitalia. If only one testis is present, the contralateral wolffian duct fails to differentiate, indicating that the systemically circulating testosterone levels are inadequate for the stimulation of wolffian differentiation. Therefore, testosterone derived from maternal sources or the fetal adrenals, as in congenital adrenal hyperplasia (CAH), does not induce wolffian development.

Although the wolffian ducts are stabilized through the effects of testosterone, the external genitalia and urogenital sinus are stimulated to undergo male differentiation by DHT, which is formed in peripheral tissues (external genitalia, liver, kidney, and bone marrow) through the conversion of testosterone by 5α-reductase. Testosterone is a weaker androgen than DHT and does not stimulate male external genital differentiation, serving instead as a prohormone for DHT in this tissue. Systemic testosterone derived from the fetal adrenals, as in CAH, or from maternal sources can induce variable masculinization of the external genitalia when it is metabolized to DHT.

The absence of one testis is usually associated with incomplete masculinization of the external genitalia, suggesting that two testes are generally required to provide adequate systemic levels of testosterone and thus adequate DHT. The period in which DHT can induce male differentiation extends up to 12 to 14 weeks. A deficiency in androgen receptor binding results in androgen insensitivity, which may be partial or complete. In terms of fetal sex differentiation, the androgen-mediated events of wolffian duct differentiation, masculinization of the external genitalia, and growth of genital structures are either impaired or completely fail to occur, depending on the extent of the receptor binding deficiency.

A CLINICAL APPROACH TO THE INFANT WITH GENITAL AMBIGUITY

The evaluation of the neonate with a suspected DSD requires prompt attention and a team approach. Depending on the institution, the team may include neonatology, pediatric endocrinology, genetics, pediatric urology, pediatric gynecology, pediatric surgery, psychology, psychiatry, nursing, and social work. Appropriate initial assessment and management of the newborn with a DSD is essential to helping the family cope with this difficult situation. This evaluation needs to begin as soon as possible and should be approached systematically.

Definition of Ambiguous Genitalia

Most individuals with a DSD have some abnormality of their external genitalia that makes them identifiable at birth. An evaluation of a DSD is needed for patients who have any of the following: male-appearing genitalia with a micropenis, severe hypospadias or bilateral cryptorchidism; the presence of two defects, such as hypospadias and unilateral cryptorchidism; infants with female-appearing genitalia, the presence of posterior labial fusion, clitoromegaly, or a labial or inguinal mass that might represent a gonad; or discordance between the prenatal karyotype and genital examination findings.[35]

History

Most DSDs are either isolated occurrences or inherited as an autosomal recessive or X-linked trait. The family may not know the specifics about other family members with DSDs but may be aware of a family history of a trait that could be a manifestation of a DSD such as infertility, amenorrhea, or hypospadias. Considering CAH, the family should be asked about other infants with unexplained deaths. Consanguinity or a genetically homogeneous population increases the chance of autosomal recessive conditions. The infant's mother should be asked about any medications taken during pregnancy, especially androgens or progestins. In the case of a masculinized female infant, the mother should be questioned about and examined for virilization.

Physical Examination

Considerable information can be obtained by performing a careful physical examination. Specifically, inferences can be made regarding gonadal development and status and the degree of androgen effects. Examples of the wide range of disorders that may cause genital abnormalities are shown in Table 49-12. A schematic representation of varying degrees of virilization, graded using a scale developed by Prader, in males and females is shown later in Figure 49-40.

DELIVERY ROOM OR NURSERY EXAMINATION OF ALL NEWBORNS

Every newborn must have a careful genital examination in the delivery room or nursery. The purposes of the examination are to verify the gender assignment; avoid missing the diagnosis of a DSD, particularly in females with CAH, and recognize mild abnormalities that are not likely to affect gender assignment but require follow-up, such as mild hypospadias or unilateral cryptorchidism. The findings of a normal genital examination are listed in Box 49-10. The genitalia do not need to be overtly ambiguous to qualify for a diagnostic evaluation. Neonates with overtly ambiguous genitalia should have gender assignment deferred. The parents of the neonate should be informed that most of the diagnostic evaluation can be performed in 2 to 3 days, at which time the appropriate gender assignment can usually be made.

GONADAL DESCENT AND SIZE

Gonads should be carefully palpated in the scrotum or labial area and along the inguinal canal. Only a gonad containing testicular tissue (testis or ovotestis) can descend to a position where it is palpable (an ovary almost never descends). A small gonad (longest diameter <8 mm) may be dysgenetic, rudimentary, or due to lack of gonadotropin stimulation. The ability to detect gonads in the inguinal area can be enhanced by applying soap or oil to the skin and the examiner's fingers to decrease friction. With the infant supine, glide two or three fingers with gentle to firm pressure along the inguinal canal toward the scrotum, repeating this action numerous times if necessary. The gonad will be felt "popping" under the fingers. With this technique, less accessible or small gonads can be palpated that would otherwise be missed. Additionally, sit the infant in a frog-leg position and, particularly with crying or increased intra-abdominal pressure, the testis may descend into the lower inguinal or scrotal region.

PENIS SIZE

It is important to assess both the length and the amount of erectile tissue of the penis. A penis that appears small must be measured fully stretched, pressing the ruler down against the pubic ramus, depressing the suprapubic fat pad completely, and measuring to the tip of the glans only, ignoring

TABLE 49–12 Associations of Genital Abnormalities

Abnormal Characteristics	Examples of Associated Disorders
Male-Appearing Genitalia	
Micropenis	Growth hormone or luteinizing hormone deficiency Testosterone deficiency (in second and third trimesters) Partial androgen insensitivity Syndrome: idiopathic
Hypospadias (more severe)	Disorders of gonadal development 46,XX DSD Ovotesticular DSD 46,XX or 46,XX DSD Syndrome: idiopathic
Impalpable gonads	Anorchia Persistent müllerian duct syndrome 46,XX DSD with 21- or 11β-hydroxylase deficiency Cryptorchidism
Small gonads	47,XXY, 46,XX DSD Dysgenetic or rudimentary testes
Inguinal mass (uterus or tube)	Persistent müllerian duct syndrome, dysgenetic testes
Female-Appearing Genitalia	
Clitoromegaly	XX with 21- or 11β-hydroxylase or 3β-hydroxydehydrogenase deficiency Other 46,XX DSD Gonadal dysgenesis, dysgenetic testes, ovotesticular DSD 46,XY DSD Tumor infiltration of clitoris Syndrome: idiopathic
Posterior labial fusion	As for clitorimegaly
Palpable gonad(s)	Gonadal dysgenesis, dysgenetic testes, ovotesticular DSD 46,XY DSD
Inguinal hernia or mass	As for palpable gonad(s)

DSD, disorder of sex development.

BOX 49–10 Findings That Constitute a Normal Genital Examination in the Newborn

FEMALE NEWBORN

Vaginal opening fully visible: 3- to 4-mm slit or stellate orifice with heaped-up mucosa (i.e., no posterior labial fusion)

Clitoris width 2 to 6 mm

Absence of gonads in labia majora or inguinal region

MALE NEWBORN

Urethra at tip of glans (which may be inferred by a fully developed foreskin)

Penis of normal stretched length (2.5 to 5 cm) and diameter (0.9 to 1.3 cm)

Bilateral testes of normal size (8 to 14 mm) in the scrotal sacs

any excess foreskin (Fig. 49-30). An excellent ruler can be made by placing marks 0.5 cm apart on a wooden stick such as a tongue blade or a flexible strip. The width is measured at the midshaft of the stretched penis. A micropenis is arbitrarily defined as a penis with a normally formed urethra that opens at the tip of the glans in which the stretched length is less than 2.5 cm in the full-term neonate. The length criteria must be adjusted to take into account the smaller phallus in the premature neonate (Fig. 49-31). The definition of a micropenis can also be used to describe a rare condition in which the penile corpora cavernosa are absent or severely deficient in size (Table 49-13), resulting in an abnormally thin penis.

CLITORIS SIZE

A clitoris that appears enlarged is best assessed by measurement of the width (diameter) of the paired corpora cavernosa that compose the erectile shaft of the clitoris. With clitoral

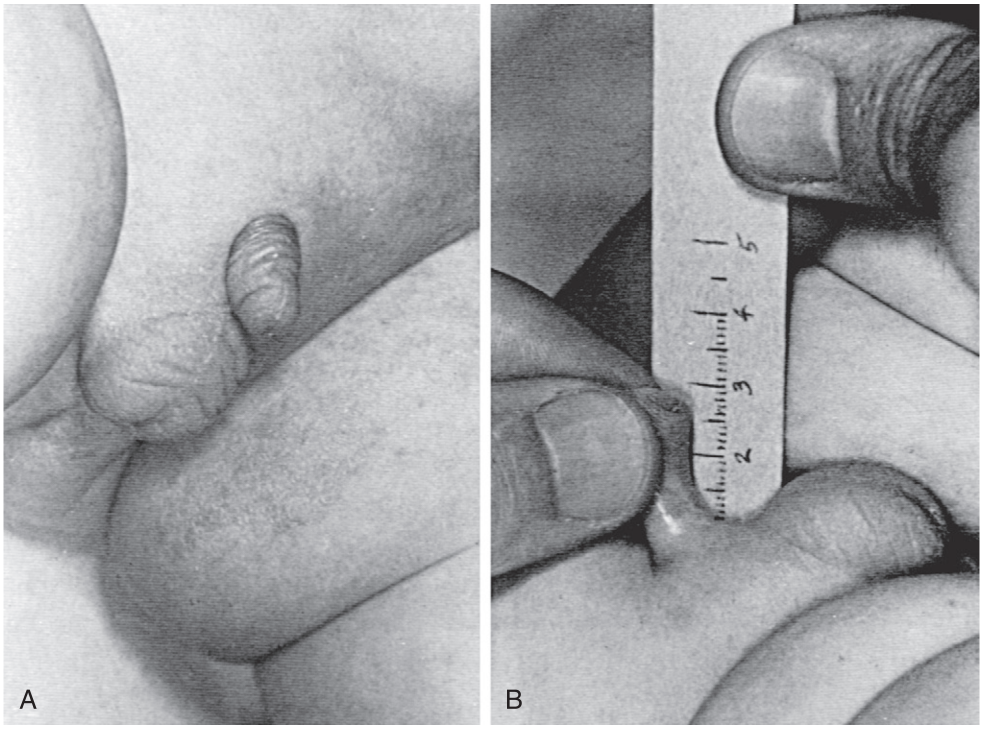

Figure 49–30. A, A 2-month-old boy with micropenis and cryptorchidism caused by luteinizing hormone and follicle-stimulating hormone deficiency. The scrotum is compact or "unlived in," and the testes are inguinal. B, Centimeter markings are inked on a wooden tongue blade, which is placed near the penis and depressed down on the pubic ramus. The penis is maximally stretched, with the measurement made to the tip of the glans (measurement here is 1.7 cm).

enlargement due to edema or birth trauma, a normal corporal width ($<$6 mm) is present,[53] whereas clitoral enlargement due to androgen stimulation (occurring in the second and third trimesters) results in increased corporal growth ($>$6 mm). The width of the clitoris is measured by gently but firmly pressing the shaft of the clitoris between the thumb and forefinger to exclude excess skin and subcutaneous tissue, thereby measuring predominantly the width of the corpora cavernosa (see Table 49-13).

URETHRAL OPENING

If the foreskin is fully formed, the urethra is almost always at the tip of the glans; on rare occasions, the foreskin covers hypospadias on the glans. In boys, hypospadias can vary from mild (off the center of the glans) to severe (at the base of the penis or on the perineum). The prepuce in the hypospadiac penis is usually deficient ventrally and thus appears hooded. Chordee (ventral curvature of the penis) is caused by fibrotic contracture in the area of failed urethral development. The presence of severe hypospadias in a male infant indicates deficient testosterone or DHT action in the first trimester. In girls, the urethral meatus is normally a 1-mm pinhole-like or flat opening located just ventral to the vagina. Androgen exposure at 8 to 14 weeks of fetal age moves the urethral meatus ventrally on the perineum or the shaft of the phallic structure.

VAGINAL OPENING

The vaginal orifice, a 3- to 4-mm slit or stellate opening surrounded by heaped-up mucosa, is normally visible when the examiner lifts up the labia majora. The presence and direct visualization of the vaginal opening indicate the absence of androgen effects and the presence of a distal vagina (of urogenital sinus origin); whether a uterus (of müllerian duct origin) is also present cannot be inferred from this finding. Conversely, at 8 to 14 weeks of fetal age, exposure of the female fetus to androgens or incomplete androgen stimulation of the male fetus results in variable masculinization. This process can be mild to moderate, with posterior midline fusion of the labia majora that partially or completely covers the vaginal opening, thereby preventing its direct visualization. With severe masculinization, there is formation of a common urogenital sinus (resulting from the internal junction of the vagina and urethra) that is seen as a single 1- to 2-mm flat orifice on the perineum or shaft of the phallus.

LABIOSCROTAL DEVELOPMENT

The labia majora are normally unfused in the female. Partial or complete midline fusion indicates androgen exposure at 8 to 14 weeks of fetal age and predicts ventral placement of the urethral meatus on the perineum or phallus. The scrotum in the male is normally completely fused, with a midline raphe. A compact or "unlived in" scrotum indicates the lack of testes or undescended testes. In the male, incomplete or absent midline fusion indicates deficient or absent androgen effects at 8 to 14 weeks of fetal age and predicts a perineal location of the urethral meatus.

ASSOCIATED DYSMORPHOLOGY

A thorough physical examination should be done to identify any other dysmorphic features. Genital abnormalities are often part of dysmorphic syndromes and are frequently associated with other midline defects. Examples include the presence of the Turner phenotype in gonadal dysgenesis and camptomelic dwarfism (bowing and angulation of the lower limbs, flat facies, shortened vertebrae) in XY gonadal dysgenesis. Some

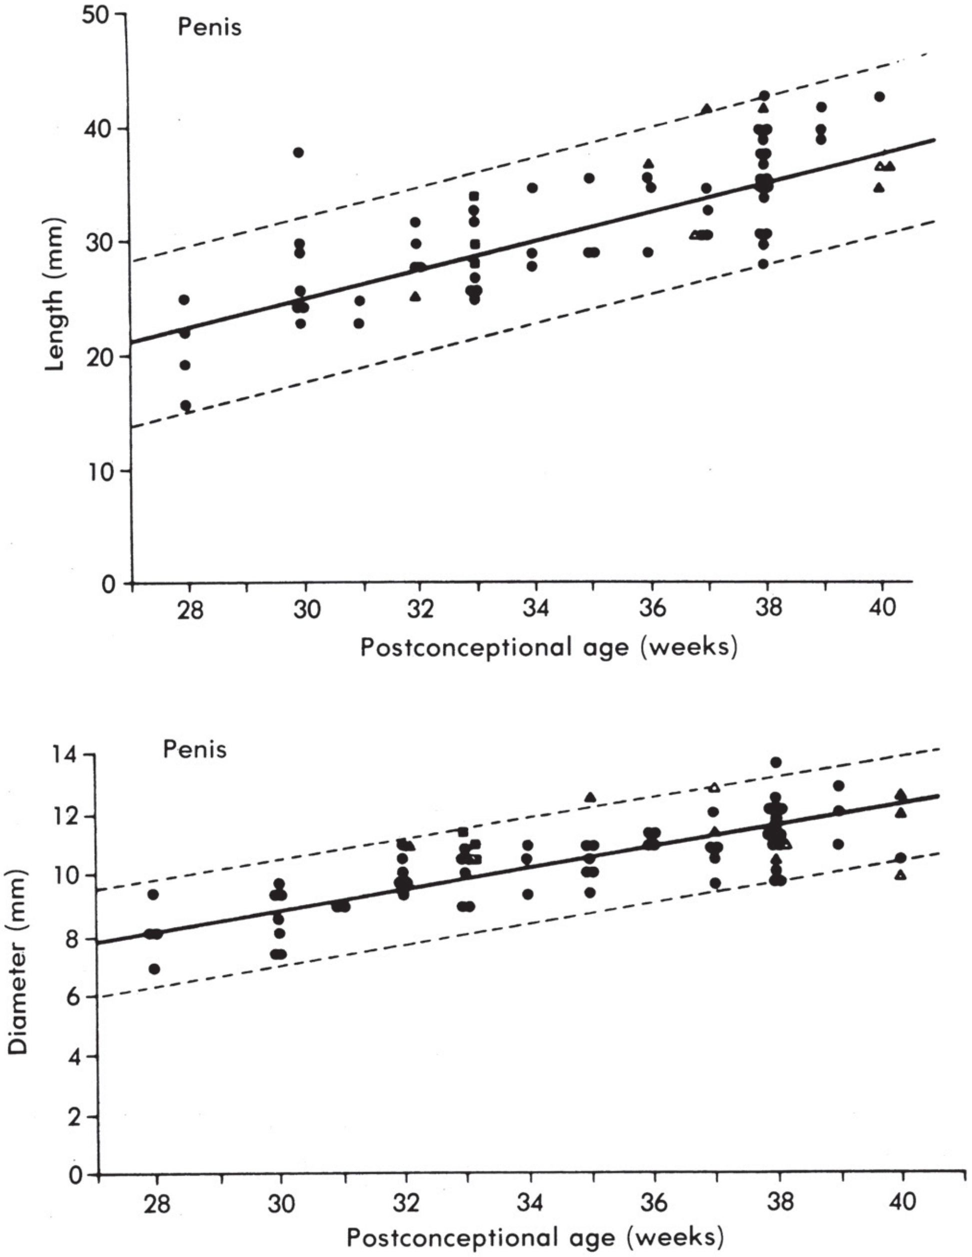

Figure 49–31. Stretched penile length (mean ± 2 SD) (**A**) and penile diameter (mean ± 2 SD) (**B**) in 63 normal premature and full-term male infants (●), two infants who were small for gestational age (△), seven infants who were large for gestational age (▲), and four twins (■). *(From Feldman KW , et al: Fetal phallic growth and penile standards for newborn male infants,* J Pediatr *86:395, 1975).*

DSD patients appear phenotypically normal at birth, including many (but not all) cases of gonadal dysgenesis, XX male, 46,XY male with persistent müllerian ducts, and complete androgen insensitivity syndrome (cAIS).

Discussion with Family and Professional Staff

It is important to recognize that the birth of an infant with a DSD is a major stress for the family. A physician experienced in the evaluation of DSD should meet with the family as soon as possible to discuss the situation, ensuring confidentiality and privacy. Both parents should be present if possible. As part of the discussion, the infant's genitalia should be examined with the parents. Parents are frequently afraid to look at their child's genitalia. Showing the anatomic abnormalities to the family in a calm and professional manner helps the family bond with their child. Outline what will happen (procedures, consultations) and the time frame in which the results will be available. Review with the parents what they plan to tell relatives and friends, which is often a source of great anxiety. Many families and cultures have strong feelings about gender assignment, and these feelings need to be known by the health professionals. Reassure the family that when the data from the tests are available there will be much more information that will help determine the appropriate gender assignment. In most cases, the correct gender assignment will be apparent when the test results become available; in some cases, the gender assignment is not clear, and the options will need to be discussed with the parents.

TABLE 49–13 Anthropometric Measurements of the External Genitalia

From Lee PA; International Consensus Conference on Intersex organized by the Lawson Wilkins Pediatric Endocrine Society and the European Society for Paediatric Endocrinology: Consensus statement on management of intersex disorders. International Consensus Conference on Intersex (see comment), *Pediatrics* 118:e488, 2006.

Below are examples of scripts for answering questions commonly asked by families with children with a new diagnosis of a DSD. These are taken largely from the Clinical Guideline for the Management of DSD in Childhood, published by the Consortium on the Management of Disorders of Sex Development.

Q: Is my child a boy or a girl?

A: Your question is very important. We wish we could tell you right this minute, but we really can't tell yet. We will have more information after we conduct some tests. It's hard for parents to wait for these test results so we will try to update you every day, and you can call (give contact person's name). Although your baby has a condition you probably haven't heard much about, it isn't that uncommon. We've encountered this before, and we'll help you through this time of confusion. As soon as the tests are completed, we will be able to talk with you about the gender in which it makes most sense to raise your child, and we'll give you a lot more information, too, since quite a lot is known about these variations and we are learning more each day. We want to reassure you that our focus is on supporting you and your child in this time of uncertainty.[28]

Q: What do we tell our friends and family while we wait for the gender assignment?

The following script may be most appropriate for talking to close family and friends. When discussing the situation with others, you may feel more comfortable just letting them know that the baby is in the hospital for tests.

A: This is important. We strongly recommend being open and honest with your friends and family about your child's situation. Even if you don't intend to, lying or withholding information will create a sense of shame and secrecy. Though it can be awkward to talk with family and friends about a child's sex development, being honest signals that you are not ashamed—because you have nothing to be ashamed of—and it also allows others to provide you with the love and support you may need. Isolating yourself at this time will probably make you feel unnecessarily stressed and lonely. Talking about it will help you feel connected with others. . . . So here is what you can tell people: Our baby was born with a kind of variation that happens more often than you hear about. Our doctors are doing a series of tests to figure out whether our baby is probably going to feel more like a boy or a girl. We expect to have more information from them within (specify realistic timeframe), and then we'll send out a birth announcement with the gender and the name we've chosen. Of course, as is true with any child, the various tests the doctors are doing are not going to tell us for sure who our baby will turn out to be. We're going to go on that journey together. We appreciate your love and support and we're looking forward to introducing you to our little one in person soon. It also helps to let your friends and family know whether your baby is healthy or whether there are some health concerns. Finally, take some pictures of your baby's face and share those pictures with others![28]

Because of the stress produced by having a child with DSD, support from a behavioral scientist (social worker, psychologist, psychiatrist) may be helpful for the family. It may be helpful for families to be informed about relevant credible resources listed at the end of this section.[35]

In addition to discussions with the family, it is important to keep the hospital staff who have contact with the family fully informed about the information that has been given to the parents. This professional candor reduces the possibility of the hospital staff personnel making insensitive comments to family members and is especially important in cases in which gender assignment must be delayed.

Initial Diagnostic Evaluation

In cases in which gender assignment is pending, all relevant tests should be obtained as soon as possible. A summary of the initial evaluation is shown in Box 49-11.

BOX 49–11 Initial Diagnostic Evaluation of Disorder of Sex Development in the Neonate

History	Maternal androgens, drugs, teratogens; affected relatives; siblings who died in infancy; consanguinity
Physical	Genitalia, gonads, hyperpigmentation, Turner stigmata, dysmorphic features
Chromosomes	Rapid test for X and Y chromosomes (fluorescent in situ hybridization [FISH], karyotype)
Anatomic	Endoscopy, retrograde genitogram; ultrasound
Biochemical	
If patient is:	Obtain serum levels at appropriate ages for:
XX with müllerian ducts	17-OHP, 11-deoxycortisol, 17-hydroxypregnenolone, testosterone
XX without müllerian ducts	Testosterone, estradiol, LH, FSH
XY with müllerian ducts	Testosterone, estradiol, LH, FSH
XY without müllerian ducts	Testosterone, dihydrotestosterone (DHT), LH, FSH, and if testosterone/DHT is increased or testosterone is normal to low, obtain androstenedione, dehydroepiandrosterone, 17-OHP, progesterone, and 17-hydroxypregnenolone
Basal hormone studies if done at:	
0 to 36 hr	Testes are active because of prior in utero hCG stimulation; testosterone and DHT levels are increased
0.5 to 4 mo	Pituitary-testicular axis is physiologically active; LH, FSH, testosterone, and DHT are increased (peak levels occur at 1 to 2 mo in term infant and later in premature infant)
Any age	Adrenal steroids are abnormal in untreated congenital adrenal hyperplasia

CHROMOSOMES

Fluorescence in situ hybridization (FISH) for X and Y markers may be available within 24 to 48 hours. Results reveal the number of X and Y chromosomes present. Most cytogenetic laboratories can provide a peripheral blood karyotype result within 2 or 3 days for cases of DSD. In cases in which the gender assignment is not clear, the laboratory should be personally contacted and asked to expedite the chromosome result.

BIOCHEMISTRY

Interpretation of biochemistry tests is dependent on the timing of the sample and understanding of the normal levels of hormones at that time. A blood sample should be obtained between 24 and 48 hours after the time of the neonatal surge of androgens, for measurement of testosterone and 17-hydroxyprogesterone (17-OHP). It is desirable to draw extra blood so that the laboratory can save the serum for analysis of other hormones that may be indicated as the evaluation continues. Increased serum levels of testosterone occur physiologically in neonates with functioning testes at 12 to 36 hours and at 2 weeks to 4 to 6 months of age (Fig. 49-32). The level may also increase pathologically at any time from the adrenal secretion of androgens in

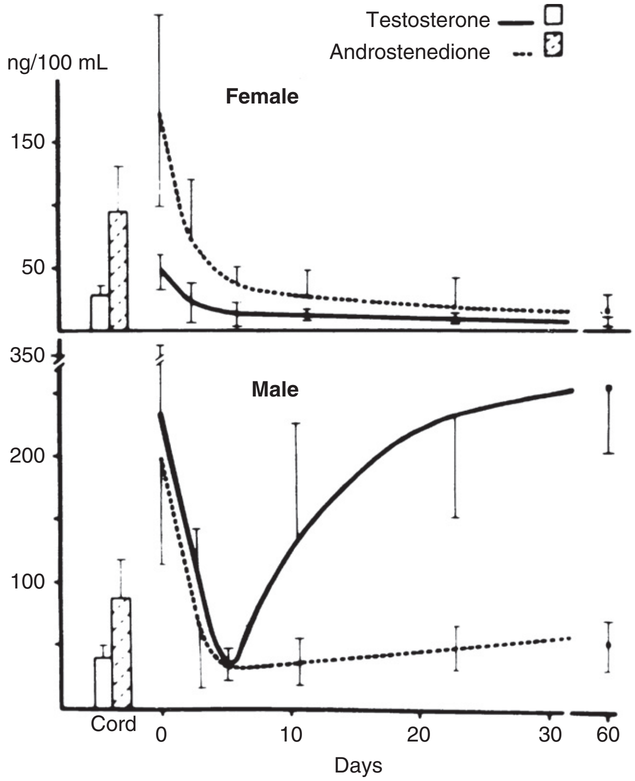

Figure 49–32. Pattern of testosterone and androstenedione plasma levels during the first 60 days of life in normal neonates. The curves join the mean values (± 1 SD) between the different age groups. *(From Forest MG , et al: Pattern of plasma testosterone and delta 4-androstenedione in normal infants: evidence for testicular activity at birth,* J Clin Endocrinol Metab *41:977, 1975. ©1975 The Endocrine Society.)*

cases of CAH. Decreased levels of testosterone occur if Leydig cells are deficient or absent, LH activity is impaired, or there is a testosterone biosynthetic defect. Blood samples are also diagnostically useful at 1 or 2 months of age to assess the peak of hypothalamic-pituitary-testicular axis function in infancy.

The measurement of serum AMH has been shown to correlate with Sertoli cell function.[8] An increased level of 17-OHP suggests 21- or 11β-hydroxylase deficiency and implies that any increased levels of testosterone were of adrenal rather than testicular origin in a 46,XX patient. The 17-OHP levels in premature infants are higher than those in full-term infants.[34] In CAH with 21-hydroxylase deficiency, the levels of 17-OHP are often 10 to 50 times the upper limit of the normal level, making the test virtually diagnostic. Inhibin B levels have been shown to rise in males in the first week of life. Its measurement is therefore useful for identifying the presence of Sertoli cells and of functional testes in newborn boys with nonpalpable gonads.[9] Other tests that may be useful, depending on the clinical presentation, are measurements of LH, FSH, estradiol, precursors of testosterone, and DHT.

ULTRASONOGRAPHY

Ultrasound examination can usually determine the presence or absence of the uterus. If no uterus is seen, it suggests that there is testicular tissue producing AMH. If a uterus is present, it suggests either bilateral ovaries, dysgenetic gonads that failed to produce AMH, or an AMH receptor defect. Intrapelvic gonads can sometimes be located. Fetal ultrasonography can identify abnormal genitalia in utero.[55] Adrenal ultrasonography has a sensitivity of 92% and a specificity of 100% for diagnosing CAH when read by an experienced pediatric radiologist.[2] Ovaries may be difficult to identify on ultrasound.

GENITOGRAPHY

Genitography is used to determine the presence or absence of a urogenital sinus and the anatomy of the urethra and vagina. Visualization of the cervix confirms the presence of müllerian duct structures. If radiographs show filling of a fallopian tube, the gonad on that side has failed to produce AMH. Endoscopy may be needed to direct where the radiopaque contrast material is to be injected; otherwise, small vaginal openings into the urethra may be missed.

HUMAN CHORIONIC GONADOTROPIN STIMULATION TEST

A short hCG stimulation test can be used to determine whether functioning Leydig cells are present. One example of a protocol for doing the test is as follows: for full-term infants, 500 units of hCG is given intramuscularly every other day for three injections. The testosterone level is measured on the day after the last injection and compared with the baseline value. There are a number of protocols but no consensus about the best way to do the test. Normal or low levels of testosterone in response to hCG should be interpreted in relation to LH, FSH, and AMH values.[50] A significant rise in testosterone concentration confirms the presence of Leydig cells and, by implication, testicular tissue.

Refining the Diagnosis

After the chromosome results are available, the initial diagnosis can be confirmed or refined. An approach that can be used to arrive at a final (differential) diagnosis is charted for 46,XY DSD in Figure 49-33 and for 46,XX DSD in Figure 49-34. Details on the specific diagnoses are discussed later.

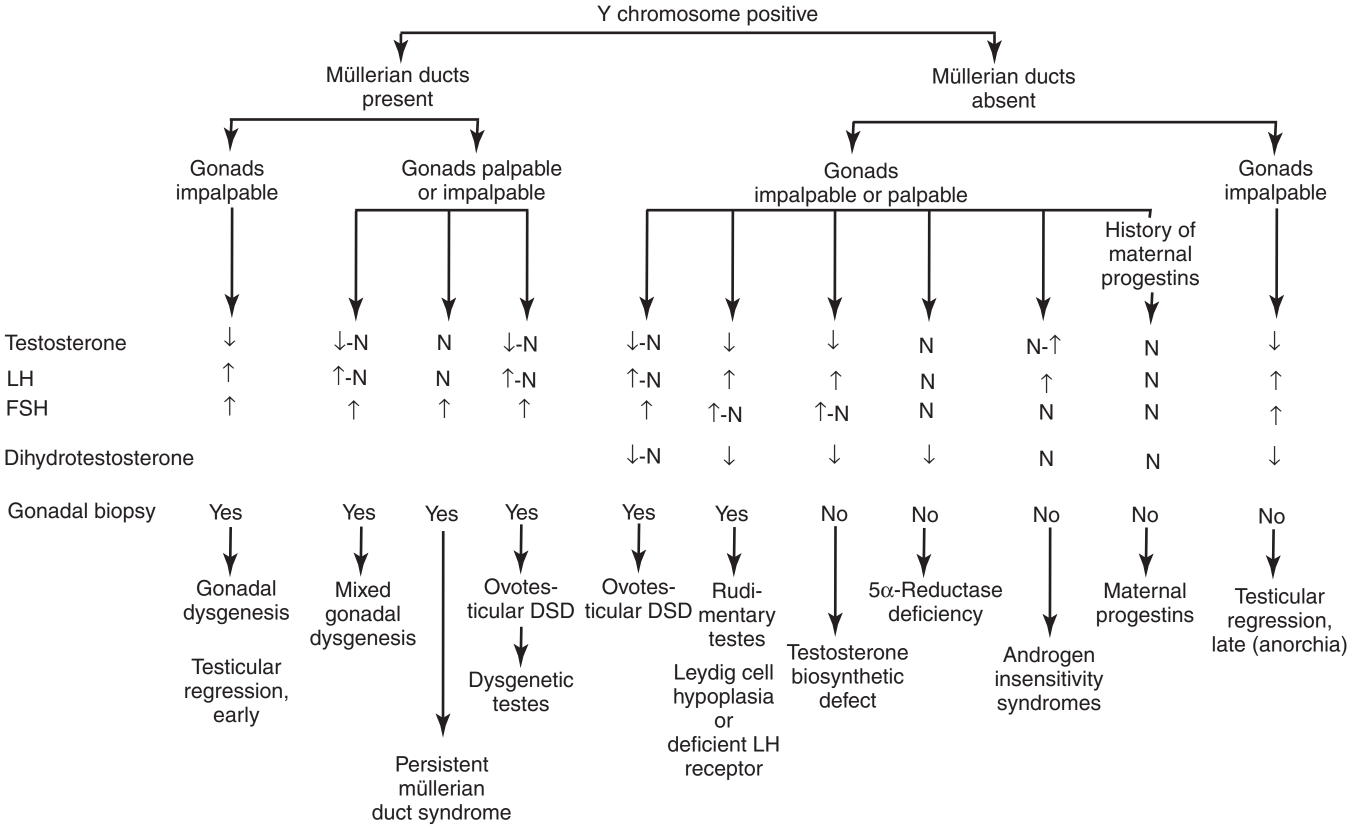
Gender Assignment in Newborns

The decision about gender assignment is complex and stressful. It should therefore be made expeditiously by a thorough assessment by a multidisciplinary team including the family, medical genetics, cytogenetics, gynecology, pediatric urology, endocrinology, and psychiatry, psychology, or social work.[57] Guiding factors include the diagnosis, appearance of the genitals, surgical options, need for lifelong sex-hormone replacement therapy, potential for fertility, and the views of the family and their cultural practices.[35] In addition, the prospect for a gender identity congruent with sex of rearing and good sexual function should be considered.

Most 46,XX patients with CAH identify as females regardless of degree of genital virilization.[7] About 60% of patients with 5α-reductase deficiency and 17β-hydroxysteroid dehydrogenase deficiency assigned female in infancy, and all those assigned male, identify as males.[15] For individuals with cAIS assigned female in infancy, all continued to live as female.[40] Among both males and females with partial AIS (pAIS) and partial gonadal dysgenesis, about 75% were satisfied with their initial sex assignment. In the case of infants with markedly ambiguous genitalia, including a micropenis and perineoscrotal hypospadias, the decision about sex of rearing should be made after thorough discussion of the results of all investigations, diagnosis, etiology, prognosis, and surgical options.[45] The gender assignment in XY infants with small phalluses remains controversial, but these infants are increasingly being assigned male gender because of lack of need for medical or surgical intervention and potential for fertility.[40] The availability of intracytoplasmic sperm injection has also created the possibility of fertility for males with a very low sperm count. If the phallus is small and associated with hypospadias, partial androgen resistance is a possible diagnosis. Androgen sensitivity can be assessed by the response of the penis to an intramuscular injection of testosterone. If the response is poor, the choice of gender assignment becomes very difficult and must be approached on a case-by-case basis, with extensive discussion with the family.

Nomenclature of Disorders of Sex Development

An improved understanding of the molecular and genetic causes of DSDs and increased awareness about patient sensitivity led to the development of an updated nomenclature for this group of disorders (Table 49-14).[35]



Y chromosome positive
Müllerian ducts present
Müllerian ducts absent
Gonads impalpable
Gonads palpable or impalpable
Gonads impalpable or palpable
Gonads impalpable

DISORDERS OF SEX DEVELOPMENT

Sex Chromosome Disorder of Sex Development

Abnormality in number or parts of sex chromosomes leads to failure of testes or ovaries to undergo normal development.

45,X (TURNER SYNDROME AND VARIANTS)

Loss of the second X chromosome results in a syndrome consisting of a phenotypic female with bilateral streak gonads and accompanying somatic abnormalities. Variant forms include partial deletions of the second X chromosome, such as deletion of the short arm of the X chromosome (XXp−) or the long arm of the X chromosome (XXq−), or various forms of X chromosome mosaicism (e.g., 45,X/46,XX).

In fetuses with 45,X gonadal dysgenesis, normal ovarian differentiation occurs at up to 13 to 15 weeks of gestation, followed by rapid degeneration and atresia of the primordial ovarian follicles. In affected neonates and infants, the late stages of this process are usually evident, with scattered primordial ovarian follicles in varying states of degeneration seen histologically. The final result is the streak gonad, which usually appears by childhood; it is an elongated, whitish streak consisting of whorls of connective tissue, suggestive of ovarian stroma, that contain no germinal elements or endocrine or other epithelial elements.

Affected patients have normal müllerian duct development, an absence of wolffian ducts, and phenotypically female external genitalia. Because the genitalia are normal, the identification of neonates is limited to those who have the accompanying Turner somatic abnormalities, as listed in Box 49-12. The cardiovascular and lymphatic abnormalities, particularly lymphedema of the dorsa of the feet or hands (Fig. 49-35), are diagnostically the most useful and may be pathogenetically related. In the 45,X fetus, impaired drainage of the lymph channels leads to stasis of lymph fluid, with distention of lymphatics, peripheral lymphedema, increased venous fluid volume, and large veins. Large nuchal cystic hygromas and generalized edema occur frequently in utero. Distention of the cardiac lymphatics is hypothesized to compress the ascending aorta, altering flow in the left atrioventricular canal and affecting pulmonary venous return and consequently resulting in cardiovascular malformations. A strong association is observed between the presence of a webbed neck and the occurrence of aortic coarctation, partial anomalous pulmonary venous drainage, a hypoplastic left heart, and secundum atrial septal defect.

BOX 49–12 Features of Turner Phenotype in the Neonate

- Intrauterine growth restriction
- Head and facies: low-set ears, low nuchal hairline, asynchronous growth of scalp hair, epicanthus, folds below lower lids, micrognathia, high palate
- Lymphatic: lymphedema of dorsa of hands and feet, hypoplasia of nails, loose neck folds (cutis laxa) or cystic hygroma, ascites, pleural or pericardial effusion, gross edema
- Cardiovascular: coarctation of aorta, bicuspid aorta, aortic stenosis, hypoplastic left heart, partial anomalous pulmonary venous drainage, ventricular septal defect, patent ductus arteriosus, and secundum atrial septal defect
- Urinary tract: rotated or horseshoe kidneys, renal hypoplasia, duplications
- Skeletal: short fourth metacarpals, shield chest

Modified from Gordon RR , et al: Turner's infantile phenotype, *Br Med J* 1:483, 1969.

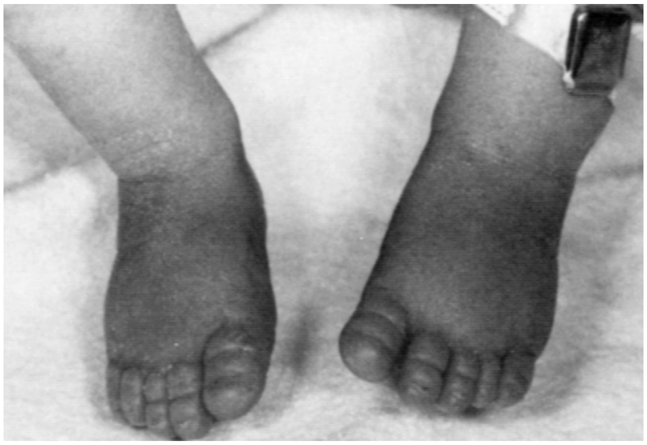

Figure 49–35. Lymphedema of the dorsa of the feet with hypoplasia of the nails in a newborn with 45,X gonadal dysgenesis (Turner syndrome).

The cause of monosomy X is unknown. The mean maternal and paternal ages are not raised, so non-disjunction is not thought to be important; a postfertilization abnormality is thought to be the most likely etiology. The single X is of maternal origin in about 80% of cases. The clinical features of Turner syndrome seem to be related to the haploinsufficiency of the short stature homeobox-containing gene (*SHOX*) and to the lymphogenic gene that causes lymphatic hypoplasia and as a result, soft tissue and visceral anomalies.[54] The parental origin of the missing short arm of the X chromosome may be associated with some of the phenotypic features in Turner syndrome, suggesting possible X chromosome gene imprinting.[65] A few familial cases have been reported. The incidence of the 45,X karyotype in spontaneous abortuses is very high, generally estimated to be 6% to 10%. However, the mean incidence of living 45,X newborns is only about 1 in 5000 female births, suggesting that more than 99% of 45,X fetuses abort. The reasons for this high mortality rate are unclear, but dysfunction of the 45,X placenta or fetal hypoalbuminemia, generalized edema, serous effusions, and cardiovascular abnormalities may play a role.

Individuals with X chromosome mosaicism or partial deletion of the second X chromosome tend to have fewer somatic and gonadal manifestations than those with the 45,X karyotype. In cases of mosaicism, the relative proportions of 46,XX to 45,X cells may determine the extent to which the normal development of gonadal and somatic tissues can occur. Individuals having only a partial deletion of the X chromosome may also manifest a modified phenotype, depending on the part of the X chromosome that is deleted. Genes related to ovarian development and Turner somatic abnormalities are located on both Xp and Xq. The combined incidence of 45,X, partial deletion, and mosaic Turner syndrome is about 1 in 2000 female newborns.

About 40% to 50% of patients with this diagnosis have a partial deletion or mosaicism of the X chromosome; at least 30 cells should be assessed for the possibility of mosaicism. The diagnosis is established by demonstration of a partial or complete deletion of one of the X chromosomes. The differential diagnosis includes XYp− gonadal dysgenesis and structural abnormalities of the Y chromosome, which may also have a Turner somatotype but carry a different prognosis. There is no increased risk for gonadal tumor development in the unequivocal absence of Y chromosome material; however, it may be difficult to establish fully because of the possibility of occult Y chromosome material.[3] Y chromosome material is associated with about a 12% risk for gonadoblastoma.[17] In one study of 171 patients with Turner syndrome, 8% were found to have Y chromosome material.[42]

The Turner phenotype is therefore not a reliable predictor of either the karyotype or the cause of gonadal dysgenesis. In Turner syndrome, serum FSH is elevated from an age of 2 weeks to about 2 to 3 years. The neonatal changes in FSH secretion are qualitatively similar to those of normal girls.[23] The antenatal diagnosis of Turner syndrome has been made after ultrasound identification of a cystic hygroma and pleural effusion.[13] Clinical practice guidelines exist that outline the required screening investigations in individuals with a new diagnosis of Turner syndrome. These include a cardiovascular evaluation by a specialist, renal ultrasound, hearing evaluation, and referral to appropriate support groups.[10] In studies of patients with Turner syndrome, a 15% to 35% incidence of heart anomalies is found. The most common cardiovascular malformations are left sided and include aortic valve abnormality (bicuspid valve, stenosis, regurgitation) in 72% and aortic coarctation in 39%. Ultrasound evaluation of the urinary tract may be performed to establish the presence of an abnormality that may predispose the patient to urinary tract infection or obstruction. Feeding difficulties in infancy, caused by oral-motor dysfunction, may result in a lower rate of weight gain. Patients who are not recognized in infancy come to medical attention later, usually because of short stature or failure of secondary sexual development. The prognosis is primarily for the absence of any ovarian function, but 5% to 15% of patients do show variable secondary sexual development; a very small number of pregnancies have been reported.

47,XXY (KLINEFELTER SYNDROME AND VARIANTS)

The major clinical manifestations of Klinefelter syndrome develop with the onset of puberty, and most patients are recognized at that time or later. The constant features are small testes with histologic evidence of impaired spermatogenesis. Infants with 47,XXY Klinefelter syndrome occasionally have small testes or a micropenis that might permit their recognition, and cases with hypospadias have been reported. Other congenital abnormalities seen in this syndrome included a cleft palate, cryptorchidism, and an inguinal hernia. The fetal testes at midgestation are normal. Testicular histology in the first year of life has varied from normal to abnormal manifestations, with decreased to absent spermatogonia.

The incidence of the 47,XXY karyotype in live newborn males is about 1 in 1000; if Klinefelter variants are added, the overall incidence is about 1 in 800. Increased maternal age is associated with an additional X chromosome, although this effect is not as marked as it is in autosomal trisomies. Among the variant forms of Klinefelter syndrome, patients with 48,XXXY and 49,XXXXY karyotypes are more likely to be recognized early in life. All have somatic abnormalities and mental retardation, and many have a hypoplastic penis. All males with the 49,XXXXY karyotype have cryptorchidism, and 14% have cardiac defects.

45,X/46,XY (MIXED GONADAL DYSGENESIS)

This group of disorders is characterized by the presence of dysgenetic and often asymmetric gonads. The streak gonad represents the end result of failed gonadal (ovarian or testicular) differentiation. *Mixed gonadal dysgenesis* is a term used to describe individuals with a unilateral, functioning testis and a contralateral streak gonad.

Ninety percent of prenatally diagnosed cases have a normal male phenotype, whereas those diagnosed postnatally show variable phenotypes.[70] Most have some degree of virilization of the external genitalia, ranging from clitoromegaly or partial labial fusion to normal male external genitalia. Slightly more than half have a urogenital sinus. All have some müllerian development consisting of an upper vagina, a uterus, and a fallopian tube, usually on the side with the streak or absent gonad. An epididymis or vas deferens is present on the testicular side in 50% of cases, and the testis is most frequently located in the inguinal canal. Normal to diminished or absent testosterone responses have been reported with hCG stimulation, and gonadotropins are normal or elevated. Gonadal tumors occur in 22%, affecting either the testis or the streak gonad. Diagnostic overlap with ovotesticular DSD, previously referred to as *true hermaphroditism*, may occur in infants if the apparent streak gonad still contains degenerating primordial ovarian follicles that suggest ovarian tissue rather than a streak gonad.

In 45,X/46,XY, Turner somatic features such as lymphedema, cardiovascular abnormalities, or short stature are frequently seen and reflect the presence of 45,X cell lines. The prevalence of the XY cell line in the gonad and the extent of structural abnormality of the Y chromosome determine the degree of testicular development and masculinization.

Appropriate gender assignment in the newborn period should be based on functional considerations and fertility. Dysgenetic gonads should be removed in infancy because of the increased risk for tumor formation.[19] The scrotal testis may be normal prepubertally, but many adults show a loss of germ cells and accompanying tubular sclerosis; a few have spermatocytes.

46,XX/46,XY (CHIMERISM)

The most common phenotype is that seen in ovotesticular DSD, discussed next.

Ovotesticular Disorder of Sex Development

Formerly known as true hermaphroditism, ovotesticular DSD is defined as the coexistence of ovarian and testicular tissue either in the same gonad or in opposite gonads. The ovarian tissue must contain ovarian follicles or corpora albicantia because fibrous stroma alone does not define ovarian tissue. The testicular tissue must contain seminiferous tubules or spermatozoa. Several karyotypes are seen in ovotesticular DSD. About three fifths are 46,XX; one fifth 46,XY or 45,X/46,XY; and the remaining one fifth show mosaicism or chimerism, being 46,XX/46,XY or 46,XX/47,XXY. The most frequently occurring gonadal combinations are an ovary and a testis or an ovary and an ovotestis. An ovotestis accounts for 44% of all gonads in this condition, an ovary 34%, and a testis 22%. Less than 1% of patients have a unilateral streak gonad or a tumor. Ovarian tissue occurs more often on the left side and testicular tissue more often on the right side.

The internal genital ducts reflect the gonadal constitution. On the side with an ovary, a fallopian tube is almost always seen, and on the side with a testis, the vas deferens and epididymis are almost always present. On the side with an ovotestis, a vas deferens is seen 35% of the time and a fallopian tube, often closed at the fimbriated end, 65% of the time. A uterus is described in about 86% of the patients, but it is usually hypoplastic, unicornuate, or otherwise maldeveloped.

The external genitalia are usually ambiguous, although some cases have been reported with normal male or female appearances. The urethra most often opens on the perineum as a urogenital sinus. The phallus is usually larger than a normal clitoris (Fig. 49-36) and often has chordee; it is frequently of sufficient size to give the genitalia a masculine appearance. Gonads are descended or palpable in 61% of patients, more frequently on the right side; about 60% are

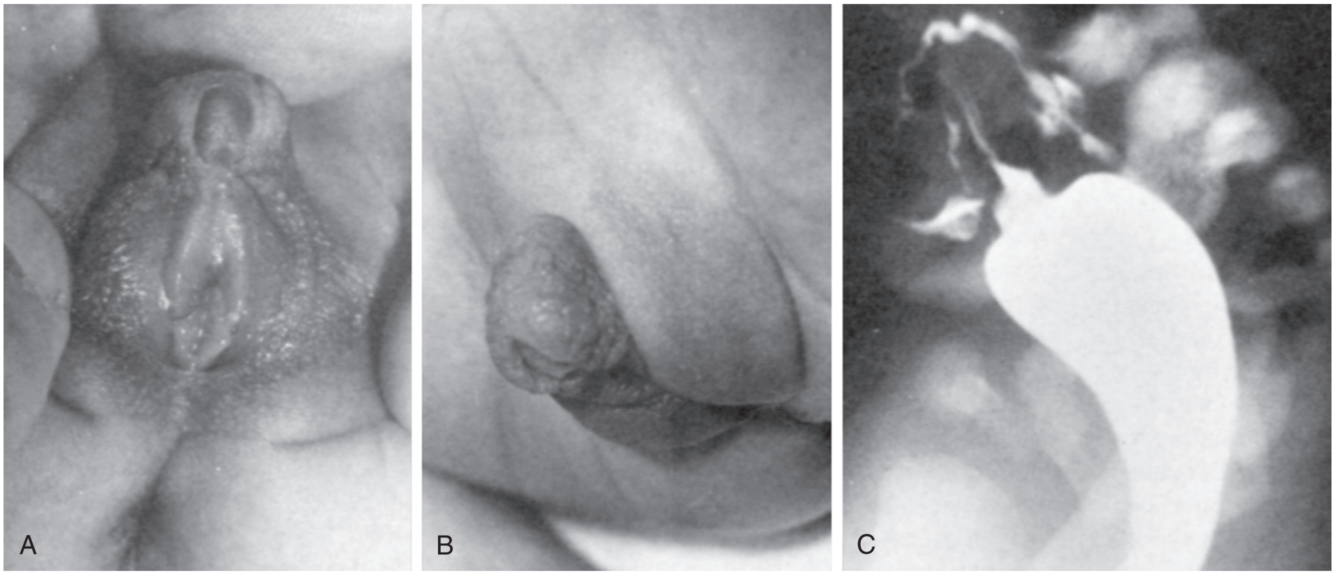

Figure 49–36. **A**, A 46,XX neonate with ovotesticular disorder of sex development was noted at birth to have clitoromegaly (1.8 × 0.8 cm), with a slightly rugose and full labia majora. **B**, The genitalia were otherwise those of a normal female; the gonads were impalpable, and a uterine cervix was present on endoscopy. **C**, A genitogram showed the presence of a 5-cm vagina, above which contrast media entered the uterus and the bilateral fallopian tubes. The serum testosterone level was high normal for a female at 60 ng/dL on day 1 of life; was abnormally elevated to 75 ng/dL and 134 ng/dL at ages 2 and 5 weeks, respectively; and increased to 389 ng/dL after stimulation with human chorionic gonadotropin (hCG). Bilateral gonads spontaneously descended into the inguinal region at age 5 weeks (before hCG stimulation) and were found to be ovotestes on biopsy.

ovotestes, and most of the remainder are testes, but only rarely does an ovary descend. The ovotestis is more likely to descend if it contains a greater proportion of testicular tissue. The ovarian portion of the ovotestis tends to be firm and convoluted and is histologically normal except for a reduction in the number of primordial follicles. The testicular portion tends to be soft, smooth, and histologically normal in infants, but it becomes abnormal in more than 90% of adults, marked as it is by tubular atrophy with undifferentiated germ cells and the absence of spermatogenesis. In intact testes, the histology is similar, with spermatogenesis seen in only 12% of the patients. The testosterone response to hCG stimulation is usually low but can be normal, depending on the amount of testicular tissue present. Gonadal tumors occur in 3% of the patients and are more frequent in those who are Y chromosome positive. Renal abnormalities have been noted in 5% of 150 cases.

Most cases of ovotesticular DSD are 46,XX and on karyotype have no separate Y chromosome material. Explanations include an autosomal or X-linked mutation that turns on a gene downstream from the *SRY* gene that induces testicular differentiation, the translocation of Y chromosome material to an autosome, and chromosome mosaicism in gonadal tissue. Familial cases of 46,XX DSD with male phenotype, 46,XX ovotesticular DSD, or both show phenotypic similarity, typically having ambiguous genitalia, and lack the *SRY* gene or other Y sequences, indicating that these conditions are closely related.

Most cases of ovotesticular DSD are potentially recognizable in the neonatal period because of ambiguous genitalia. The definitive diagnosis requires a gonadal biopsy, but it is preferably delayed until after the neonatal period. Fertility is often impaired in this condition for both males and females. Gender assignment is guided by the same principles outlined for other DSDs. See "Gender Assignment in Newborns," earlier.

46,XY Disorder of Sex Development

DISORDERS OF GONADAL (TESTICULAR) DEVELOPMENT

Complete and Partial Gonadal Dysgenesis

In testicular dysgenesis, the underlying defect is disordered testicular differentiation or development that results in anatomically or histologically abnormal testes and secondary impairment of hormonogenesis or spermatogenesis. Dysgenetic testes are defined by the following characteristics: a failure to induce regression of the ipsilateral müllerian duct structures, an association with incomplete masculinization of the genitalia, variably abnormal histology, and an increased predisposition toward the development of tumors originating from the germinal structures. The testes may be of normal or small size and are usually cryptorchid. The karyotype is typically 46,XY, but other karyotypes are also seen. Dysgenetic testicular tissue can be seen in ovotesticular DSD.

Individuals with complete gonadal dysgenesis (Swyer syndrome) have a 46,XY karyotype, absent testes, female-appearing external genitalia, normal müllerian structures, and streak gonads similar to those of Turner syndrome.[72] A mutation in the *SRY* gene has been reported in 20% to 67% of those with complete gonadal dysgenesis.[35] XY gonadal dysgenesis occurring in families has been described and attributed to mutations in the *SRY* gene that resulted in the reduction rather than loss of DNA binding. The reduced binding presumably leads to variability in sex reversal, allowing some individuals to have near-normal gonadal development. Most cases occur sporadically, but family aggregates have been reported, some involving two or three generations, that are compatible with either X-linked recessive, autosomal recessive, or autosomal dominant and male-limited inheritance.

The clinical recognition of 46,XY gonadal dysgenesis may be possible in the newborn period in infants with clitoromegaly. A neonate occasionally presents with edema of the feet. There is a very high risk for the development of gonadal tumors in XY gonadal dysgenesis. Prophylactic removal of the streak or dysgenetic gonads is indicated in infancy. The gender assignment is most commonly female. Gonadal dysgenesis associated with a Y chromosome is significantly different from the Y-negative forms described previously. Both forms have in common the presence of bilateral or unilateral streak gonadal tissue, the association of the Turner phenotype in some, and a similarity in the gonadotropin sex steroid profiles. However, the streak gonads in patients with Y-positive gonadal dysgenesis differ in important ways.

1. The combination of a streak or dysgenetic gonad and a Y chromosome carries a significant risk for tumor development (Y-negative streak gonads have no increased risk for tumor formation).
2. The streak gonads may show residual dysgenetic tubular elements and develop calcification.
3. Androgen or estrogen production may occur from gonadotropin stimulation of theca or lutein cells lying within a tumor (or occasionally within the streak gonad), causing virilization or feminization.

The causes of Y-positive gonadal dysgenesis are heterogeneous and include a small deletion of distal Yp (the short arm of chromosome Y) with loss of the *SRY* gene, an X chromosome or autosomal mutation that interferes with or prevents testicular differentiation, and Y chromosome abnormalities or mosaicism. A structurally abnormal Y chromosome frequently results in 45,X/46,XY or 45,X/47,XYY mosaicism. When the result is two streak gonads, a female phenotype is usually seen. Varying degrees of testicular development, reflecting the relative prevalence of the XY cell lines, may result in ambiguous or predominantly male genital development. The finding of genital ambiguity, Turner somatic stigmata, or associated malformations allows many patients to be identified in the neonatal period.

Yp gonadal dysgenesis is due to an abnormal X-Y recombination involving the distal ends of Xp and Yp. This may result in translocation and thus loss of the *SRY* gene from the Y to the X chromosome. The resulting XYp− individual has bilateral streak gonads and a female phenotype; most have lymphedema or other Turner somatic features thought to be caused by the loss of certain Yp genes. The incidence of these XY females (1 in 100,000) is much lower than that of their reciprocal XX males (1 in 20,000); it is speculated that the edema associated with Yp deletions has lethal effects on many affected fetuses. Y autosome translocations may also result in loss of the *SRY* gene.

The risk for tumor development in those with mutations in *SRY* is up to 50%.[72] The gonadoblastoma locus on the Y chromosome (*GBY*) must be present for malignant transformation to occur. Testis-specific protein on the Y chromosome (*TSPY*) is a likely candidate gene responsible for malignant transformation.[38] The most common tumor is a gonadoblastoma, which may arise in a streak gonad or a dysgenetic testis, is frequently bilateral, and occurs from the first year of life up to the fourth decade. Although pure gonadoblastomas do not metastasize, they are frequently associated with dysgerminomas or other malignant germ cell tumors. The risk for a tumor is the greatest for poorly differentiated gonadal tissue and an intra-abdominal or inguinal position; only rarely is there tumor formation in a scrotal testis. Unexpected testosterone or estrogen formation may signal tumor development. Total gonadectomy is recommended for those reared as females and considered for undescended gonadal tissue for those reared as males.

MUTATION AND DELETION OF *WT1*: DENYS-DRASH, FRASER, AND WAGR SYNDROMES

The Wilms tumor suppressor gene (*WT1*), which is on chromosome 11p13, encodes a transcription factor that is expressed in the urogenital embryonic tissues that develop into the kidney and gonad. A mutation or deletion of *WT1* causes abnormal gonadal development, as seen in Denys-Drash syndrome (nephropathy, genital abnormalities, Wilms tumor), WAGR syndrome (*W*ilms tumor, *a*niridia, *g*enitourinary malformations, mental *r*etardation), and Fraser syndrome (gonadal dysgenesis and chronic renal failure). Therefore, *WT1* appears to be required for the early commitment and maintenance of gonadal tissue and to exert its effects upstream from the *SRY* gene (see Fig. 49-26). Both 46,XY and 46,XX individuals may be affected. Although many patients present at birth with ambiguous genitalia ranging from clitoromegaly with labial fusion to hypospadias with undescended testes, others have external genitalia that are phenotypically normal male or female but may be inappropriate for the karyotype. Their underlying DSD defect is in the development of the gonads, which anatomically show wide variation ranging from streak gonads (complete gonadal dysgenesis) to dysgenetic or rudimentary testes or ovaries to ovotestes; gonadoblastomas have developed in some of the dysgenetic gonads. The internal genital ducts usually reflect the gonadal makeup; müllerian duct structures are usually present.

MUTATION OF *SOX9* (*SRY*-LIKE HMG BOX-RELATED GENE 9)

SOX9 mutation is a cause of camptomelic dwarfism and XY gonadal dysgenesis. In the presence of *SRY*, *SOX9* expression is repressed in the female gonad but is upregulated in the developing testis and is crucial in the pathway for testis development. *SOX9* is also responsible for synthesis of collagen type II, and mutations of *SOX9* result in camptomelic dysplasia.[14] Camptomelic dysplasia is a cartilage and skeletal malformation syndrome with congenital angulation and bowing of long bones that is associated with 46,XY complete gonadal dysgenesis in about three fourths of the XY cases. Testicular development in the XY patients ranges from streak gonads to dysgenetic testes to normal testes; the external genitalia show a gradation of defects, from the female phenotype in those with complete gonadal dysgenesis to ambiguous genitalia to a normal male phenotype. The internal genital ducts reflect the gonadal makeup. Patients who have more severe skeletal dysplasia die in the first months of life from respiratory failure, but less severely affected patients may live into adulthood. The mode of inheritance is now recognized to be autosomal dominant, with haploinsufficiency for *SOX9* on chromosome 17 as the cause of both camptomelic dysplasia and gonadal or testicular dysgenesis.

DUPLICATION OF DOSAGE-SENSITIVE SEX REVERSAL

Duplication of the dosage-sensitive sex reversal, adrenal hypoplasia congenita critical region, on the X chromosome, gene 1 (*DAX1*), located on the short arm of the X chromosome, overrides the *SRY* gene and impairs or prevents testicular development, resulting in partial or complete XY gonadal dysgenesis. Affected patients have either ambiguous genitalia or a female phenotype and may also exhibit adrenal insufficiency. Familial cases have been reported.

STEROIDOGENIC FACTOR-1

The steroidogenic factor-1 (*SF1*) gene codes for a nuclear hormone receptor and regulates the expression of other genes involved in sexual development.[41] Mutations in *SF1* can be associated with 46,XY DSD and normal adrenal function and lead to impaired Leydig cell function and androgen biosynthesis.[37]

46,XY Ovotesticular Disorder of Sex Development

See earlier section, "Ovotesticular Disorder of Sex Development."

Gonadal Regression

EARLY REGRESSION WITH GENITAL AMBIGUITY (XY GONADAL AGENESIS)

This condition is characterized by the complete absence of testes, including the absence of gonadal streaks, and associated with the almost complete absence of both müllerian and wolffian duct derivatives and female or partially masculinized genitalia (clitoromegaly and posterior labial fusion). The gonadal and genital features may be explained by very early regression of the developing fetal testes between about 8 and 10 weeks. Testicular failure must have occurred after the initial production of AMH by Sertoli cells but before the Leydig cells could produce sufficient testosterone for a reasonable time. It has been suggested that testicular regression is part of the clinical spectrum of 46,XY gonadal dysgenesis.

Other XY individuals have testes with quite well developed wolffian structures but incomplete masculinization of the external genitalia. Testicular regression presumably occurred slightly later than it did in those patients with the absence of internal genital ducts. Affected siblings have been reported, raising the possibility of autosomal recessive inheritance. In another family, there were subjects from two generations affected, with X-linked or autosomal dominant, sex-limited inheritance suggested. The differential diagnosis includes Leydig cell hypoplasia.

LATE REGRESSION: CONGENITAL ANORCHIA (VANISHING TESTES SYNDROME)

Many cases have been reported of cryptorchid 46,XY males who on exploration were found to have bilateral anorchia but with normal wolffian structures, the absence of müllerian structures, and normal male external genitalia. The vas deferens ends blindly, often without an epididymis, in either the inguinal canal or upper scrotum (sometimes palpable as a small knot of tissue), which is retroperitoneally near the usual location of the internal inguinal ring, or in the iliac fossa. Neonates and infants with congenital anorchia fail to show any rise in testosterone during either endogenous LH or exogenous hCG stimulation, and they lack AMH. In the 46,XY individual with a male phenotype, these findings are usually but not always diagnostic. If uncertainty exists, laparoscopy or surgical exploration may be necessary. The cause of congenital anorchia is not established, but infections, teratogens, immune mechanisms, or hereditary factors may play a role.[5] About half of those with congenital anorchia also have micropenis.[76] The possibility that bilateral congenital anorchia is part of a continuum with early testicular regression has been suggested.

DISORDERS OF ANDROGEN SYNTHESIS OR ACTION

In these disorders, there is abnormal differentiation of either the internal genital ducts or the external genitalia in a 46,XY individual who has bilateral testes with intact tubular elements (seminiferous tubules with Sertoli and germinal cells). Disordered synthesis or action of testosterone is the underlying cause of the observed abnormalities. Some cases of dysgenetic testes and rudimentary testes overlap phenotypically with this category, but their underlying cause is testicular dysgenesis and not a primary disorder of the testicular hormone synthesis. In patients with 46,XY DSD who are severely undermasculinized, a blind, distal vaginal pouch is present. It appears when a lack of androgen stimulation permits the urovaginal septum to persist.

Androgen Biosynthesis Defect

Five enzymatic steps are involved in the synthesis of testosterone from cholesterol (Fig. 49-37). A defect in any one results in decreased to absent androgen synthesis and 46,XY DSD. Three of these enzymes are also necessary for the adrenal biosynthesis of cortisol: cholesterol side-chain cleavage enzyme (20,22-desmolase), 17α-hydroxylase, and 3β-hydroxysteroid dehydrogenase. Their defects result in accompanying cortisol deficiency with or without aldosterone deficiency (see later section, "Congenital Adrenal Hyperplasia"). The remaining two testosterone biosynthetic enzymes, 17,20-desmolase and 17β-hydroxysteroid dehydrogenase, are not needed for cortisol synthesis. Their deficiencies primarily cause impaired testosterone synthesis that leads to abnormal male differentiation and hypogonadism. Clinical diagnoses are made by finding biochemical evidence of disorders along the testosterone biosynthetic pathway, often accentuated by hCG stimulation testing.

17,20-DESMOLASE (17,20-LYASE) DEFICIENCY

17,20-Desmolase is necessary to form the C19 steroids DHEA and androstenedione, which are precursors of both testosterone and estradiol (see Fig. 49-29). 46,XY individuals who have 17,20-desmolase deficiency show incomplete masculinization ranging from mild hypoplasia of male genitalia to significant ambiguity to female-appearing genitalia, depending on the severity of the defect. Some of those with a female phenotype may be recognized early because of an inguinal or

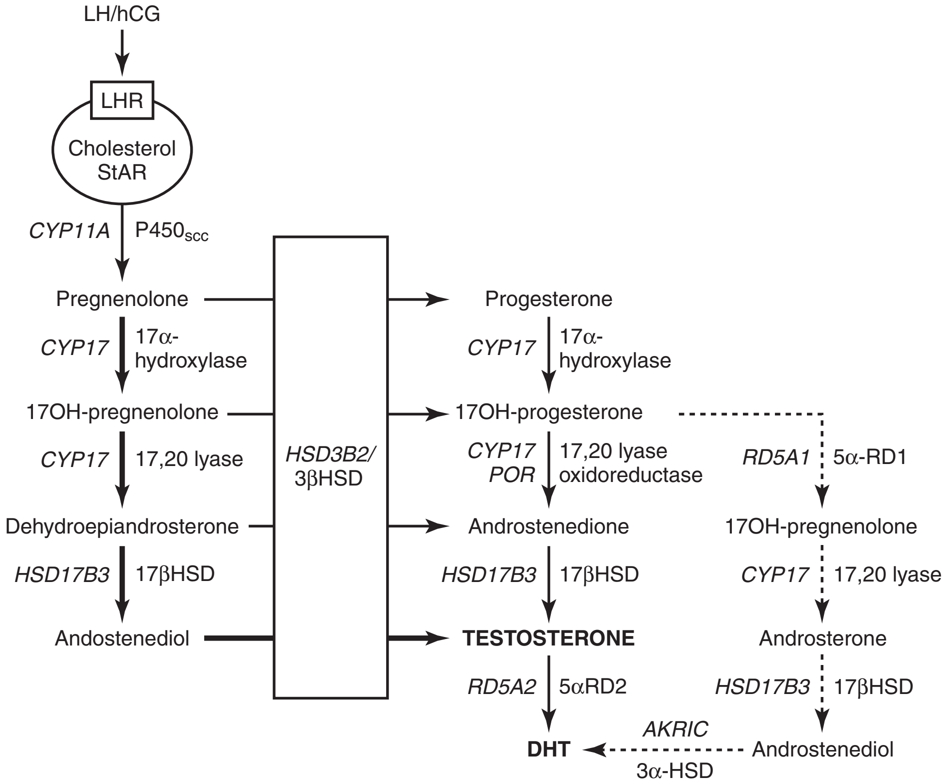

Figure 49–37. Pathway of testicular steroidogenesis. *Bold arrows* indicate a predominant Δ^5 pathway of steroid production. *Dotted lines* denote a "backdoor" pathway to dihydrotestosterone (DHT) synthesis postulated to be specific to the fetus. The steroidogenic enzymes and their cognate genes are shown. hCG, human chorionic gonadotrophin; LH, luteinizing hormone; LHR, LH receptor; StAR, steroidogenic acute regulatory protein; HSD, hydroxysteroid dehydrogenase deficiency; RD5A1, 5α-reductase type 1; RD5A2, 5α-reductase type 2; *AKRIC*, aldo-keto reductase. (*From Hughes IA: Disorders of sex development: a new definition and classification,* Best Pract Res Clin Endocrinol Metab *22:119, 2008.)*

labial gonad or gonads; others are diagnosed later because of delayed puberty. The inheritance is autosomal recessive. If a 46,XY neonate is assigned a female gender, the testes should be removed before puberty. Affected 46,XX patients appear normal in infancy but have delayed puberty because of inadequate estradiol production.

17β-HYDROXYSTEROID DEHYDROGENASE DEFICIENCY

17-Ketosteroid reductase catalyzes the only reversible step involved in testosterone and estradiol synthesis, the interconversion of androstenedione and testosterone and of estrone and estradiol (see Fig. 49-29). It is present in both gonadal and peripheral tissues but only minimally so in adrenocortical tissue. Its deficiency is associated primarily with diminished testosterone synthesis with a decreased plasma testosterone-to-androstenedione ratio. This results in failure of male differentiation in utero.

Of those who are identified in the neonatal period, most affected 46,XY patients have slightly masculinized genitalia (clitoromegaly, posterior labial fusion); a few have more masculinization. The epididymis and vas deferens are well developed, and in many patients, the testes are descended in the inguinal canal or labioscrotal folds. Because the degree of undermasculinization of the external genitalia can be severe, the diagnosis may not be possible in infancy. The inheritance of 17-ketosteroid reductase deficiency is autosomal recessive. It has a high prevalence in the Arab population in the Gaza Strip, Lebanon, Syria, and Turkey.

Untreated 46,XY patients undergo significant masculinization at puberty and may have an accompanying change in gender identity from female to male (a similar change in gender identity is seen in patients with untreated 5α-reductase deficiency).

5α-REDUCTASE DEFICIENCY

5α-Reductase is located peripherally in the tissues of the urogenital sinus, external genitalia, liver, prostate, hair follicles, and sebaceous glands, where it catalyzes the conversion of testosterone to its 5α-reduced product, DHT. Its deficiency in the 46,XY fetus results in failure of the external genitalia to undergo male differentiation. Affected males have normally developed testes that may be descended, absent müllerian duct structures, and male internal ducts (stimulated by testosterone) but phenotypically female or ambiguous external genitalia. Most patients are potentially recognizable at birth, with apparent clitoromegaly, a single perineal orifice that is a urogenital sinus, and posterior labial fusion (Fig. 49-38). A few patients have hypospadias or a micropenis. Most are reared as females; however, in some cultures in which the disorder is widely known and recognized, individuals may be recognized as a third gender. At puberty, noncastrated individuals show striking virilization due to the increase in testosterone, and about 60% change gender as adults.[15] Many undergo a change in gender identity from female to male. DHT-dependent secondary sexual characteristics such as acne, body and facial hair, and prostatic enlargement develop minimally or not at all. The inheritance of primary 5α-reductase deficiency is autosomal recessive.

LEYDIG CELL HYPOPLASIA

Patients with testicular unresponsiveness to hCG and LH fail to undergo male genital differentiation. It is due to an autosomal recessive inactivating mutation in the LH receptor.[62]

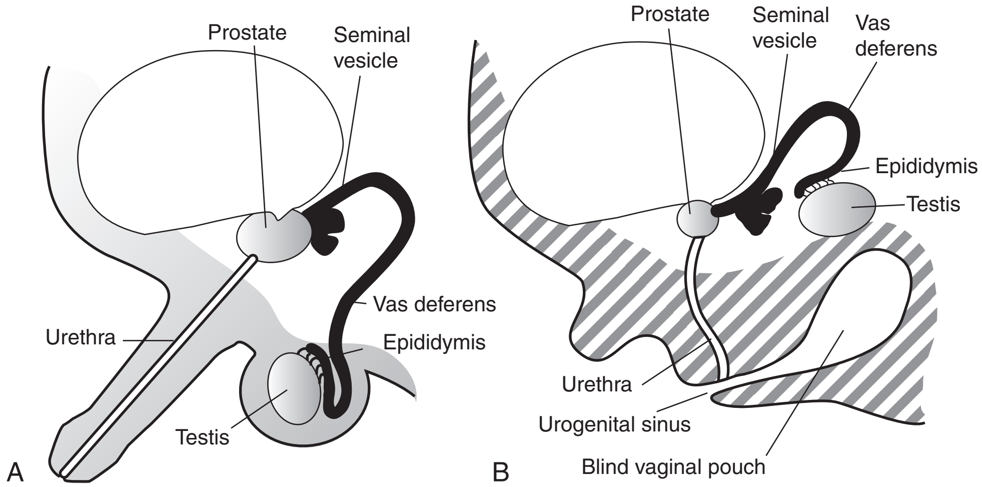

Figure 49–38. **A**, Male differentiation of the external genitalia and urogenital sinus structures is stimulated by dihydrotestosterone (DHT) (*gray areas*), whereas wolffian duct differentiation is stimulated by testosterone (*solid black area*). **B**, 5-Reductase deficiency results in impaired male differentiation of DHT-responsive tissues (*gray bars area*). The external genitalia appear female, and the vesicovaginal septum develops to create a distal, blind vaginal pouch opening into a urogenital sinus. The wolffian duct differentiation is normal (*solid black area*). (*From Imperato-McGinley J , et al: Male pseudohermaphroditism: the complexities of male phenotypic development,* Am J Med *61:251, 1976.)*

Primary agenesis or hypoplasia of the Leydig cells is a possible alternative explanation. In the complete absence of hCG binding, a female phenotype with a blind vaginal pouch but no wolffian ducts is seen. Other patients have shown clitoromegaly, posterior labial fusion, or perineal hypospadias with good development of the epididymis and vas deferens, suggesting an incomplete defect. AMH is produced, so müllerian structures are absent. The testes are usually cryptorchid and small postpubertally, although possibly of normal size in infancy. The characteristic findings are a low basal level of testosterone and its precursors, the failure of testosterone response to hCG stimulation, and a marked paucity or absence of Leydig cells on biopsy of the testes. The seminiferous tubules and Sertoli cells are normal, but spermatogenic arrest or absence is seen. The differential diagnosis includes XY gonadal agenesis, rudimentary testes, and those forms of 46,XY DSD involving deficient androgen synthesis or action.

Defect in Androgen Action

ANDROGEN INSENSITIVITY SYNDROMES

The androgen insensitivity syndromes are disorders in which peripheral tissues are partially to completely incapable of responding to stimulation by any androgen because of an androgen receptor or postreceptor defect.[33] Many mutations in the X-linked, androgen receptor gene have been described, leading to variable phenotypes in this disorder.[74] Androgen-mediated events, such as masculine differentiation in utero or virilization during puberty, fail to occur or are impaired to a variable extent, depending on the completeness of the defect.

COMPLETE ANDROGEN INSENSITIVITY SYNDROME

Affected individuals have a 46,XY karyotype with bilateral testes but a failure in wolffian duct development and complete absence of any masculinization of the external genitalia. They have female-appearing external genitalia with a distal vaginal pouch. The müllerian structures are absent, but microscopic remnants have been reported, possibly from the interference of high, unopposed levels of estrogen with the action of AMH. The testes are of normal size and may be descended into the inguinal canal or labia majora, and more than half of these individuals have an inguinal hernia, which may lead to their clinical recognition in infancy. At puberty, these individuals undergo female breast development and acquire a female habitus due to the testicular production of estradiol and the peripheral conversion of testosterone to estradiol; however, they have primary amenorrhea. No masculinization is seen, and gender identity remains female.

Studies of genital skin fibroblasts derived from patients with cAIS reveal that most have an absence of functional androgen receptors, which is determined by the absence of specific binding of DHT, thus confirming the biochemical cause of their androgen unresponsiveness. The occurrence of cAIS is familial in about 30% of the cases, and a family history of infertile female relatives is sometimes found. Spontaneous mutations are thought to account for the sporadic cases. Screening for the syndrome in an at-risk fetus can be carried out in utero by ultrasound examination of the genitalia and determination of the karyotype. The diagnosis is inferred in the phenotypically female neonate by establishing the absence of a uterine cervix and the presence of a Y chromosome. Both plasma testosterone and LH have been shown to be low at 30 days of age, suggesting that the expected postnatal testosterone rise requires the hypothalamic-pituitary axis to be responsive to testosterone.[11]

The differential diagnosis includes other causes of 46,XY DSD; hCG stimulation testing may be needed to rule out these possibilities. The gender is unequivocally female. There is a 2% increased risk for germ cell malignancy, probably related to the intra-abdominal location of the testes. For this reason, gonadectomy is indicated, however, the timing remains controversial because testosterone is converted to estradiol peripherally and allows for spontaneous development of secondary sexual characteristics.[16] Virtually all malignant tumors have occurred postpubertally.

PARTIAL ANDROGEN INSENSITIVITY SYNDROME

Affected 46,XY individuals have bilateral testes and absent müllerian ducts but incomplete masculinization of their external genitalia, ranging from female-appearing genitalia with clitoromegaly or posterior labial fusion to phenotypically normal male-appearing genitalia. Many have perineal, penoscrotal, or penile hypospadias (Fig. 49-39), and others have a micropenis. There also is wolffian duct development, but it is often incomplete, which may not correlate with the extent of external genital masculinization. At puberty, both masculinization and feminization are seen, the extent depending on the severity of the androgen insensitivity.

The causes of pAIS are heterogeneous. Most individuals have qualitatively abnormal receptors with variable function.[12] Others have reduced amounts of normal receptors, and a few have postreceptor defects. There is an X-linked recessive inheritance of the receptor-related mutations. The phenotype in pAIS is variable and does not necessarily correlate with the genotype.[17]

Except for very few individuals with a normal male phenotype, all individuals with pAIS are infertile. The risk for development of gonadal tumors is not known, but intratubular germ cell neoplasia (a precancerous lesion) frequently occurs in patients with pAIS at as early as 2 months of age. Monitoring for the development of a testicular tumor is needed if the testes are not removed.[16] The testes are removed in those reared as females.

OTHER

Disorders of Antimüllerian Hormone and Antimüllerian Hormone Receptor (Persistent Müllerian Duct Syndrome)

Isolated AMH deficiency or AMH receptor abnormalities result in failure of the müllerian ducts to regress. The clinical picture in the 46,XY individual is that of a phenotypic male with bilateral fallopian tubes, a uterus (occasionally hypoplastic or absent), wolffian duct development, and bilaterally normal testes. Two clinical forms are seen. The typical clinical presentation is in a male with bilateral cryptorchidism and inguinal hernias and normal male external genitalia. During surgery for hernia repair, a uterus and fallopian tubes are found in the inguinal canal. Alternatively, one testis is at least partially descended and accompanied by a fallopian tube and uterus that easily enter the inguinal canal. In addition, about one third have transverse ectopia, the opposite testis being pulled to the side with the inguinal hernia, so that both testes are in the same inguinal canal. Such patients may have an inguinal mass or the appearance of an incarcerated hernia without evidence of intestinal obstruction. Less commonly, the uterus is fixed in the pelvis, and the testes are in an ovarian position. The vas deferens and epididymis

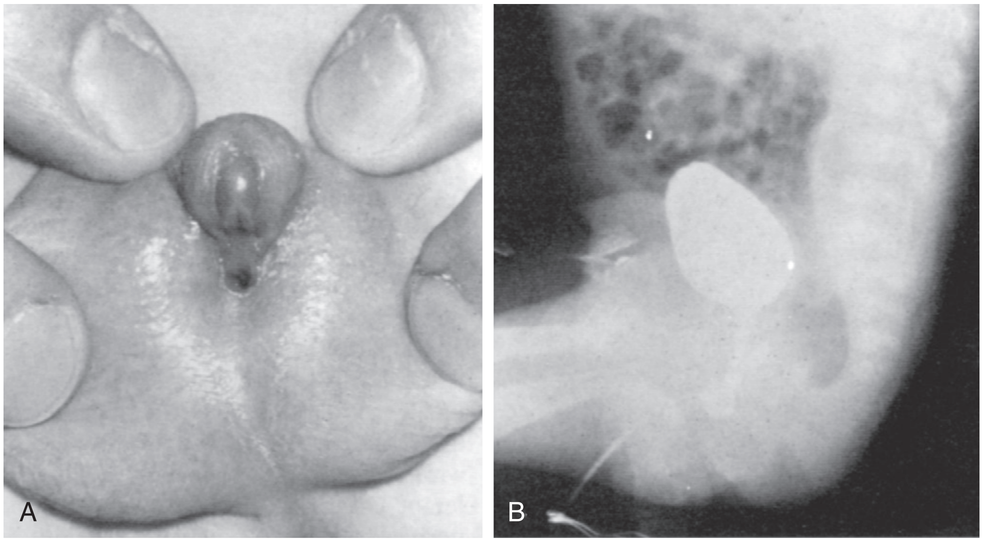

Figure 49–39. **A**, This 46,XY infant with partial androgen insensitivity had ambiguous genitalia at birth (phallus, 1.8 × 0.8 cm; penoscrotal hypospadias; 1-cm testes in scrotum and the absence of a uterine cervix). **B**, Genitogram performed after endoscopy shows a 2-cm utriculus, or blind pouch, opening into the urethra just below the verumontanum; no evidence of a uterus was found. Serum testosterone was elevated at 475 ng/dL at age 40 hours and increased to 1517 ng/dL at age 7½ weeks, with elevated serum luteinizing hormone of 23 mIU/mL at age 7½ weeks. Androgen receptor binding in genital skin fibroblasts showed no demonstrable abnormality, which is often found in partial defects. The parents insisted on male gender. Testosterone therapy did not increase penile size until the dose was increased fourfold above physiologic replacement. Repair of hypospadias was performed in infancy. A younger brother was born with a similar defect.

are typically enmeshed in the uterine wall and mesosalpinx, making it difficult to bring the testes down into the scrotum.

Persistent müllerian duct syndrome is due to a mutation in either the *AMH* gene or its receptor and is inherited according to an autosomal recessive pattern.[18] The gender assignment is male. Orchiopexy should be performed early in infancy to improve testicular outcome. Achieving testicular descent into the scrotum usually requires extensive dissection to free the spermatic cord. The müllerian structures do not need to be removed because they do not develop malignancy and there is a strong risk for damaging the vas deferens. Spermatogenesis is intact, but many patients are infertile, possibly because of abnormal epididymal development, cryptorchidism, or injury to the vas deferens. Intracytoplasmic sperm injection may produce fertility in some of these cases. There is no evidence of an increased risk for testicular tumors compared with other causes of cryptorchidism.

Environmental Influences: Endocrine Disrupting Chemicals

Attention has been drawn to the study of endocrine disrupting chemicals (EDCs), substances that influence the function of an endocrine system and cause adverse health effects.[1] Specifically, there have been concerns about the effects of pesticides, industrial chemicals, and natural plant compounds on sex development. These stem from results of laboratory and animal experiments and have yet to be shown definitively to apply to humans. The effects of EDCs on sex differentiation and development in humans remain unknown. Further studies of these chemicals are needed to gain a better understanding of their role, if any, in human sexual development.

46,XX Disorder of Sex Development

DISORDERS OF GONADAL (OVARIAN) DEVELOPMENT

Gonadal Dysgenesis

Patients with XX gonadal dysgenesis have bilateral streak gonads or hypoplastic ovaries with intact müllerian duct structures and female external genitalia. They differ from patients with Turner syndrome in that they usually have normal stature, an absence of Turner stigmata, no abnormality of the X chromosome, and frequently a familial condition. An abnormality of an autosomal gene that regulates germ cell migration, formation of the bipotential gonad, or ovarian differentiation may be the cause. Familial cases occur frequently. Associated defects are seen in some families, including sensorineural hearing loss (Perrault syndrome), neurologic abnormalities, and renal disease. Isolated instances of clitoromegaly have been described, resulting from testosterone production by either hilar cells or luteinized gonadal stromal cells in a streak gonad. The differential diagnosis includes defects in estradiol synthesis, Slotnick-Goldfarb syndrome (streak gonad plus a hypoplastic ovary that may present as a neonatal ovarian cyst), Malouf syndrome (ovarian dysgenesis, dilated cardiomyopathy, ptosis, broad nasal bridge), and Denys-Drash and Fraser syndromes.

46,XX Ovotesticular Disorder of Sex Development

See earlier section, "Ovotesticular Disorder of Sex Development."

Testicular Disorder of Sex Development (46,XX Male)

Individuals with 46,XX male phenotype have bilateral testes but absence of a Y chromosome on karyotype analysis. Most have normal male internal and external genitalia, but 10% to 20% have ambiguous genitalia because of decreased fetal testosterone production. The testes are of normal size but may be cryptorchid. As with Klinefelter syndrome, the detrimental influence of the second X chromosome results in the absence of spermatogonia, hyalinization of the tubules, and small testes in adults. The testicular histology is almost normal in the first year of life, but after 1 year of age, the spermatogonia are lacking. Most if not all XX males inherit one maternal and one paternal X chromosome. The incidence is about 1 in 20,000 male births. The most common cause is an abnormal X-Y interchange, occurring during paternal meiosis and involving a crossover of variable amounts of adjacent Y sequences to the distal end of the paternal short arm of the X chromosome. Most *SRY*-positive individuals have a normal male phenotype and no disability except infertility. A few have lost more of the X chromosome sequence, resulting in short stature or mental retardation; others with a very small Y interchange have hypospadias or other incomplete male genital development, which is thought to be caused by altered *SRY* gene expression.

A few XX males are found to have no *SRY* gene and no detectable Y sequences. Most of these *SRY*-negative and Y-negative individuals have ambiguous genitalia. The cause is believed to be autosomal, possibly involving a mutation that turns on a gene downstream from the *SRY* gene that leads to testicular differentiation. A mutation in an X-linked gene, unrecognized 46,XX/46,XY mosaicism, and a duplication of *SOX9*[25] are other possible explanations. Gonadal tumors have not been reported.

ANDROGEN EXCESS

The external genital ambiguity is almost always androgen induced; most cases are caused by fetal CAH, and a few result from a maternal androgen source. However, in rare cases, a source of androgens is not found, and an error in morphogenesis is presumed to be the cause.

Androgen exposure between 8 and 14 weeks of fetal age results in variable male differentiation of the external genitalia—that is, labioscrotal fusion, regression of the urovaginal septum to form a urogenital sinus, ventral displacement of the urethral (urogenital) meatus toward or on the phallus, and male phallus differentiation. See Figure 49-40 for a schematic representation of the degrees of virilization adapted from a scale developed by Prader.[73] Androgen exposure occurring beyond 12 or 14 weeks produces growth but not differentiation of the external genitalia—namely clitoral hypertrophy, defined in the neonate by a clitoral width of greater than 6 mm. Most 46,XX DSDs are identified at birth because of genital ambiguity, but the more severely affected neonates may be initially missed, being incorrectly identified as males with hypospadias or undescended testes. The major reason to identify 46,XX DSDs in the immediate neonatal period is that CAH, if present, is potentially life-threatening.

Congenital Adrenal Hyperplasia

CAH comprises a group of disorders in which there is an inherited defect in one of the enzymes required for the adrenocortical synthesis of cortisol from cholesterol. Each of the

Diagrams of normal female and male anatomy flank a series of schematic representations of different degrees of virilization of females, graded using the scale developed by Prader. Note that the uterus persists in virilized females even when the external genitalia have a completely masculine appearance (Prader grade 5). **B**, Normal and abnormal differentiation of the external genitalia (external view). *(From White PC, Speiser PW: Congenital adrenal hyperplasia due to 21-hydroxylase deficiency,* Endocr Rev *21:245, 2000.)*

enzyme defects leads to impaired cortisol production that causes a secondary increase in adrenocorticotropic hormone (ACTH). The elevated ACTH stimulates increased adrenocortical steroidogenic activity in an attempt to normalize cortisol production. Clinical problems arise as a consequence of impaired synthesis of the steroid hormones (glucocorticoids, mineralocorticoids, or gonadal sex steroids) beyond the enzymatic block and overproduction of the precursor steroids or their side products before the block (Fig. 49-41). Adrenal enzyme defects not involving cortisol synthesis are excluded from the CAH designation.

The five enzymes or enzymatic steps involved in the synthesis of cortisol from cholesterol are cholesterol side-chain cleavage enzyme complex (or 20,22-desmolase), 3β-hydroxysteroid dehydrogenase (3βHSD), 17α-hydroxylase, 21-hydroxylase, and 11β-hydroxylase (see Fig. 49-29). All except 3βHSD are members of the cytochrome P-450 group of oxygenases. Except for 17α-hydroxylase, these enzymes are also necessary for mineralocorticoid (aldosterone) biosynthesis. The first three enzymes are present in gonadal tissue, where they are necessary for synthesis of the sex steroids. A deficiency in males results in inadequate testosterone formation and incomplete male sex differentiation; in females, it results in deficient estrogen synthesis, which is clinically significant at puberty.

The 21- and 11β-hydroxylases are found predominantly in the adrenal cortex and only minimally in gonadal tissue and are not necessary for the synthesis of sex steroids. However, their deficiencies (and to a lesser extent the deficiency of 3βHSD) result in excess formation of precursor steroids, which yield an increased production of androgens that induce masculinization of affected female fetuses in utero. By this mechanism, 46,XX DSD occurs, and affected females

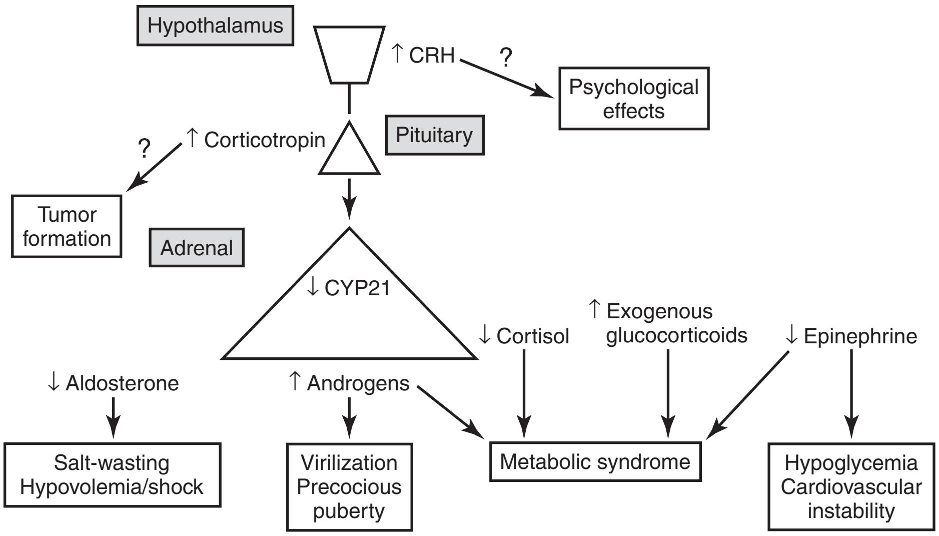

Figure 49–41. Endocrine imbalances characteristic of congenital adrenal hyperplasia. Potential clinical manifestations are given in the text boxes. (*From Merke DP, Bornstein SR: Congenital adrenal hyperplasia,* Lancet *365:2125, 2005.*)

should be identifiable at birth by their abnormal genitalia. Affected males who have 21- or 11β-hydroxylase deficiency do not manifest recognizable penile enlargement or other virilization at birth but develop these symptoms postnatally if untreated. On the other hand, affected males with 3βHSD deficiency do have genital ambiguity at birth because of testosterone deficiency. Finally, all five enzyme deficiencies are clinically important because of the associated adrenal glucocorticoid deficiency (with or without mineralocorticoid deficiency). This condition is life-threatening and needs to be recognized and managed early.

21-HYDROXYLASE DEFICIENCY

21-Hydroxylase enzyme deficiency is the most common cause of CAH, accounting for 95% of all cases. Two forms are seen in neonates: a simple virilizing form, in which the enzyme deficiency is partial, and a salt-losing form, in which the enzyme deficiency is more complete. A third form, late-onset or nonclassic 21-hydroxylase deficiency, represents a mild enzyme deficiency that does not have clinical manifestations in the fetus, neonate, or infant. Both of the classic forms are characterized by abnormal virilization of the female fetus. In the simple virilizing form, the salt loss is mild, so adrenal insufficiency does not tend to occur except in stressful circumstances. In the salt-losing form, there is adrenal insufficiency under basal conditions that tends to manifest in the neonatal period or soon thereafter as an adrenal crisis. Seventy percent of all reported cases of CAH are salt wasting and 30% are not salt wasting. The incidence of the classic form estimated from data from 13 countries (United States, France, Italy, New Zealand, Japan, United Kingdom, Brazil, Switzerland, Sweden, Germany, Portugal, Canada, and Spain) is 1 in 15,000 live births, and the carrier frequency of classic CAH is about 1 in 60 individuals.[43]

Simple Virilizing Form. The simple virilizing form is due to a partial deficiency in the 21-hydroxylase enzyme. 21-Hydroxylase is necessary for the conversion of 17-OHP to 11-deoxycortisol (compound S) and of progesterone to 11-deoxycorticosterone (DOC). A deficiency of this enzyme results in an impairment of cortisol and aldosterone biosynthesis, which is compensated for by the increased secretion of ACTH and angiotensin. This process causes overproduction of the steroids before the enzyme block and a secondary increased secretion of adrenal androgens, which are converted in peripheral tissues to testosterone and DHT, where they cause abnormal virilization (see Fig. 49-41).

Affected fetuses produce increased amounts of androgens beginning in the first trimester. In the female fetus, it leads to varying degrees of male differentiation of the external genitalia and urogenital sinus, but the internal genital ducts develop normally along female lines without any wolffian duct development because its development requires high local and not systemic levels of androgen. At birth, the spectrum of masculinization in females ranges from mild clitoromegaly, usually with some posterior labial fusion, to perineal or penile hypospadias to occasionally complete male differentiation, with the urethra opening at the tip of a male-sized phallus; the latter phenotype may have a normal male appearance except that the gonads are impalpable. The extent of male differentiation in female fetuses tends to reflect the severity of the enzyme defect. Females with the simple virilizing form often show less extensive male differentiation than those with the salt-losing type. In the male fetus, the increased secretion of adrenal androgens is insignificant compared with the fetal production of testicular androgens. The external genitalia are usually normal at birth; some enlargement of the penis may occur, but it is rarely recognizable as such. Female and male neonates may have increased pigmentation of the genitalia or areolae.

Patients with untreated, simple virilizing 21-hydroxylase deficiency continue to produce excess androgens postnatally, resulting in accelerated growth and skeletal maturation and the appearance of androgen-induced sexual changes. Patients with mild CAH generally do not develop symptoms of adrenal insufficiency unless they are exposed to major stress or significant salt depletion (reduced salt intake, vomiting, excessive sweating). A few patients with either form have received medical attention because of recurrent hypoglycemic episodes or seizures, usually occurring during common infections.

Salt-Wasting Form. The salt-wasting form is due to a severe deficiency of the 21-hydroxylase enzyme that results in significant impairment of cortisol and aldosterone synthesis that cannot be compensated for by the increased levels of ACTH and angiotensin. The development of cortisol and aldosterone deficiency, usually in the first weeks of life, results in acute adrenal insufficiency and sodium wasting (see Fig. 49-41). Females with the salt-losing form of CAH may show more complete masculinization of the external genitalia, and some are incorrectly identified as males at birth (Fig. 49-42). Males generally receive medical attention when they develop a salt-losing crisis due to adrenal insufficiency. The symptoms or signs of adrenal insufficiency are not present at birth and rarely occur before 3 to 4 days of age. About half of the untreated patients with salt-losing CAH have onset of adrenal crisis between 6 and 14 days of age; by 1 month of age, more than three fourths have developed adrenal crisis. Less severely affected individuals may present in the following months, usually in association with a stressful condition causing decreased salt intake or increased salt losses, and a few escape crisis entirely. The early symptoms and signs of adrenal crisis are nonspecific and include lethargy, a poor appetite, regurgitation of feedings, failure to thrive, and weight loss. Hyperkalemia, hyponatremia, and metabolic acidosis may be seen early. The regurgitation of feedings may progress to projectile vomiting. Severe symptoms and signs may occur within 1 to 2 days, including dehydration (with accompanying azotemia), hypotension, muscle weakness, obtundation, a gray or cyanotic appearance, cold and clammy skin, hyperkalemic cardiac conduction abnormalities, and hyponatremic or hypoglycemic seizures.

The development of acute adrenal crisis is partially caused by hypoaldosteronism, which results in renal sodium wasting, with depletion of total-body sodium content and an impaired ability to secrete potassium and hydrogen ions in the distal tubule. The decreased total-body sodium content results in hyponatremia, hypovolemia, and decreased tissue perfusion, which account for many of the early symptoms and eventually result in hypotension and shock.

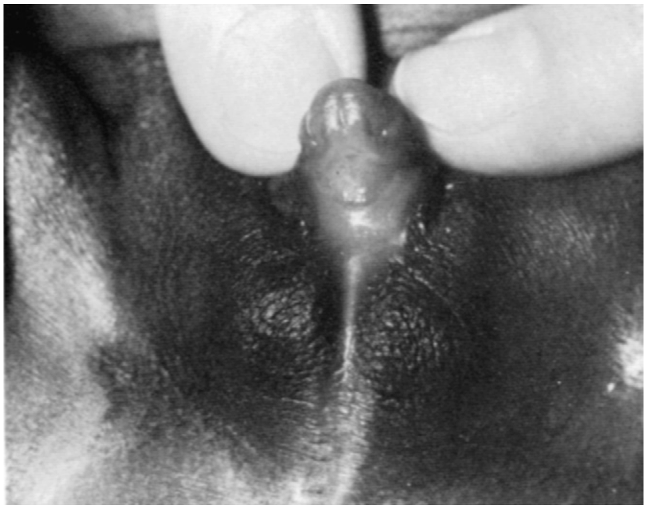

Figure 49–42. A 4-week-old 46,XX neonate with salt-losing 21-hydroxylase deficiency was erroneously thought to be a male with penile hypospadias at birth. There was a small phallus (2.3 × 0.8 cm) and impalpable gonads.

Hypocortisolemia represents the other major component of adrenal insufficiency and results in impairment of cardiovascular, metabolic, and other systemic functions. Among the cardiovascular effects associated with glucocorticoid deficiency are decreased stroke volume and cardiac output, decreased blood pressure, and decreased vascular tone or reactivity. Depletion of the renin substrate occurs in the presence of cortisol deficiency and impairs the renin-angiotensin axis, leading to circulatory failure. Norepinephrine raises the peripheral blood pressure only in the presence of cortisol, suggesting that cortisol exerts a permissive action. There is also an impaired ability of the urine to be concentrated because of the reduced responsiveness of the renal collecting tubules to vasopressin.

Cortisol deficiency is associated with an inability to maintain and mobilize normal hepatic glycogen stores, which during a period of starvation may lead to hypoglycemia. Fat becomes the primary source of energy, a condition that may lead to lipid depletion. Cortisol is normally important for the mobilization of increased glucose production by the liver by both inducing gluconeogenic enzymes and exerting its permissive effects on epinephrine and glucagon-induced glycogenolysis. Cortisol deficiency is associated with impaired muscle activity; normochromic, normocytic anemia; and eosinophilia.

Hormonal Abnormalities. The hormonal abnormalities include a serum level of cortisol that is normal or low with an inadequate rise in response to ACTH administration. ACTH levels in untreated patients with either form of CAH are elevated, but more so in the patients with salt-losing CAH. Plasma renin activity is also elevated, especially in salt-losing CAH. However, in contrast to the simple virilizing form, in salt-losing CAH, there is no increase in aldosterone production in response to sodium restriction or ACTH administration.

Of the steroids preceding the enzyme block, 17-OHP is the most strikingly elevated. Serum concentrations are increased 40 to 400 times above the upper limit of normal values and occasionally higher. Androstenedione can be up to 40 times higher than the normal limit. About 15% of the androstenedione produced is metabolized in peripheral tissues to testosterone, with the adrenals synthesizing very little testosterone. Serum testosterone levels in affected children can be elevated by 20 times the normal range.

Pathology. Pathologically, the adrenal glands are characteristically hyperplastic and enlarged. The effects of excessive ACTH stimulation are seen microscopically. The zona glomerulosa, from which mineralocorticoids are produced, is two to four times wider in the simple virilizing form of CAH but is either normal or absent in the salt-losing form.

Diagnosis. The diagnosis of 21-hydroxylase deficiency in a neonate or infant should be considered in females with any masculinization of the external genitalia, in presumed males with impalpable gonads (including males with hypospadias), in females or males who develop symptoms or signs of adrenal insufficiency or crisis (females should be recognized by their genital abnormalities), and in those who have a family history of CAH or an unexplained death in infancy.

For 21-hydroxylase deficiency, the most useful diagnostic test is the determination of an increased level of serum 17-OHP (more than 80 times higher than normal in a full-term infant).

Newborn Screening. Many jurisdictions have newborn screening programs that include the measurement of 17-OHP and allow the early identification of infants with CAH. Their justification lies in the increased mortality that occurs in infants who are not diagnosed and die of salt-losing crisis or sudden infant death and the increased morbidity that results from adrenal insufficiency, incorrect gender assignment, and premature virilization.[22] Caution is needed in interpreting the values of 17-OHP on newborn screening tests, particularly in the first week of life because many affected neonates show normal levels of 17-OHP on the first day of life and only mild elevation in the first several days before the levels become very high. Conversely, the levels in unaffected full-term neonates may be elevated in cord serum and are high in peripheral serum in the first 12 hours of life before declining to the normal range after 24 hours of age. Levels in premature[34] and sick neonates may overlap with those found in many affected infants in the first few days of life. Many jurisdictions with newborn screening programs have cutoff values that are adjusted according to gestation age or weight, or both.

The method of detection is based on finding an increased level of 17-OHP in blood collected on filter paper at 2 to 5 days of age. False-positive results are usually associated with prematurity (presumably caused by decreased metabolic clearance of 17-OHP) or low birthweight and, less often, with serious illness (probably caused by increased 17-OHP production associated with stress), age less than 24 hours (fetoplacental contribution of 17-OHP), or technical problems.

The overall incidence of 21-hydroxylase deficiency in screened neonates is about 1 in 15,000, ranging from 1 in 11,000 to 1 in 21,000 for most programs. As expected, the male-to-female ratio is about 1:1; salt losers have about a 72% incidence. Although females identified by screening often have variable masculinization of the external genitalia, one third to one half were missed clinically, including some of them inappropriately assigned to male gender. In addition, identification at 5 to 21 days of age has prevented adrenal crisis in many affected but unrecognized neonates. Such screening clearly improves the detection of 21-hydroxylase deficiency in neonates for whom the diagnosis might otherwise have been missed.

In response to administration of synthetic ACTH (Cortrosyn, 35 μg/kg to a maximum of 250 μg intravenously), 17-OHP levels can be plotted on a nomogram to predict the genotype.[49] The measurement of plasma ACTH or serum cortisol is not useful in defining the enzyme defect of CAH but may have value when other causes of adrenal insufficiency are considered.

Despite a negative result of newborn screening, if the diagnosis of CAH is suspected clinically, testing should be done. The diagnosis of the salt-losing form of CAH is based on obtaining clinical or biochemical evidence for sodium wasting. There is typically a clinical diagnosis that is based on the presence of varying degrees of hyponatremia, hyperkalemia, or hypovolemia and its clinical consequences. High urinary sodium concentrations in the presence of normal or low serum sodium concentrations may indicate that an infant is a salt loser. The measurement of aldosterone or plasma renin activity in the untreated state is not diagnostically useful because of the overlap with levels seen in untreated patients with simple virilization.[32] Patients with mild, salt-losing CAH may show normal electrolytes and lack the clinical signs of hypovolemia. Their diagnosis is made biochemically by finding an increased level of plasma renin activity during physiologic glucocorticoid replacement therapy; mineralocorticoid replacement should be added.

Ultrasonography. An experienced pediatric radiologist reading an adrenal ultrasound can identify enlargement and lobulation of the adrenal glands with stippled echogenicity, findings consistent with CAH. Adrenal ultrasonography has been shown to have a sensitivity of 92% and a specificity of 100% for diagnosing CAH.[2]

Treatment. The goals of the treatment of CAH are to normalize ACTH secretion, thereby lowering ACTH-stimulated precursor steroids and their side products, and provide replacement or correction of end product (cortisol, aldosterone, gonadal sex steroid) deficiencies. The two goals are closely interrelated. Normalization of ACTH secretion requires both cortisol replacement and the correction of hypovolemia, with adjustments made during medical stress. Insufficient replacement permits increased ACTH and sodium wasting, and excessive replacement produces a cushingoid state, growth suppression, and hypertension.

In the simple virilizing form of 21-hydroxylase deficiency, normalization of ACTH requires only cortisol replacement. The addition of mineralocorticoid therapy may decrease the amount of cortisol that is needed. The adequacy of cortisol replacement is monitored by the measurement of serum 17-OHP and androstenedione.

In the salt-losing form of 21-hydroxylase deficiency, normalization of ACTH requires the correction of sodium wasting and hypovolemia in addition to the physiologic replacement of cortisol. Hypovolemia is monitored by the measurement of plasma renin activity. Increased levels indicate the presence of hypovolemia caused by sodium wasting, and subnormal levels indicate sodium retention caused by excessive mineralocorticoid replacement.

With regard to maintenance cortisol replacement, allowance must be made for differences in potency, absorption, and duration of action among the available preparations. Hydrocortisone is the oral preparation of choice. Oral replacement doses in CAH usually range from 12 to 20 mg/m^2 per day given in three divided doses. One study using once-daily dexamethasone at a dose of 0.27 mg/m^2/d showed normal growth.[64]

Increases in the dose of hydrocortisone (or other glucocorticoid) should be made during periods of stress, with doubling or tripling of the dose during moderate and severe illnesses. Major illnesses, surgery, or trauma should be covered by the intramuscular or intravenous administration of hydrocortisone at three to six times the maintenance dose to avoid adrenal crisis. At the initiation of therapy, the hydrocortisone dose may be prescribed at maintenance levels or at three times the maintenance dose if stress is present.

For infants who require maintenance mineralocorticoid replacement therapy, it is provided orally.

9α-Fludrocortisone acetate (Florinef Acetate), 0.05 to 0.30 mg, is administered daily. Sodium supplementation (1 to 5 mEq/kg per day) may be needed in the first 1 to 2 years, in part because the renal tubules are less able to conserve sodium. Measurements of blood pressure and the level of plasma renin activity are used to adjust the mineralocorticoid dosage and sodium supplementation. Unlike hydrocortisone or other glucocorticoids, the dose of Florinef Acetate does not change with increases in body size or during stress. As infancy progresses, mineralocorticoid requirements diminish; salt supplementation should be discontinued, and the dose of Florinef Acetate may need to be lowered.

In acute salt-losing adrenal crisis, fluid replacement (beginning with 20 mL/kg of body weight of 0.9% saline), sodium replacement, continuous glucose infusion, glucocorticoid therapy at 50-100 mg/m^2 (initially given intravenously as the phosphate or succinate ester of hydrocortisone), and mineralocorticoid replacement (Florinef Acetate, 0.1 to 0.2 mg orally every 12 to 24 hours) are needed. Acidosis, hypoglycemia, and hyperkalemia may be present and should be managed, and the patient should be monitored for potassium toxicity. In patients stable enough for diagnostic testing, glucocorticoid therapy may be withheld until the tests are completed. However, therapy should be administered if blood pressure or other functions are not correctable with fluid, saline, glucose, and mineralocorticoid replacement.

Gender Assignment. See the earlier section, "Gender Assignment in Newborns," for a full discussion. Here we discuss gender assignment issues specific to CAH. Female gender assignment is usually recommended in 46,XX CAH individuals regardless of the extent of masculinization of their genitalia. This recommendation is based on the observation that these patients have normal ovaries and müllerian structures and have the potential to lead normal, fertile lives as females. Surgical correction and its timing in females with masculinized external genitalia are controversial. If done, it is usually performed when a reasonable body size has been achieved, commonly in the first 2 to 6 months. Females with CAH have been shown to engage in more masculine play activities.[58] Mixed results have been reported about whether females with CAH have a more masculine pattern on cognitive function tests.[39] Although lower rates of heterosexual orientation,[44] marriage, and fertility have been reported, they generally identify as females and do not have gender dysphoria. Gender identity in girls with CAH is not related to the degree of genital virilization or the age at which genital reconstructive surgery was done.[44] Observed psychological differences have been attributed to insufficient androgen suppression, inadequate vaginal introitus, and possible effects of in utero androgen exposure on the central nervous system.

Genetics. 21-Hydroxylase deficiency is inherited as an autosomal recessive disorder. Genotyping studies of families have established a genetic link with the gene responsible for 21-hydroxylase deficiency. Molecular genetic studies show that two 21-hydroxylase genes are present on each chromosome 6. However, the first gene is nonfunctional (a pseudogene); only the second one is functional. These two genes are named *CYP21P* and *CYP21*, respectively.

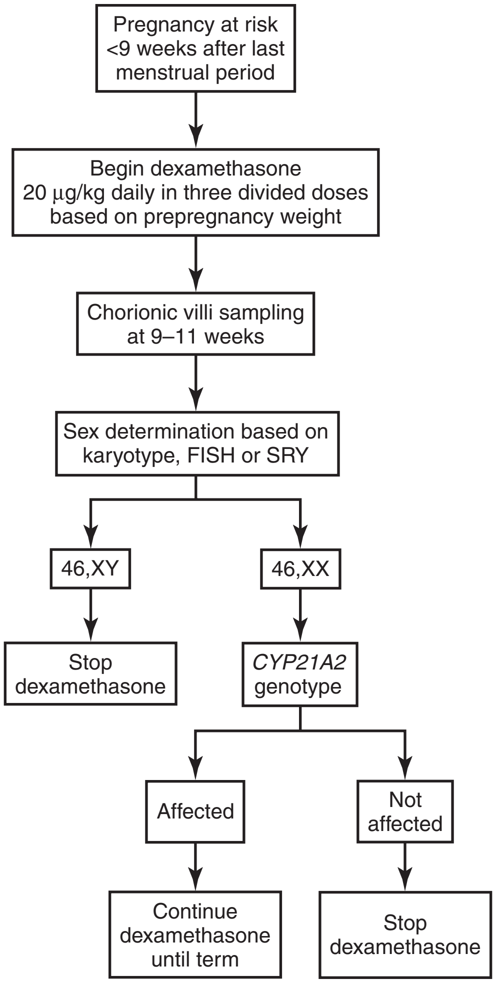
Diverse mutational abnormalities of the *CYP21* gene have been described for 21-hydroxylase deficiency, including point mutations, gene conversions (transfer of an abnormal sequence from the pseudogene to the active gene), and deletions. Point mutations and small-gene conversions represent most *CYP21* mutations. They may have mild or severe consequences, affecting messenger RNA stability, enzyme conformation, and function. Gene deletions and large-gene conversions account for the remaining *CYP21* changes, which usually result in defective or absent messenger RNA. Patients with salt wasting have the most deleterious mutations and almost no residual enzyme activity, although there is an overlap among phenotype-genotype correlations. Genotyping to identify the mutation is available.[75]

Prenatal Diagnosis and Treatment. The prenatal diagnosis of 21-hydroxylase deficiency is advocated by many for the affected female fetus because therapy is available to minimize or prevent masculinization of the external genitalia. It is, however, considered experimental by others. To be effective, therapy must be initiated by 8 weeks of gestation. A gene-specific diagnosis in utero can be made on cells obtained by chorionic villus sampling or amniotic fluid analysis.[51] This has replaced the method of making the diagnosis by measuring hormone levels.

If undertaken, the in utero treatment of the female fetus with 21-hydroxylase deficiency requires sufficient glucocorticoid replacement to suppress fetal ACTH and androgen, reducing levels to normal or less than normal; any fetal sodium wasting is presumably corrected by the maternal-placental unit. Dexamethasone given to the mother readily crosses the placenta, and the generally recommended dose (20 μg/kg per pre-pregnancy body weight per day given in three divided doses, preferably not exceeding 1.5 mg/day) is usually effective in limiting or preventing adrenal masculinization of the fetal external genitalia, indicating that dexamethasone can suppress fetal ACTH. Treatment of the fetus at risk is begun optimally when the pregnancy is confirmed and before 9 weeks after the last menstrual period. Because one in four fetuses will be affected and only affected female fetuses need to be treated, there is a seven out of eight chance that continuation of treatment is unnecessary. An algorithm for the diagnosis and prenatal treatment of fetuses at risk for CAH is shown in Figure 49-43. If chorionic villus sampling and amniocentesis are not performed, fetal sex determination by ultrasonography performed later in the second trimester should identify the males and result in continuation of therapy to term only in the females. Among the maternal side effects that are occasionally seen are those of glucocorticoid excess (weight gain, edema, glucose intolerance, and hirsutism); the dexamethasone-induced suppression of the maternal hypothalamic-pituitary-adrenal axis needs to be managed during delivery or other major stress. Untoward effects have not been encountered in the newborns or their mothers.[51] The risks for long-term effects on brain development or psychosexual outcome, if any, are currently being investigated.

11β-HYDROXYLASE DEFICIENCY (HYPERTENSIVE CONGENITAL ADRENAL HYPERPLASIA)

A deficiency of 11β-hydroxylase (cytochrome P-450c11) results in impaired synthesis of cortisol and aldosterone, abnormal virilization from increased androgens formed from the cortisol precursors, and low-renin hypertension from increased formation of DOC, a moderately potent mineralocorticoid. It is the second most common form of CAH, accounting for about 5% of the cases.



Pregnancy at risk <9 weeks after last menstrual period
Begin dexamethasone 20 μg/kg daily in three divided doses based on prepregnancy weight
Chorionic villi sampling at 9–11 weeks
Sex determination based on karyotype, FISH or SRY
46,XY
46,XX
Stop dexamethasone
CYP21A2 genotype
Affected
Not affected
Continue dexamethasone until term
Stop dexamethasone

Figure 49–43. Simplified algorithm of treatment, diagnosis, and decision making for prenatal treatment of fetuses at risk for 21-hydroxylase deficiency congenital adrenal hyperplasia. *(From Nimkarn S, New MI: Prenatal diagnosis and treatment of congenital adrenal hyperplasia owing to 21-hydroxylase deficiency,* Nat Clin Pract Endocrinol Metab *3:405, 2007.)*

The clinical presentation of 11β-hydroxylase deficiency is varied, and not all the patients develop hypertension. Classically, females are born with virilization ranging from clitoral enlargement to extensive masculinization of the external genitalia, which may lead to incorrect gender assignment; male neonates may have a somewhat larger penis, but this is not routinely recognizable. There may be hyperpigmentation of the genitalia and the areolae. Sodium retention and volume-induced hypertension develop in 50% to 80% of the classic cases. Severe hypertension may occur as early as the first 4 days of life, but more often blood pressure is normal in neonates. The relative severities of the hypertension, virilization, and biochemical findings do not always correlate. Serum sodium levels tend to be in the upper-normal range or minimally elevated, but hypokalemia is inconsistently present.

In exception to the classic presentations, some affected and untreated neonates present with salt losing, which may lead to diagnostic confusion with 21-hydroxylase deficiency. The cause of their salt-losing conditions is unclear, but possibilities include a combination of physiologic renal immaturity of sodium reabsorption, more severe aldosterone deficiency and less adequate DOC, and the presence of precursor steroids with mineralocorticoid antagonist properties.

The characteristic biochemical abnormality that is observed is an increased level of serum 11-deoxycortisol (compound S), with concentrations usually more than 5 times the upper limit of the normal range. Serum DOC concentrations have also been elevated to more than 10 times the upper limit of normal. Serum 17-OHP, androstenedione, and urinary 17-ketosteroids are also increased and may cause diagnostic confusion with 21-hydroxylase deficiency.

11β-Hydroxylase deficiency should be considered in 46,XX neonates with masculinization of the external genitalia, in salt-losing neonates, in any patient beyond the neonatal period with abnormal virilization, and in hypertensive patients. The diagnosis is supported by the finding of increased levels of serum 11-deoxycortisol and DOC, demonstrating their suppressibility with cortisol replacement therapy, and ACTH stimulation testing showing elevation in 11-deoxycortisol.

11β-Hydroxylase deficiency is autosomal recessive. Two 11β-hydroxylase genes have been identified, which are located on the long arm of chromosome 8; they are linked and show greater than 90% sequence homology. The *CYP11B1* gene is responsible for 11β-hydroxylase deficiency, and the *CYP11B2* gene encodes for aldosterone synthase.[59] Prenatal diagnosis by genotyping of the *CYP11B1* gene by chorionic villus sampling is available.[52]

Treatment of the fetus suspected of having 11β-hydroxylase deficiency is the same as that for 21-OHD. Treatment consists of cortisol replacement therapy, as outlined for 21-hydroxylase deficiency. Glucocorticoid replacement reduces ACTH and precursor steroids toward normal levels, with cessation of virilization. Decreased DOC formation leads to the correction of hypertension in most affected patients. Glucocorticoid therapy is adjusted based on the patient's growth; blood pressure; and levels of serum 11-deoxycortisol, DOC, androstenedione, and plasma renin activity. The gender is usually assigned in agreement with the gonadal sex because normal sexual function and fertility can be attained.

3β-HYDROXYSTEROID DEHYDROGENASE DEFICIENCY

3βHSD type 2 is required for the formation of all three classes of steroids—the glucocorticoids, mineralocorticoids, and sex steroids. Severe deficiency can result in genital ambiguity for both sexes: males with severe penile or perineal hypospadias and females with minimum virilization at birth, with posterior labial fusion and clitoral hypertrophy but normal placement of the urethral meatus. Salt-losing adrenal crisis results from impaired cortisol and aldosterone biosynthesis in the adrenal gland, and the incomplete male genital differentiation results from decreased testosterone biosynthesis in the testes. Mild prenatal virilization in females is thought to result from increased precursor steroid formation; that is, the increased amounts of DHEA are probably converted by peripheral 3βHSD type 1 in the liver, skin, and other tissues. 3βHSD type 2 is required for the formation of biochemically active androgens that induce mild masculinization of the genitalia in the female.

The characteristic biochemical finding in the untreated patient is a marked elevation of ACTH-stimulated 17-hydroxypregnenolone and ratios of 17-hydroxypregnenolone to cortisol.[56] Aldosterone levels are low, and plasma renin activity is increased. A diagnosis can be made on baseline or ACTH-stimulated steroid levels, or both.

Clinical heterogeneity is seen in 3βHSD deficiency, as in the 21- and 11β-hydroxylase deficiency disorders. Multiple gene defects in the *HSD3B2* gene have been described.[69] Sodium wasting varies by degree, ranging from severe to mild to none. The severity of the defect also varies, with some patients having no genital ambiguity at birth but presenting with adrenal insufficiency and some having delayed virilization.

Treatment is the same as that for 21-hydroxylase deficiency; serum levels of 17-hydroxypregnenolone and DHEA serve as guides for the adequacy of glucocorticoid replacement. Mineralocorticoid therapy is monitored by means of measurements of plasma renin activity. There is autosomal recessive inheritance.

CONGENITAL LIPOID ADRENAL HYPERPLASIA

The first step in steroid hormone biosynthesis is the transport of cholesterol into the mitochondria mediated by the steroidogenic acute regulatory (*StAR*) protein. Mutations in this gene cause an autosomal recessive condition known as congenital lipoid adrenal hyperplasia.[46]

It is a rare but serious disorder; many patients have died within the first few months of life. The clinical course for most cases has been the development of severe adrenal insufficiency, sometimes occurring in the first days of life but in milder cases beginning beyond several weeks of age. Sodium wasting has often been extreme, and hypoglycemia may occur. Affected 46,XX females have normal female genitalia; XY males have female or ambiguous external genitalia, often with a blind vaginal pouch, and the testes may be descended. Hyperpigmentation and respiratory problems may occur.

The adrenal glands are enlarged, with a characteristically enormous accumulation of lipid, thus the name *congenital lipoid adrenal hyperplasia*. The testes and Leydig cells show analogous pathology in some but not all males. There may be wolffian duct development, presumably resulting from the partial testicular production of testosterone. Biochemically, there is decreased to absent production of all adrenal and gonadal steroids, depending on the severity of the defect, and an accumulation of cholesterol and its esters in the adrenals and gonads. Prenatal diagnosis by molecular genetic testing for mutations in the *StAR* gene are now available.[29]

The second step in steroid hormone biosynthesis is the conversion of cholesterol to pregnenolone by the cholesterol side-chain cleavage enzyme (P-450scc). A deficiency in this enzyme (SCC deficiency) results in impaired synthesis of all adrenal and gonadal steroids. P-450scc activity is needed to produce placental progesterone, a hormone that is needed to maintain a pregnancy. For this reason, it was thought that SCC deficiency would lead to spontaneous abortion. There are some rare reports of SCC deficiency with variability in timing of presentation of adrenal failure and not all were found to have adrenal hyperplasia.[30]

SCC deficiency should be considered in cases of adrenal insufficiency and hyperpigmentation and in cases of XY males with ambiguous genitalia. The diagnosis is based on the demonstration of a deficiency of the glucocorticoids, mineralocorticoids, and androgens. Treatment includes cortisol, mineralocorticoid, and salt replacement therapy, as outlined for 21-hydroxylase deficiency. This therapy should be administered aggressively in infancy to reduce the high mortality risk.

17α-HYDROXYLASE DEFICIENCY

17α-hydroxylase/17,20-lyase (P-450c17) deficiency is manifested clinically as hypertension and hypogonadism. Biochemically, it results in impaired conversion of pregnenolone and progesterone to their 17α-hydroxy product. The consequence is reduced cortisol, androgen, and estrogen production. Increased ACTH stimulation produces increased progesterone and its products DOC, corticosterone, and 18-hydroxycorticosterone. The increased mineralocorticoids produce low-renin hypertension (frequently severe and often associated with hyperkalemic alkalosis and borderline hypernatremia), which often develops in infancy. Adrenal insufficiency usually does not develop because of the mineralocorticoid and glucocorticoid properties of DOC and corticosterone. Affected XX females have normal genitalia at birth but fail to undergo secondary sexual development at puberty. The 46,XY males have phenotypically female to variably masculinized external genitalia, often with a distal vagina, variable testicular descent, and the frequent occurrence of inguinal hernia, which may lead to their identification. The internal genital ducts are appropriate for the gonadal sex, except that wolffian duct development may be incomplete. The differential diagnosis for XY individuals includes AIS and other causes of 46,XY DSD.

Cortisol replacement therapy corrects these abnormalities and hypertension; in most, aldosterone secretion returns to a normal level, although in several cases, it has remained abnormally low. Serum levels of testosterone are low and show a poor rise after hCG stimulation. Several different mutations of *CYP17* have been found, with the consequent enzyme deficiencies varying from partial to complete.

Cortisol replacement is given as described for 21-hydroxylase deficiency, but mineralocorticoid therapy is not necessary unless aldosterone secretion fails to return to a normal level.

P-450 OXIDOREDUCTASE DEFICIENCY

The P-450 oxidoreductase deficiency (POR) enzyme acts as a cofactor for P-450 microsomal enzymes including 17-hydroxylase/17,20-lyase, P-450c21 (21-hydroxylase), and P-450aro (aromatase), which are involved in steroid biosynthesis.[67] Because of the complexity of function of the enzyme, deficiency manifests as a wide spectrum of biochemical and clinical features.

Biochemical abnormalities can include elevated 17-OHP and low androgen levels; cortisol may be normal but is poorly responsive to adrenocorticotropic hormone. These indicate partial deficiencies in 21-hydroxylase, 17-hydroxylase, and 17,20-lyase (Fig. 49-44).

Clinical features are a result of abnormalities in steroid hormones, skeletal development, and drug metabolism. Abnormal genital development can be seen in both sexes; males can be undervirilized, and females can be virilized. In

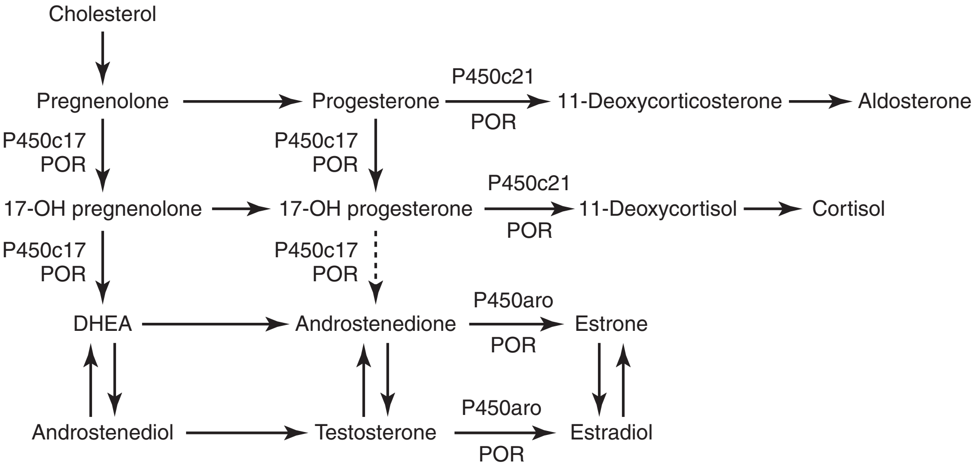


Figure 49–44. Simplified steroid biosynthetic pathway indicating the steps where POR acts as a cofactor. (*From Scott RR, Miller WL: Genetic and clinical features of P450 oxidoreductase deficiency,* Horm Res *69:266, 2008.)*

pregnancy, maternal virilization and low maternal estriol and estrone levels may be seen.

Most have associated skeletal malformations, termed *Antley-Bixler syndrome* (ABS). ABS is a syndrome that includes craniosynostosis, midface hypoplasia, choanal atresia or stenosis, radiohumeral or radioulnar synostosis, femoral bowing, and joint contractures and has been found to be caused by POR deficiency.[31] Both autosomal recessive inheritance and an autosomal dominant mutation in fibroblast growth factor receptor-2 (*FGFR2*) gene have been proposed as a cause of ABS.

Since 2004, when the POR mutation was first described, 50 cases have been reported. A number of different mutations have been described, all of which cause apparent partial deficiency of 21-hydroxylase and 17α-hydroxylase/17,20-lyase. Functional assays assessing POR function have been able to link genotype with phenotype.[67] The diagnosis of POR can be made by mutation analysis.

Initial management should include an ACTH stimulation test for cortisol production, with hydrocortisone replacement given if cortisol production is found to be insufficient. Aldosterone deficiency causing salt-wasting is possible because 17-hydroxolase activity is influenced by POR. In infants, the risk for upper airway obstruction caused by skeletal abnormalities, including choanal obstruction, should be assessed. Because some hepatic P-450 enzymes are dependent on POR, effects on drug metabolism due to POR deficiency are possible. Insufficient information is currently available to describe the clinical implications.

Placental Aromatase (CYP19) Deficiency

Placental-fetal aromatase (*CYP19*) is a cytochrome P-450 enzyme that is necessary for the conversion of androgens to estrogen. Placental aromatase deficiency can cause maternal and fetal virilization because of an inability to convert fetal adrenal androgens.[36] There is wide phenotypic variation observed due to mutations in *CYP19*.

Maternally Derived Androgenic Substances

Masculinization of the female fetus occasionally occurs from exposure to androgens or certain other agents derived from the maternal circulation. The extent of masculinization is related to the compound, dosage, duration, and timing of exposure. Exposure at 8 to 14 weeks of gestation may result in midline fusion of the labioscrotal folds; opening of the vagina and urethra into a common urogenital sinus; and (in more severe cases) development of a penile urethra, prostate, and possibly seminal vesicles. Exposure beginning after 12 to 14 weeks results in only clitoromegaly and hypertrophy of the labia majora but no midline fusion and no development of a urogenital sinus. Maternally derived androgens do not usually stimulate wolffian duct development, and the müllerian duct structures and bilateral ovaries develop normally in the absence of AMH. A considerable number of female fetuses do not undergo masculinization because the placenta aromatizes most maternal androgens before they cross over to the fetus, and the high maternal levels of globulin binding to sex steroids favor the concentration of these androgens on the maternal side.

Maternal androgens may be of ovarian, adrenal, or exogenous origin. The Krukenberg tumor and luteoma of pregnancy cause increased androgen production. Maternal androgen-secreting tumors of the ovary rarely occur in pregnancy. Several cases of maternal adrenocortical tumor are reported; maternal virilization in some has been mild compared with that in neonates or that not recognized until years later. Other cases of 46,XX DSD have been reported in association with maternal CAH and maternal polycystic ovarian disease. The measurement of the maternal serum levels of testosterone and DHEA or its sulfate is diagnostically useful even in the absence of maternal virilization. The maternal ingestion of synthetic progestins and androgens may cause abnormal masculinization of the female fetus. In the male fetus, progestin exposure at 8 to 14 weeks of gestation may result in hypospadias. Because these medications have often been given for only part of the pregnancy, the extents of clitoral enlargement, urethral displacement, and labioscrotal fusion are often discordant, contrasting with the other causes of 46,XX DSD. The mother may rarely show mild androgenization. Advanced skeletal maturation may occur in offspring exposed to the more androgenic substances.

The masculinization of females that occurs with androgen or other drug exposure in utero does not progress postnatally. Biochemical studies of the neonate show normal levels of androgens or their metabolites and of 17-OHP. The surgical correction of midline labioscrotal fusion or major clitoromegaly is usually performed by 12 to 18 months of age; mild clitoromegaly may not need to be corrected because the clitoris will become less prominent as the body size increases.

OTHER

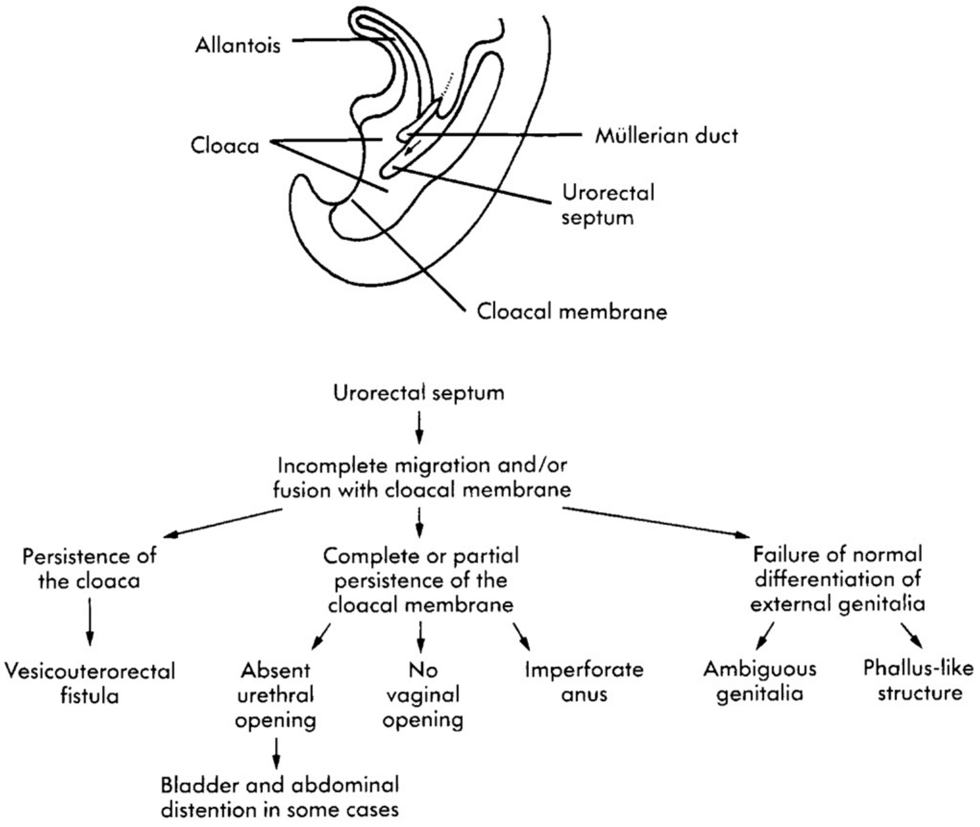
Dysgenesis of External Genital Primordia

On rare occasions, the external genitalia of a 46,XX fetus may have a masculinized appearance because of an error in morphogenesis occurring at 4 to 7 weeks of fetal age rather than abnormal androgen exposure at 8 to 12 weeks. The formation of the urorectal septum and differentiation of the cloacal membrane into the urogenital and anal membranes, followed by their breakdown into the urogenital sinus and anus, are critical for the development of the indifferent external genitalia (at 7 weeks) and the lower genital, urinary, and intestinal tracts. In cloacal dysgenesis (Fig. 49-45), a small phallus-like structure develops from the genital tubercle (there is variable formation of a phallic urethra and corpora tissue), and the labioscrotal swellings may or may not develop; the absence of a urogenital groove makes for a more male-appearing perineum. Associated abnormalities include an imperforate anus, the absence of urethral and vaginal outlets (unless a phallic urethra forms), and urinary tract and müllerian (uterine and vaginal) anomalies (these anomalies are not found in any of the traditional forms of 46,XX DSD). The ovaries are usually normal. These abnormalities may be seen in the VATER association (*v*ertebral abnormalities, *a*nal atresia, *t*racheoesophageal fistula with *e*sophageal atresia, *r*adial and renal dysplasia). Pulmonary hypoplasia is often an associated condition, and obstructive uropathy may infrequently be associated with Eagle-Barrett (prune-belly) syndrome. Less severe clinical forms are reported associated with a small phallus, partial vaginal outlet obstruction, and other urinary and genital tract anomalies.

Müllerian and Vaginal Dysgenesis

There is a frequent association of abnormal to absent müllerian duct structures with vaginal agenesis in 46,XX females with normal ovaries known as Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome. MRKH syndrome is further classified as type 1 (isolated) or Rokitansky sequence and type II or MURCS association (müllerian duct aplasia, renal dysplasia, and cervical somite anomalies). It is sometimes also referred to as CAUV (congenital absence of the uterus and vagina), MA (müllerian aplasia), or GRES (genital renal ear syndrome).[48] A disturbance in mesodermal organization partially involving the formation of the caudal segments of the müllerian ducts in the fourth and fifth weeks of embryogenesis is suggested; the possibilities of both teratogenic and pleiotropic genetic causes have been raised. The differential diagnosis includes cAIS. Some patients have an abnormal karyotype. An examination to determine the presence or absence of a vaginal orifice (absent in this disorder), the occasional occurrence of hydrometra, and the presence of somatic abnormalities help to identify affected neonates. Vaginal construction is necessary; the extent of the uterine malformation needs to be assessed. About 70% of female patients with unilateral renal agenesis have ipsilateral müllerian duct abnormalities.

It has been proposed that MRKH syndrome is caused by a developmental field defect. The *WNT4* gene is important in



Allantois
Cloaca
Müllerian duct
Urorectal septum
Cloacal membrane
Urorectal septum
Incomplete migration and/or fusion with cloacal membrane
Persistence of the cloaca
Complete or partial persistence of the cloacal membrane
Failure of normal differentiation of external genitalia
Vesicouterorectal fistula
Absent urethral opening
No vaginal opening
Imperforate anus
Ambiguous genitalia
Phallus-like structure
Bladder and abdominal distention in some cases

Figure 49–45. Diagram showing proposed mechanism for urorectal septum malformation sequence. The resulting cloacal dysgenesis leads to malformation of the external genital primordia and other accompanying abnormalities. In the affected 46,XX fetus, the genital tubercle (between the cloaca and allantois) forms a small phallus-like structure. This development, coupled with the failure to form a urogenital groove, produces ambiguous or male-appearing external genitalia. (*From Escobar LF , et al: Urorectal septum malformation sequence: report of six cases and embryological analysis,* Am J Dis Child *141:1021, 1987.)*

the development and maintenance of müllerian duct formation and ovarian steroidogenesis. For this reason, WNT4 deficiency had been proposed as a cause of MRKH syndrome. However, it is now known to be responsible for a clinically distinct phenotype. Currently, no single gene mutation has been implicated as an explanation for the MRKH syndrome.

Common Presenting Problems

HYPOSPADIAS

Hypospadias is a condition of failed male urethral differentiation in which the urethral meatus lies somewhere proximal to the tip of the glans penis. It occurs between 9 and 14 weeks of gestation. In mild cases, the meatus opens on the ventral surface of the glans, corona, or upper penile shaft, and in severe cases, on the lower shaft, penoscrotal junction, or perineum. Hypospadias is the second most common genital abnormality (after cryptorchidism) in male newborns, with an incidence in different series ranging between 0.3% and 0.8%. About 87% of the cases are glandular or coronal, 10% penile, and 3% penoscrotal or perineal.

Other anomalies that may accompany hypospadias include meatal stenosis, hydrocele, cryptorchidism (8% to 10% of cases), and inguinal hernia (8% of cases). More severe forms of hypospadias are often associated with a shawl scrotum or incompletely translocated labioscrotal folds and with a prostatic utricle. Patients with severe hypospadias, urinary tract symptoms, a family history of ureteral reflux, or multiple congenital anomalies are also more likely to have significant abnormalities and should have a uroradiographic evaluation.

Eight percent of patients with hypospadias have a similarly affected brother or father; this figure reaches 16.7% for individuals with penoscrotal or perineal hypospadias. This familial tendency is thought to result from a polygenic mode of inheritance. *CXorf*, a gene on the X chromosome, has been identified as a causative gene for hypospadias.[21] Additional studies investigating other candidate genes involved in male genital development are underway. Mild hypospadias (glandular to penile) without other genital abnormalities or dysmorphic features is very unlikely to be associated with an identifiable endocrinopathy, intersex, or chromosomal abnormality. Severe hypospadias (penoscrotal or perineal) (see Fig. 49-39) is associated with about a 15% risk for such problems occurring. The addition of other genital abnormalities (cryptorchidism or abnormally small penis) (see Fig. 49-42) increases the risk for the occurrence of a DSD or endocrinopathy to 35% in mild and 79% in severe hypospadias.

The differential diagnosis of hypospadias includes female neonates with CAH, other DSDs, various syndromes (e.g., Smith-Lemli-Opitz, Beckwith-Wiedemann), and unknown causes. Rare causes of hypospadias include a deficiency in testosterone production due to the decreased conversion of testosterone to DHT (5α-reductase deficiency), decreased function of the androgen receptor protein (pAIS), and maternal exposure to progestins; they occur between 8 and 14 weeks of gestation. In a study of 48 patients with hypospadias, no androgen production defects could be identified.[24]

The evaluation of hypospadias in the newborn includes a history of possible maternal progestin or estrogen exposure; family history of hypospadias, endocrine disorders, or DSDs; examination to evaluate hypospadias (phallus length, urethral meatus location, chordee, scrotal folds); determination of the presence of gonads and a uterus; determination of an anatomic abnormality of the kidneys; and identification of somatic abnormalities. The major concern in the evaluation of hypospadias is to rule out CAH in a virilized female; if both gonads are impalpable, this possibility must be seriously considered (see Fig. 49-42). If hypospadias is mild and not associated with other abnormalities, diagnostic studies are usually not needed. The surgical repair of hypospadias is performed ideally after 6 months of age by an experienced surgeon. Multistage procedures may be required for severe forms of hypospadias.

MICROPENIS

For a description of how to examine and interpret penis size please see earlier section, “Penis Size” under “Physical Examination.” A micropenis is caused by a deficiency in the factors (testosterone or DHT and possibly growth hormone [GH]) needed for normal penile growth to occur after 14 weeks of gestation, when formation of the urethra is complete. The major causes include hypopituitarism (LH deficiency with or without GH deficiency, 30%), primary hypogonadism (25%), pAIS (2%), and idiopathic or undiagnosed causes (43%). The association of a micropenis with early neonatal hypoglycemia (GH and ACTH-cortisol deficiencies), cryptorchidism (LH deficiency) (see Fig. 49-30), persistent neonatal jaundice (hypothyroidism, ACTH-cortisol deficiency), or cleft palate should immediately raise the possibility of congenital hypopituitarism. Other congenital malformations (e.g., septo-optic dysplasia) and chromosome abnormalities are occasionally associated. The complete absence of the penis may rarely occur. The diagnostic evaluation of a micropenis includes the assessment of GH, testosterone, LH, and FSH status and consideration of testing for hypopituitarism. An hCG stimulation test may be performed if testosterone levels are low to assess biosynthetic defects. The karyotype may need to be determined. A course of testosterone therapy to assess penile responsiveness may be administered to exclude significant androgen insensitivity. Testosterone therapy should be planned to normalize penis size and consequently promote a positive body image in childhood.

CRYPTORCHIDISM

Cryptorchidism, or testicular maldescent, is present when one or both testes have failed to descend completely into the scrotum (to a position 4 cm or more below the pubic crest in full-term males weighing more than 2.5 kg). Because the testes normally descend after 7 months of fetal age through the first several months of postnatal age, most affected newborns are found to be normal when they are reevaluated. The incidence of cryptorchidism at birth is about 3.7% in full-term males and 21% in premature males, approaching 100% in the very premature. However, the postnatal completion of testicular descent is seen in 50% of the full-term cryptorchid males by 6 weeks of age and in 67% of the full-term and 73% of the premature cryptorchid males by 3 months of age. A few additional individuals attain full descent by 6 to 9 months of age. The net result is that about 75% of full-term and 90% of premature cryptorchid newborns have full testicular descent by the age of 9 months without therapeutic intervention. Spontaneous testicular descent is very rare after 9 months of age. The incidence of cryptorchidism is about 1% at 1 year of age. In addition to prematurity and low birthweight, other factors associated with an increased incidence of cryptorchidism are birth by cesarean delivery and maternal obesity.

The mechanism of testicular descent is a complex process involving hormonal, mechanical, and genetic factors.[72] Factors thought to affect descent include the gubernaculum, attachment of the epididymis to the testis, rising abdominal pressure, AMH, testosterone or DHT, the genitofemoral nerve, and possibly LH and FSH. Cryptorchidism frequently occurs with disorders of the hypothalamic-pituitary-testicular hormone axis, with dysgenetic testes, and with anatomic defects of the epididymis and the abdominal wall. Cryptorchidism is seen with a higher incidence in patients with umbilical hernia (6%), gastroschisis (15%), omphalocele (33%), and Eagle-Barrett (prune-belly) syndrome (100%), in which intra-abdominal pressure may be important. It is also seen in individuals with meningomyelocele (25%), particularly when the defect is above L2, and in those with cerebral palsy (41%). True cryptorchidism is associated with lower LH and testosterone levels during the pituitary-testicular hormonal surge at ages 1 to 3 months and occurs frequently in cases of hypopituitarism or hypogonadotropism, Prader-Willi syndrome, primary hypogonadism, and androgen insensitivity. A role for AMH is suggested by the association with persistence of the müllerian ducts. An association is also seen with trisomies 13 and 18 and with Aarskog, Noonan, Robinow, Smith-Lemli-Opitz, and other syndromes. Familial cases are reported, and cryptorchidism is found in 6.2% of the brothers and 1.5% to 4% of the fathers of affected patients.

Associated anomalies include an inguinal hernia in many patients, abnormal epididymal formation in 36% to 66%, and hypospadias in about 3%. There are major upper urinary tract anomalies in about 3% of patients, but routine invasive diagnostic studies are not warranted. Some complications of cryptorchidism include (1) progressive histologic deterioration, with changes beginning after 6 months of age; (2) impaired spermatogenesis, with a decrease in the number of germ cells after the first year of life (and later reduced fertility potential); (3) an increased (4-fold to 10-fold) risk for cancer in the undescended testis and also in the contralateral testis in unilateral cryptorchidism; (4) trauma to the testis that is relatively fixed in position; (5) torsion; (6) symptomatic inguinal hernia; and (7) psychological factors related to altered body image. An associated inguinal hernia may require repair in early infancy if it is large enough to permit the abdominal contents to enter or if it causes symptoms.

If both testes are impalpable, the differential diagnosis includes an XX female with CAH or other severe virilizing disorder; anorchia, which occurs in 1% of bilaterally cryptorchid patients; and intra-abdominal testes, which are either normal (as in persistent müllerian duct syndrome) or dysgenetic (as in mixed gonadal dysgenesis or testicular dysgenesis). The evaluation of the infant with impalpable testes includes the determination of CAH and sex chromosomes. Hormone studies, both basal hormones (LH, FSH, and testosterone between 2 weeks and 3 months of age) and the testosterone response to hCG, may provide information about the presence of functioning Leydig cells. The measurement of AMH, ultrasound, magnetic resonance imaging, and laparoscopy have been useful in locating intra-abdominal testes, but laparotomy with exploration to the ends of the spermatic blood vessels is definitive in cases that are not otherwise resolved. The presence of wolffian structures suggests that torsion, vascular accident, or other late in utero degeneration has occurred. Alternatively, a dysgenetic testis may be present. Parental counseling should be undertaken in anticipation of this likelihood.

Because of the early appearance of histologic changes in the cryptorchid testis and initial findings that early treatment improves the histologic outcome, the correction of cryptorchidism is recommended between 6 and 12 months of age, or as soon as possible after diagnosis, if that occurs later.[61] Because spontaneous descent may occur up to 6 to 9 months of age, treatment before that time is not indicated unless the testis is ectopic or has other associated abnormalities. Orchiopexy is optimally performed by an experienced surgeon because the risk for subsequent loss of the testis is high. Hormonal treatment with gonadotropin-releasing hormone is no longer recommended because of its poor efficacy and potentially serious side effects.[69]

CLITOROMEGALY

For a description of how to examine clitoral size, see the earlier section, "Clitoris Size" under "Physical Examination." *Clitoromegaly* is defined as the appearance of clitoral enlargement regardless of cause. The clitoris may be prominent (protruding from between the labia majora), swollen, widened, or elongated. The causes are listed in Box 49-13. The clitoris must be measured to determine whether the paired corpora cavernosa are abnormally enlarged and to rule out the extremely rare finding of a tumor. More commonly, the corpora cavernosa are of normal size and have no evidence of a tumor, making clitoromegaly a benign finding. No further diagnostic evaluation is necessary, and the parents should be reassured that their newborn girl is normal. If the corpora cavernosa are enlarged, a DSD is more likely, and an evaluation should be performed. The assessment should include other signs of androgenization or incomplete masculinization (posterior labial fusion, ventral placement of the urethra,

BOX 49–13 Causes of Clitoromegaly in the Neonate

CORPORA CAVERNOSA OF NORMAL SIZE

- Normal variation such as prominent clitoral hood or infant who is small for gestational age
- Swelling, edema, or both due to bruising (e.g., breech presentation)

CORPORA CAVERNOSA ENLARGED DUE TO ANDROGEN STIMULATION

- 46,XX DSD, particularly 21-hydroxylase deficiency
- 46,XY DSD
- Gonadal dysgenesis, dysgenetic testes
- Ovotesticular DSD
- Tumor infiltration of clitoris (neurofibromatosis, lymphoma)

DSD, disorder of sex development.

or hypospadias); determination of whether the gonads are palpable; determination of the presence or absence of a uterus; and measurement of androgens and 17-OH progesterone levels. A karyotype may also be warranted.

CHAPTER 50

Inborn Errors of Metabolism

Arthur B. Zinn

This chapter is a guide for the practicing physician in recognizing and caring for the neonate who might have an inherited metabolic disease. The chapter presents a practical approach to recognizing representative entities belonging to the biochemical groups of metabolic disorders expressed in the neonatal period. Key clinical and laboratory findings that are components of these diseases are discussed (see also references 11, 18, and 45). A metabolic approach to the dysmorphic child also is presented because a small percentage of dysmorphic children have inborn errors of metabolism.

The main problems facing the physician caring for the sick newborn infant are to know when to consider the possibility of a metabolic disorder and what to do to determine quickly and efficiently whether a child has a metabolic disease. After a tentative diagnosis is reached, several reference sources can provide appropriate information about specific diseases.[22,23,84]

Two ongoing, complementary approaches to providing medical care for neonates with inborn errors of metabolism are (1) prospective care of the healthy newborn infant and (2) reactive care of the clinically abnormal newborn infant. Prospective care seeks to identify neonates who have a specific metabolic disorder before clinical manifestations of that disorder develop. The aim of the prospective approach is to prevent the morbidity or mortality that often occurs in the period before recognition, diagnosis, and initiation of therapy for what might be a preventable or treatable disease. The reactive approach aims to arrest or minimize the sequelae of the disease state after the affected child becomes ill or is recognizably abnormal.

This chapter outlines several common misconceptions about inborn errors of metabolism, addresses prospective recognition of inborn errors, including newborn screening programs, and discusses reactive recognition and care of the abnormal newborn infant. In 1983 the US Orphan Drug Act was passed and has generated new therapies for inborn errors of metabolism.[92a]

COMMON MISCONCEPTIONS

Metabolic diseases of infancy are a difficult subject for many physicians and others caring for newborns. Several misconceptions contribute to this difficulty. Eight of these misconceptions are stated below. These misconceptions are expressed in an exaggerated, tongue-in-cheek way to emphasize that, on reflection, most physicians would not acknowledge that these ideas are true. Nevertheless, experience suggests that in the intense atmosphere generated in response to the sick neonate, these misconceptions often influence the care of the child with an inborn error of metabolism.

Misconception 1

Inherited metabolic diseases are rarely a cause of disease in the neonate and should therefore be considered diagnostically as a last resort.

Although individual metabolic diseases are relatively rare, inherited metabolic diseases collectively represent a more common cause of disease in the neonatal period. The estimated incidence in the general population of inherited metabolic diseases varies by more than an order of magnitude, ranging from 1 case per 10,000 live births for phenylketonuria (PKU) to 1 case per 200,000 for homocystinuria. About 100 inherited metabolic disorders are identifiable in the neonatal period.

Assuming that most of these disorders have an incidence closer to the lowest incidence rather than the highest, the overall incidence of metabolic disease is about 1 case per 2000 persons. Newborn screening programs have found an incidence of approximately 1 in 4000 for a subset of these diseases. There is good reason to believe that this estimate of the incidence of metabolic disease in neonates is an underestimate, because many metabolic diseases are underdiagnosed and many diseases are yet to be identified.

Misconception 2

The possibility of a genetic metabolic disease should be considered only when there is a family history of the disease.

Most neonates with an inborn error of metabolism do not have a similarly affected sibling or relative.

The reasons for this pattern follow from the rules of mendelian inheritance. Most inborn errors of metabolism are inherited as autosomal recessive traits, for which the odds are 3:1 in each pregnancy that two heterozygous parents will have an unaffected child. Small family sizes in developed countries make it unlikely to see two affected offspring in a sibship. In a family of two siblings, the odds are about 6% that both siblings will have the disease. In a family of three children, the odds are about 14% that two of the three siblings will be affected and about 2% that all three siblings will be affected.

There often is no forewarning of the birth of a sick boy with an X-linked disorder because he may have one or more healthy older sisters; heterozygous females do not express most X-linked disorders. Many X-linked disorders are the result of new mutations, and the birth of a sick newborn would not be anticipated. Similarly, because many autosomal dominant disorders are also the result of new mutations, a positive family history would not be expected.

Misconception 3

It is difficult to know when to suspect that a sick newborn infant may have a metabolic disorder because presentation of such disorders often mimics that of sepsis in the newborn infant.

Three responses to this point may be made. First, the clinical manifestations of many metabolic diseases are similar to the presentation of many neonatal infections, but this does not mean that the physician should not investigate the possibility of a metabolic disorder. The “sepsis workup” is a broadly focused approach to identifying a putative infection. The metabolic evaluation should be considered for most infants as part of the evaluation for suspected sepsis. Second, a neonate with a metabolic disease may be at greater risk of sepsis than other newborn infants, and the presence of documented sepsis does not exclude the possibility of an underlying metabolic disorder. Galactosemia is a well-documented example of a metabolic disease that predisposes an infant to serious infection. Third, many metabolic diseases do not have sepsis-like features.

Misconception 4

Many metabolic diseases are detectable in the neonatal period, and it is difficult to remember the presentation of each one.

Many metabolic diseases occur in the neonatal period, and it is impossible to remember the pattern of presentation of each; however, the great redundancy in clinical presentations simplifies evaluation. Relatively few algorithms are required to evaluate diseases that have overlapping phenotypes. Algorithms that have clear and multiple branch points are available to facilitate the clinical and laboratory evaluation of patients in whom a metabolic disease is suspected.

Misconception 5

The biochemical pathways and nomenclature of inborn errors of metabolism are impossible to remember.

The biochemical pathways and nomenclature of inborn errors of metabolism are often overwhelming for the expert in metabolic disorders as well as for the practitioner, but detailed knowledge of the pathways and nomenclature is not the important part of the metabolic evaluation. The important aspect of the metabolic evaluation is the development of general approaches to different clinical or laboratory findings that can rapidly reveal whether a metabolic problem exists and, if so, help direct the patient’s care.

Misconception 6

It is difficult to diagnose a metabolic disease.

The examination of patients with suspected metabolic disease must be staged, progressing from broad screening tests, which should be available in all settings where care is given to sick neonates, to highly specialized tests, which may be available in only a handful of centers. The idea of a staged evaluation is perhaps best illustrated by the congenital hyperammonemias. The ability to diagnose hyperammonemia should be available in most settings, but the subsequent delineation of a specific cause of hyperammonemia and care of the patient are probably best reserved to a few specialized centers. The job of the physician faced with a sick newborn infant is to think of the possibility of hyperammonemia and to measure the blood ammonia level before the patient is irreversibly damaged by the effects of a disease.

Misconception 7

Metabolic test results take forever to return.

There is often a sense of frustration on the part of physicians, especially house officers, who believe that they order many metabolic studies but rarely learn the results of these studies or find an answer. Some metabolic tests do take a long time to perform. It is important to stage the evaluation. It is generally best to begin with relatively broad-based screening tests that come back quickly and can then be followed by more specific diagnostic studies that usually take longer to perform. The aim is to use the screening studies to obtain preliminary indications on which to base further evaluation and care.

Misconception 8

Relatively few metabolic diseases can be treated, so why spend a great deal of effort looking for something that you cannot fix?

A number of metabolic disorders can be treated, often successfully. The approach to the differential diagnosis should give greater consideration to detecting potentially treatable entities. The initial screening studies should permit identification of classes of disease for which there are therapies. For example, the congenital hyperammonemias are a group of disorders for which generic therapy is available; therapy can be modified after a more specific diagnosis is made. It is also important to establish a diagnosis for the sake of the parents, who almost always seek to understand why they have a sick baby, and for the purpose of formal genetic counseling.

PROSPECTIVE APPROACHES

There are two types of prospective care. The first type is the screening of a high-risk segment of the population—the siblings or other at-risk relatives of patients known to have a particular metabolic disorder. The second type is screening of the entire population or specific subset of newborn infants. The former is of much more limited scope than the latter, but both require the attention of a pediatrician or neonatologist.

The Newborn Infant at High Risk for a Particular Metabolic Disorder

Neonates at high risk for metabolic disorders are the siblings or other at-risk relatives of patients with a known metabolic disorder. These infants include those at risk for diseases for which there is no prenatal diagnosis and those who are at risk for diseases for which prenatal diagnosis is available but whose parents did not wish to have such testing performed. Also included are patients for whom prenatal testing was performed and who require postnatal confirmation of the prenatal test result. Postnatal confirmation is required for a positive or a negative prenatal test result. Postnatal confirmation is especially important for avoiding the unlikely situation of a false-negative prenatal test result that could lead to failure to treat an affected patient.

Management of pregnancies and neonates at high risk requires a coordinated effort among the obstetrician, the geneticist, the metabolic expert (if different from the geneticist), and the pediatrician. The first decision is to determine where the at-risk baby will be delivered. If the baby will not be delivered at a center where a metabolic expert is available, the indications for transfer after birth must be developed before birth. Regardless of where the baby is delivered, a detailed plan must be prepared and made available to all personnel caring for the newborn. The plan should include specific details of what tests will be needed to identify the disease, how the tests will be performed, where the samples for testing are to be sent after they are obtained, and who will follow up on the test results and inform the family.

Newborn Screening Programs

Newborn screening is an important issue for all physicians caring for neonates because it combines a number of significant medical and legal issues. These issues will become progressively more complex and diverse as an increasing number of inborn errors of metabolism become amenable to newborn screening and as the role of physicians in the administration and follow-up of such testing becomes greater.[1,49,52,81,101]

Although there is ongoing discussion and some debate about which medical conditions should be screened and how they are to be screened, there is a consensus about the goals of mass newborn screening. The medical requirements of an acceptable mass screening program for a particular disease include the following:

- The availability of a reliable screening test with a low false-negative rate
- A test that is simple and inexpensive, because many tests will be performed for each case identified
- A rapid screening test that can provide results quickly enough to permit effective intervention
- A definitive follow-up test that is available for unambiguous identification of true-positive results and elimination of false-positive results
- A disorder of a sufficiently deleterious nature that, if untreated, would result in significant morbidity or death
- An effective therapy that significantly alters the natural history of the disease

Relatively few metabolic disorders satisfy all these requirements. These criteria have probably been demonstrated, in a strict sense, only for biotinidase deficiency and PKU. On the other hand, neonates with classic galactosemia or maple syrup urine disease (MSUD), for example, often become very sick within the first few days of life before the results of newborn screening tests are available, thereby compromising the benefit of the screening program. Ascertainment and diagnosis of these disorders depend on specific biochemical testing of a sick infant (see “Specialized Biochemical Testing”).

PRINCIPLES OF SCREENING PROGRAMS

A few principles apply to all screening programs. First, all screening tests are subject to false-positive results because of normal biologic variation, genetic heterogeneity, and human error. Accordingly, all positive screening results must be confirmed by definitive analysis. It is important that all patients who require therapy receive it and, conversely, that patients who do not require therapy not be treated.

Second, all positive results must be considered medical emergencies. Many positive results turn out to be falsely positive, but the concept underlying newborn screening is that identification of the few affected patients is crucial. In addition to the potential tragedy of misdiagnosis of the individual neonate, lack of attention that permits delayed care of a single affected patient can seriously jeopardize the public’s confidence in and the cost-benefit structure of an entire statewide screening program and can compromise the continuation of such programs.

Third, the disorders that are part of newborn screening programs are the result of autosomal recessive traits, which exhibit variable clinical expression even within families. Thus the siblings of a patient identified by a screening program should be biochemically evaluated for the same disorder because they could be affected although they appear free of symptoms.

Fourth, all patients should be referred to an experienced specialist for definitive diagnosis because these disorders are characterized by clinical and genetic heterogeneity, which can significantly affect care of the patient and genetic counseling for the family.

There is considerable variation in the screening programs of different states in the United States and in various nations.

All states and U.S. territories screen for PKU. Until relatively recently, most states performed newborn screening for three to six metabolic disorders (including PKU, homocystinuria, MSUD, and galactosemia), one endocrine disorder (congenital hypothyroidism), and the hemoglobinopathies. The requirements and procedures for the screening programs for congenital hypothyroidism and the hemoglobinopathies are discussed in Part 3 of Chapter 49 and in Chapter 46, respectively.

Since the 1990s, intensive efforts have been made to expand the scope of newborn screening.[49,52,69,101] These efforts started from the premise that the available newborn screening tests were relatively inefficient and not easily generalized to detect new diseases either within the current categories of disease or in new categories of metabolic disease. Testing programs employed separate tests for each disease of interest.

SCREENING TECHNIQUES

Most state screening programs had focused primarily on the classic disorders of amino acid metabolism, which can be evaluated by bacterial inhibition assays. These assays cannot be easily adapted to screen for the more recently described disorders of organic acid metabolism and fatty acid oxidation. Similarly, the standard methods being used to diagnose the organic acidemias and fatty acid oxidation defects—gas chromatography, or combined gas chromatography and mass spectrometry (GC/MS)—could not be upgraded to large-scale newborn screening programs because they require tedious sample preparation and long analysis times.

Tandem mass spectrometry (MS/MS) circumvents these limitations of the bacterial inhibition assay, gas chromatography, and GC/MS methods. In brief, MS/MS permits analysis of a broad range of metabolites in hundreds of blood samples per day. Most states have adopted, or are in the process of adopting, the MS/MS approach to newborn screening as part of their program.

Newborn screening by MS/MS starts, as did the traditional screening programs, by collecting by heel stick a small blood sample and applying it to a standardized paper card. The period for appropriate collection remains between 1 and 3 days postpartum. Samples collected from either premature infants or sick newborns are potentially more difficult to interpret and are subject to greater false-positive and false-negative rates. The blood samples are shipped to a centralized laboratory where a standardized amount of the specimen card is punched out, following which the metabolites of interest are extracted from the punch, subjected to specific chemical modifications to make them compatible for subsequent MS/MS analysis, and automatically introduced into and analyzed by the MS/MS system.

As opposed to traditional screening protocols that required different analytic approaches for each disorder, the current MS/MS techniques permit analysis of a large number of metabolites belonging to a particular category of disease—hence, many disorders—in each sample. Hundreds of samples can be prepared for analysis, analyzed, and interpreted each day. The analysis is performed by state-of-the-art mass spectrometers that permit highly sensitive, accurate, and concurrent identification of multiple metabolites. Computer software permits pattern recognition using several related metabolites, thereby improving the reliability of the testing. In summary, the MS/MS technology is ideally suited for newborn screening of many samples for many possible disorders.

As with traditional newborn screening programs, the current MS/MS screening programs must determine the normal range for the different metabolites they analyze in their system. More importantly, the programs must set cutoffs above or below which they identify a case as at-risk. This is a difficult, ongoing task. Programs that set their cutoffs too high have an unacceptable false-negative rate, and programs that set their cutoffs too low have an unacceptable false-positive rate.

Pilot programs in the United States and elsewhere have demonstrated that MS/MS programs can detect PKU, MSUD, and homocystinuria as well as or better than the traditional screening approaches.[1,49,69,81,101] Nevertheless the practitioner must still be aware that the MS/MS-based screening programs have similar problems with false-positive and false-negative results as their older counterparts, although they appear to have lower false-positive rates. The practitioner must still determine whether a particular result is truly positive or falsely positive as rapidly and safely as possible. The expanded newborn screening programs have found that approximately 1 in 4000 newborns have an identifiable inborn error of metabolism.

SCREENING FOR DISORDERS

Most states in the United States and many other countries have adopted MS/MS screening to analyze disorders of amino acid metabolism (including several urea cycle disorders), organic acid metabolism, and fatty acid oxidation. The amino acid disorders and urea cycle disorders are detected by analyzing for increased blood concentrations of specific amino acids or combinations of amino acids. Most programs do not screen for disorders that are associated with reduced concentrations of specific amino acids. Similarly, the organic acidemias and fatty acid oxidation disorders are detected by analyzing for increased blood concentrations of specific acylcarnitines, namely, the esters formed between carnitine and the accumulated acids in the various organic acidemias and fatty acid oxidation disorders. As in the case of the amino acid disorders, many programs evaluate samples for combinations of particular acylcarnitines to increase the reliability of their results. Screening for the plasma membrane carnitine uptake defect is an exception to the rule, because it looks for a reduced (rather than increased) concentration of free carnitine.

Table 50-1 lists abnormal laboratory findings, along with the disorders associated with those findings, and the additional testing recommended to evaluate the significance of the findings. In the case of the amino acid disorders, a particular abnormal laboratory finding can be associated with more than one disorder because different enzymatic defects can lead to excessive accumulation of that metabolite.

This is also true for the disorders detectable by acylcarnitine analysis, but in addition, there is some ambiguity in identifying several of the acylcarnitines evaluated in the program. For example, C4 (an acylcarnitine that contains an acid group with four carbons) can be either butyrylcarnitine (wherein the four carbons are arranged in a linear pattern) or

TABLE 50–1 Differential Diagnosis and Follow-up for Abnormal Laboratory Findings Commonly Reported by Newborn Screening Programs

Abnormal Laboratory Finding*	Associated Disorders	Follow-up Studies†
Amino Acids		
Glycine	Nonketotic hyperglycinemia (NKHG)	Plasma amino acids Cerebrospinal fluid amino acids Urine organic acids
Leucine (and valine)	Maple syrup urine disease (MSUD)	Plasma amino acids Urine organic acids
Methionine	Homocystinuria	Plasma amino acids Plasma total homocysteine Urine amino acids
Phenylalanine	Phenylketonuria (PKU)	Plasma amino acids Urine biopterins
Tyrosine	Tyrosinemia type I Tyrosinemia type II	Plasma amino acids Urine organic acids (succinylacetone)
Urea Cycle Defect		
Arginine	Arginase deficiency	Plasma amino acids Plasma ammonia
Argininosuccinic acid	Argininosuccinate lyase deficiency	Plasma amino acids Urine amino acids Plasma ammonia
Citrulline	Argininosuccinate synthetase deficiency Argininosuccinate lyase deficiency Citrin deficiency	Plasma amino acids Plasma ammonia
Acylcarnitines‡		
C0 (↓)	Carnitine transporter deficiency	Plasma carnitine analysis with acylcarnitine profile Urine carnitine analysis Urine organic acids
C3	Methylmalonic acidemia (MMA) or cofactor (vitamin B_{12}) biosynthesis defect Multiple carboxylase deficiency (MCD) Propionic acidemia (PA)	Plasma carnitine analysis with acylcarnitine profile Plasma total homocysteine Plasma amino acids Urine organic acids
C4	Isobutyryl-CoA dehydrogenase deficiency Short-chain acyl-CoA dehydrogenase (SCAD) deficiency	Plasma carnitine analysis with acylcarnitine profile Urine organic acids
C5	Isovaleric acidemia (IVA) 2-Methylbutyryl-CoA dehydrogenase deficiency	Plasma carnitine analysis with acylcarnitine profile Urine organic acids
C5-3OH,3M-DC	3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	Plasma carnitine analysis with acylcarnitine profile Urine organic acids
C5-OH	Biotinidase deficiency β-Ketothiolase deficiency 3-Methylcrotonyl-CoA carboxylase deficiency Multiple carboxylase deficiency Maternal 3-methylcrotonyl-CoA carboxylase deficiency	Plasma carnitine analysis with acylcarnitine profile Urine organic acids Biotinidase analysis Maternal urine organic acids and carnitine analysis

TABLE 50–1 Differential Diagnosis and Follow-up for Abnormal Laboratory Findings Commonly Reported by Newborn Screening Programs—cont'd

Abnormal Laboratory Finding	Associated Disorders	Follow-up Studies
C5-DC	Glutaric aciduria type I (GAI)	Plasma carnitine analysis with acylcarnitine profile Urine organic acids
C8 and C10 (and C10:1)	Medium-chain acyl-CoA dehydrogenase (MCAD)	Plasma carnitine analysis with acylcarnitine profile Urine organic acids Mutational analysis (MCAD)
C14 and C16 (and C14:1)	Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency	Plasma carnitine analysis with acylcarnitine profile Urine organic acids
C16 and C18	Carnitine-acylcarnitine translocase (CACT) deficiency Carnitine palmitoyltransferase II (CPT II) deficiency	Plasma carnitine analysis with acylcarnitine profile Urine organic acids
C16-OH	Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency	Plasma carnitine analysis with acylcarnitine profile Urine organic acids Mutational analysis (LCHAD)
C4-DC, C5-OH, C6 - C16	Multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type II, GAII)	Plasma carnitine analysis with acylcarnitine profile Urine organic acids

*All abnormal findings reflect increased blood concentrations except where otherwise indicated.

†The studies listed are those that should be done at the first encounter following receipt of the abnormal newborn screening result. Additional, more specific, confirmatory studies such as enzyme analysis or in vitro cell studies using blood cells, cultured skin fibroblasts, or organ biopsies are generally obtained after the results of the initial confirmatory tests are available.

‡The acylcarnitines associated with these disorders are designated by a capital C followed by the number of carbons contained within the fatty acyl group attached to the carnitine; for example, C8 refers to octanoylcarnitine. A colon followed by an arabic numeral indicates one or more unsaturated carbons in the fatty acylcarnitine ester; for example, C10:1 refers to a monounsaturated C10 acylcarnitine. An OH in the designation indicates a hydroxylated acylcarnitine; for example, C5-OH refers to a monohydroxylated 5-carbon acylcarnitine. DC following the carbon number indicates a dicarboxylic acylcarnitine; for example, C5-DC refers to a dicarboxylic 5-carbon acyl group.

↓, decreased.

isobutyrylcarnitine (wherein the four carbons are arranged in a branched pattern). The diseases associated with these two acylcarnitines are quite different, and further studies are required to determine which metabolite, or which disorder, is present.

The confirmatory studies listed in Table 50-1 are readily available in most clinical settings, and discussed in detail later (see "Specialized Biochemical Testing"). The confirmatory studies cited include tests that have a relatively rapid turnaround time, generally 1 to 2 weeks, hopefully leading to rapid confirmation or elimination of a possible diagnosis. Additional, more refined studies, including specific enzyme analysis, whole cell studies, or genetic mutational analysis, are often required to definitively establish a specific diagnosis, but these generally have a longer turn-around time.

The abnormal laboratory findings listed in Table 50-1 permit the diagnosis of more than 20 genetic disorders, including amino acid disorders that encompass several urea cycle disorders, organic acidemias, and fatty acid oxidation disorders. The list of metabolites provided in Table 50-1 is not comprehensive. Many other metabolites have been identified or can theoretically be identified, but they are not listed because of the rarity or uncertain clinical phenotype of the associated disorder. Not all states test for this particular list of metabolites; some test for fewer and others for more. Practitioners should be familiar with the scope of their local newborn screening program. In any event, the laboratory findings listed in Table 50-1 should provide all practitioners with a foundation for interacting with their local program.

Table 50-2 provides basic information about the disorders cited in Table 50-1, including the name of each disorder along with its common abbreviation (if one is available), the underlying enzymatic defect, the clinical features and natural history, the general approach to treatment, and the prognosis. The frequency of these disorders ranges between approximately 1 in 15,000 for PKU and medium-chain acyl-CoA dehydrogenase (MCAD) deficiency to 1 in 200,000 for MSUD; some disorders have been reported in only a few single-case reports. In addition to their rarity, most of these disorders are characterized by a high degree of clinical variability, making it difficult to provide a succinct but accurate summary. Hopefully, the information will provide the practitioner with a reasonable place to start when confronted with a patient who has an abnormal newborn screening result, following which

(text continued on page 1635)

TABLE 50–2 Inborn Errors of Metabolism That Can Be Ascertained by Tandem Mass Spectrometry-Based Newborn Screening Programs*

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis with Treatment
Amino Acid Disorders				
Homocystinuria	Cystathionine β-synthetase deficiency	Generally asymptomatic at birth Developmental delay, dislocated lens, skeletal deformities, and thromboembolic episodes	Dietary protein restriction Selective amino acid restriction (methionine) Vitamin B_6 supplementation plus betaine, folate, and vitamin B_{12}	Patients with vitamin B_6-responsive form of disease have fewer complications and later age of onset of complications than do patients with vitamin B_6-nonresponsive form
Maple syrup urine disease (MSUD)	Branched-chain α-keto acid dehydrogenase deficiency	Patients might present before newborn screening results are available Difficulty feeding, vomiting, lethargy progressing to coma, opisthotonic posturing, and possibly death Ketoacidosis	Emergency treatment might be indicated for symptomatic neonates Chronic care includes: Dietary protein restriction Selective branched-chain amino acid restriction (leucine, isoleucine, valine) Thiamine supplementation for thiamine-responsive patients	Improved intellectual outcome can be expected if treatment is initiated before first crisis, but there is developmental delay in the severe cases Recurrent episodes of ketoacidosis
Nonketotic hyperglycinemia (NKHG)	Glycine cleavage enzyme deficiency	Patients might present before newborn screening results are available Hypotonia, apnea, intractable seizures, and lethargy progressing to coma Burst-suppression EEG pattern Hiccups (characteristic) Transient forms very rare	Various drugs can lower plasma glycine, but none lower CSF glycine or improve clinical outcome Dextromethorphan for seizures	Intractable seizures and poor intellectual development in patients who survive the neonatal period, except in rare instances
Phenylketonuria (PKU)	Phenylalanine hydroxylase deficiency or	Generally asymptomatic at birth After a few months, microcephaly, seizures, and pale pigmentation develop, followed in later years by abnormal posturing, mental retardation, and behavioral or psychiatric disturbances	Dietary protein restriction Selective amino acid restriction (phenylalanine)	Normal development can be expected (although a mild decrease in IQ and behavioral difficulties relative to non-affected sibs might be seen) if diet is instituted early
	Tetrahydrobiopterin (BH_4) biosynthesis or recycling defect	Patients with BH_4 defects have additional problems secondary to dopamine and serotonin deficiency	Biopterin defects require special care	Patients with biopterin defects have a more guarded prognosis

TABLE 50–2 Inborn Errors of Metabolism That Can Be Ascertained by Tandem Mass Spectrometry-Based Newborn Screening Programs—cont'd

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis with Treatment
Tyrosinemia type I	Fumarylacetoacetate hydrolase deficiency	Patients might present before newborn screening results are available Severe liver failure associated with jaundice, ascites, and bleeding diathesis Peripheral neuropathy and seizures can develop Renal Fanconi syndrome leading to rickets Survivors develop chronic liver disease with increased risk of hepatocellular carcinoma	Emergency treatment might be indicated for symptomatic neonates Chronic care includes: Dietary protein restriction Selective amino acid restriction (phenylalanine and tyrosine) Administration of selective enzyme inhibitor (NTBC) Liver transplantation when indicated to prevent hepatocellular carcinoma	Liver disease could progress despite dietary treatment NTBC treatment improves liver, kidney, and neurologic function, but it does not eliminate risk for hepatocellular carcinoma Liver transplantation might still be required
Tyrosinemia type II	Tyrosine aminotransferase	Corneal lesions and hyperkeratosis of the soles and palms	Selective amino acid restriction (tyrosine)	Good
Urea Cycle Disorders				
Argininosuccinic acidemia	Argininosuccinic acid lyase deficiency	Patients might present before newborn screening results are available Anorexia, vomiting, lethargy, seizures, and coma, possibly leading to death Hyperammonemia	Emergency treatment might be indicated for symptomatic neonates Chronic care includes: Dietary protein restriction Essential amino acid supplementation Arginine or citrulline supplementation Alternative pathway drugs for removing NH_3 (sodium benzoate and phenylbutyrate)	Improved intellectual outcome could be expected if treatment is initiated early, but there is developmental delay in the severe cases Recurrent hyperammonemic episodes
Arginemia	Arginase deficiency	Rarely symptomatic in neonatal period Progressive spastic diplegia or tetraplegia, opisthotonus, seizures Low risk of symptomatic hyperammonemia	Dietary protein restriction Selective amino acid restriction (arginine) Alternative pathway drugs for removing NH_3 (sodium benzoate and phenylbutyrate)	Uncertain, but might improve neurologic outcome

Citrullinemia	Argininosuccinate synthetase deficiency	Patients might present before newborn screening results are available Anorexia, vomiting, lethargy, seizures, and coma, possibly leading to death Hyperammonemia	Emergency treatment might be indicated for symptomatic neonates Chronic care includes: Dietary protein restriction Essential amino acid supplementation Arginine or citrulline supplementation Alternative pathway drugs for removing NH_3 (sodium benzoate and phenylbutyrate)	Improved intellectual outcome can be expected if treatment is initiated early, but there is developmental delay in the severe cases Recurrent hyperammonemic episodes
Organic Acidemias				
Glutaric acidemia type I (GAI)	Glutaryl-CoA dehydrogenase deficiency	Rarely symptomatic in neonatal period, although macrocephaly may be present Progressive macrocephaly, ataxia, dystonia and choreoathetosis, developmental regression, seizures, and strokelike episodes, possibly exacerbated by infection or fasting	Dietary protein restriction Selective amino acid restriction (lysine, tryptophan) Riboflavin and carnitine supplementation	Improved intellectual outcome if treatment is initiated early, but poor neurologic outcome if treatment is started after acute neurologic injury occurs Treatment might slow neurologic deterioration
Glutaric acidemia type II (GAII)	Electron transfer flavoprotein (ETF) deficiency or ETF dehydrogenase deficiency	Commonly manifests in neonatal period Hypotonia, hepatomegaly, abnormal odor, with or without congenital anomalies including facial dysmorphism and cystic kidney disease Metabolic acidosis and hypoglycemia Generally lethal Late-onset forms variable, rarely have structural birth defects	Emergency treatment might be indicated for symptomatic neonates Chronic care includes: Dietary protein restriction Selective amino acid restriction (isoleucine, methionine, threonine, and valine) Carnitine supplementation	Treatment for neonatal-onset forms invariably unsuccessful Dietary fat and protein restriction and riboflavin and carnitine supplementation might help patients with late-onset disease
3-Hydroxy-3-methylglutaric aciduria	3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	Generally does not manifest in neonatal period Episodic hypoglycemia leading to developmental delay	Dietary protein restriction Selective amino acid restriction (leucine) Low-fat diet	Improved intellectual outcome may be expected if treatment is initiated early, but there is developmental delay in the severe cases Recurrent hypoglycemic episodes decrease in frequency and severity over time

TABLE 50–2 Inborn Errors of Metabolism That Can Be Ascertained by Tandem Mass Spectrometry-Based Newborn Screening Programs—cont'd

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis with Treatment
Isobutyric acidemia	Isobutyryl-CoA dehydrogenase deficiency	Uncertain because number of cases is small	Dietary protein restriction Selective amino acid restriction (valine)	Unknown
Isovaleric acidemia (IVA)	Isovaleryl-CoA dehydrogenase deficiency	Patients might present before newborn screening results are available Vomiting, lethargy and coma, possibly death Abnormal odor Thrombocytopenia, leukopenia, anemia Ketoacidosis Hyperammonemia	Emergency treatment might be indicated for symptomatic neonates Chronic care includes: Dietary protein restriction Selective amino acid restriction (leucine) Glycine and carnitine supplementation	Improved intellectual outcome if diagnosed and treated early If treated appropriately, most have normal development Recurrent metabolic episodes
β-Ketothiolase deficiency	Mitochondrial acetoacetyl-CoA thiolase deficiency	Patients might present before newborn screening results are available Vomiting, lethargy and coma, possibly death Abnormal odor Thrombocytopenia, leukopenia, anemia Possible basal ganglia damage Ketoacidosis Hyperammonemia	Dietary protein restriction Selected amino acid restriction (isoleucine) Avoidance of fasting Bicarbonate therapy and intravenous glucose in acute crises Carnitine supplementation	Highly variable clinical course Improved intellectual outcome if diagnosed and treated early If treated appropriately, some patients have normal development Recurrent metabolic episodes
2-Methylbutyric acidemia	2-Methylbutyryl-CoA dehydrogenase deficiency	Uncertain because number of cases is small	Dietary protein restriction Selected amino acid restriction	Uncertain
3-Methylcrotonylglycinuria	3-Methylcrotonyl-CoA carboxylase deficiency	Neonatal form: Hypoglycemia and metabolic acidosis Maternal form: Transplacental transport of 3-methylcrotonyl glycine from generally asymptomatic mother to fetus	Neonatal form: Dietary protein restriction Selected amino acid restriction (leucine) Carnitine and glycine supplementation Maternal form: Mother might benefit from carnitine supplementation if she has carnitine insufficiency	Neonatal form: Generally good Maternal form: Mother might benefit from carnitine supplementation

2-Methyl-3-hydroxybutyric acidemia	2-Methylbutyryl-CoA dehydrogenase deficiency	Uncertain because number of cases is small	Dietary protein restriction Selected amino acid restriction	Uncertain
Methylmalonic acidemia (MMA)	Methylmalonyl-CoA mutase deficiency or Vitamin B$_{12}$ (cobalamin) metabolism defect	Patients might present before newborn screening results are available Vomiting, lethargy and coma, possibly death Seizures and risk of basal ganglia infarcts Thrombocytopenia, leukopenia, anemia Ketoacidosis Hyperammonemia	Emergency treatment might be indicated for symptomatic neonates Chronic care includes: Dietary protein restriction Selective amino acid restriction (isoleucine, methionine, threonine, and valine) Carnitine supplementation Antibiotic suppression of gut flora (metronidazole) Liver and/or kidney transplantation might be considered Cobalamin defects require special treatment	Improved intellectual outcome if diagnosed and treated early If treated appropriately, most have normal development Recurrent metabolic episodes Renal failure often develops despite appropriate therapy
Propionic acidemia (PA)	Propionyl-CoA carboxylase deficiency	Patients might present before newborn screening results are available Vomiting, lethargy and coma, possibly death Seizures and risk of basal ganglia infarcts Thrombocytopenia, leukopenia, anemia Ketoacidosis Hyperammonemia	Emergency treatment might be indicated for symptomatic neonates Chronic care includes: Dietary protein restriction Selective amino acid restriction (isoleucine, methionine, threonine, and valine) Carnitine supplementation Antibiotic suppression of gut flora (metronidazole and neomycin) Liver transplantation might be considered	Improved intellectual outcome if diagnosed and treated early If treated appropriately, most have normal development Recurrent metabolic episodes
Biotinidase deficiency	Biotinidase deficiency	Generally does not manifest in neonatal period Skin rash and alopecia, optic atrophy, hearing loss, seizures, and developmental delay Metabolic ketoacidosis	Biotin supplementation	Excellent if diagnosed and deficiency treated before irreversible neurologic damage occurs

Continued

TABLE 50–2 Inborn Errors of Metabolism That Can Be Ascertained by Tandem Mass Spectrometry-Based Newborn Screening Programs—cont'd

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis with Treatment
Multiple carboxylase	Holocarboxylase synthetase deficiency	Commonly manifests in neonatal period Lethargy leading to coma and possibly death Skin rash, impaired T cell immunity, seizures, and developmental delay Metabolic ketoacidosis and hyperammonemia	Biotin supplementation	Most patients respond to some degree to biotin supplementation, but others show poor or no response to biotin supplementation and have significant residual neurologic impairment
Fatty Acid Oxidation				
Carnitine transporter deficiency	Carnitine transporter deficiency	Commonly manifests in neonatal period Cardiomyopathy, skeletal myopathy, and inability to tolerate prolonged fasting	Carnitine supplementation Avoid fasting Low-fat diet	Good response to treatment, often associated with reversal of cardiomyopathic changes
Carnitine/acylcarnitine translocase deficiency	Carnitine/acylcarnitine translocase deficiency	Commonly manifests in neonatal period Lethargy leading to coma, hepatomegaly Cardiomyopathy with ventricular arrhythmia, skeletal myopathy, and early death Hypoketotic hypoglycemia and hyperammonemia	Avoid fasting High-carbohydrate, low-fat diet Nightly cornstarch supplementation Carnitine supplementation	Severe neonatal cases generally have poor outcome and early death Patients with later onset might respond to treatment, but they often succumb to chronic skeletal-muscle weakness or cardiac arrhythmias
Carnitine palmitoyltransferase type II (CPT II) deficiency	CPT II deficiency	Commonly manifests in neonatal period Coma, cardiomyopathy and ventricular arrhythmias, hepatic disease, and congenital malformation (brain and cystic renal disease) Hypoketotic hypoglycemia Late-onset forms (child or adult) characterized by weakness and exercise-induced rhabdomyolysis	Avoid fasting High-carbohydrate, low-fat diet supplemented with MCT oil Nightly cornstarch supplementation Carnitine supplementation	Severe neonatal cases generally have poor outcome and early death Patients with late-onset disease generally do well

Long-chain-3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency	LCHAD deficiency	Sometimes manifests in neonatal period Cardiomyopathy, hypotonia, hepatic disease, and hypoketotic hypoglycemia Patients later develop rhabdomyolysis, peripheral neuropathy, and pigmentary retinopathy and are at risk for sudden death Heterozygous pregnant women are at risk for acute fatty liver of pregnancy if they are carrying a homozygous fetus	Avoid fasting High-carbohydrate, low-fat diet supplemented with MCT oil Nightly cornstarch supplementation Carnitine supplementation	Early diagnosis and treatment generally leads to improved outcome, but no change in risk of peripheral neuropathy and visual impairment
Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency	MCAD deficiency	Generally does not manifest in neonatal period Recurrent episodes of vomiting, coma, seizures, and possibly sudden death associated with prolonged period of fasting Cardiomyopathy not generally seen Hypoketotic or nonketotic hypoglycemia	Avoid fasting High-carbohydrate, low-fat diet (controversial) Nightly cornstarch supplementation Carnitine supplementation	Excellent intellectual and physical outcome generally seen if treatment is initiated before irreversible neurologic damage occurs
Short-chain acyl-CoA dehydrogenase (SCAD) deficiency	SCAD deficiency	Generally does not manifest in neonatal period Highly variable presentation primarily associated with failure to thrive, developmental delay, Hypoglycemia uncommon Many patients detected by newborn screening program have been asymptomatic	Avoid fasting High-carbohydrate, low-fat diet Nightly cornstarch supplementation Carnitine supplementation	Efficacy of treatment is unknown and metabolic acidosis
Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency	VLCAD deficiency	Commonly manifests in neonatal period Lethargy leading to coma, hepatomegaly, cardiomyopathy with ventricular arrhythmia, skeletal myopathy, and early death Hypoketotic hypoglycemia Later-onset forms (childhood or adult) characterized primarily by weakness and exercise-induced rhabdomyolysis	Avoid fasting High-carbohydrate, low-fat diet supplemented with MCT oil Nightly cornstarch supplementation Carnitine supplementation	Severe neonatal cases generally have poor outcome Patients with late-onset disease respond to treatment and do well

TABLE 50–2 Inborn Errors of Metabolism That Can Be Ascertained by Tandem Mass Spectrometry-Based Newborn Screening Programs—cont'd

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis with Treatment
Other				
Galactosemia	Galactose-1-phosphate uridyltransferase deficiency	Early onset characterized by lethargy, poor feeding, jaundice, and possibly sepsis (especially with *Escherichia coli*) Chronic problems include growth failure, cirrhosis, cataracts, seizures, mental retardation, and (in females) ovarian failure	Strict dietary galactose restriction must be started immediately	Improved intellectual outcome and milder problems if diagnosed and treated early Ovarian failure develops despite appropriate therapy Recurrent metabolic episodes

*This table does not provide a complete listing of all the inborn errors that have been identified or might be identified by tandem mass spectrometry. The last inborn error listed, galactosemia, is not detected currently using tandem mass spectrometry, but it is included in the table because it is part of current screening programs. It is important to note that all these disorders are characterized by considerable clinical variability and that treatment must be individualized for each patient.

CSF, cerebrospinal fluid; MCT, medium-chain triglycerides; NTBC, 2-(2-nitro-4-trifluoro-methylbenzoyl)-1,3-cyclohexanedione.

he or she can turn to other resources after a diagnosis is established.

HANDLING TEST RESULTS

The first obligation of the practitioner who receives an abnormal newborn screening report is to inform the parents of the result. The practitioner should explain that the results are provisional and that confirmation is required. The physician must aim for an appropriate balance between his or her own natural desire to reassure the parents that the result might be falsely positive and the desire to instill a sense of appropriate concern in the parents so that they can carry through with appropriate follow-up evaluation. The practitioner's burden is generally more straightforward when the abnormal metabolite is associated with only a single disorder, but the principles of reassurance and follow-up are the same for metabolites that can be found in more than one disorder (see Table 50-1). The physician should then assess the newborn's clinical status and arrange to see the family as expeditiously as possible.

The primary physician should either see the patient or refer the patient to a metabolic disorders specialist for further evaluation and care. It is often best that the primary physician see the patient as soon as possible to assess the patient's status and then work with the metabolic disorders specialist to develop an expeditious plan for evaluation. Confirmatory testing should be initiated as soon as possible.

The decisions about when to initiate treatment and how to treat are based on the nature of the laboratory abnormality found, the quantitative degree of the abnormality, the program's prior experience with false positives for that metabolite, and the patient's clinical status. In general, starting a treatment immediately after the initial confirmatory studies are obtained is both safe and unlikely to compromise the ability to establish a diagnosis. However, this option is predicated on the ability of the physician to make certain that the diagnostic samples are collected properly, sent to the appropriate laboratory, and received in satisfactory condition by the laboratory. Failure to do this before starting treatment might significantly delay the time required to establish a diagnosis and initiate appropriate treatment.

Most of the disorders identified are treated, at least in part, by some form of dietary restriction. A family's desire to continue breast feeding while the diagnostic studies are in progress should be carefully considered in all cases. However, depending on the disorder under consideration and the patient's clinical status, the default position should be in favor of stopping, or at least interrupting, breast feeding until a provisional diagnosis has been established. It is generally a matter of days to a week before the results of the initial confirmatory studies are available, when a more definitive decision can be made about the advisability of breast feeding. Similar reasoning should be exercised about starting vitamin or cofactor supplementation.

EFFECT OF SCREENING PROGRAMS

The impact of the expanded newborn screening programs is still being determined. There have clearly been many instances when the programs have led to the early recognition of an as-yet unaffected newborn, followed by the introduction of appropriate treatment. In some cases, this has meant that a newborn with one of the organic acidemias or urea cycle defects that can manifest with an acute neurologic intoxication syndrome in the first few days of life does not suffer an insult that produces severe, irreversible neurologic damage. In other cases, the newborn screening result becomes available after a newborn is already ill, but the result provides a rapid diagnosis for the illness and leads to earlier introduction of appropriate therapy, thereby improving the patient's outcome.

However, it is not yet clear whether early recognition and institution of appropriate treatment changes the long-term prognosis for many of these diseases, such as recurrent hyperammonemic crises in the urea cycle defects or renal failure in methylmalonic acidemia. There may also be negative consequences to these new programs. For example, the screening programs could produce undesirable effects on the family of a child with a false-positive result, including increased hospitalization of the child, parental stress, and parent-child dysfunction.[97] Carefully organized multicenter studies are needed to determine the long-term benefits of the expanded newborn programs.

In addition to the current MS/MS newborn screening programs for amino acid and acylcarnitine analysis, new methods for evaluating other groups of inborn errors of metabolism, including the lysosomal storage disorders, are under development. It seems reasonable to anticipate that many of these methods will be introduced over the next several years, further expanding the responsibility and role of the pediatrician and neonatologist in caring for children with metabolic disorders.

Separate summaries of several disorders that were part of the traditional screening programs and that are now evaluated by MS/MS programs (i.e., homocystinuria, MSUD, and PKU) are provided next because they are useful paradigms for understanding the benefit of the newborn screening programs and how they work.[39] A summary is also provided for MCAD deficiency because it is the most common of the fatty acid oxidation disorders that are now evaluated by MS/MS programs, and it is one of the paradigms for this group of disorders. Summaries are also provided for biotinidase deficiency and galactosemia, which are disorders that are primarily evaluated by methodologies other than MS/MS. Other disorders that are now part of expanded newborn screening programs are discussed elsewhere in this chapter, including fatty acid β-oxidation disorders (see "Hypoglycemia"), nonketotic hyperglycinemia (see "The Sick Newborn Infant"), organic acidemias (see "Metabolic Acidosis"), tyrosinemia type I (see "Hepatic Dysfunction"), and urea cycle defects (see "Hyperammonemia").

Screening for Specific Disorders

BIOTINIDASE DEFICIENCY

Biotinidase is an enzyme necessary for recycling biotin, a vitamin cofactor required for four critical intracellular carboxylation reactions: acetyl-coenzyme A (acetyl-CoA) carboxylase, β-methylcrotonyl-CoA carboxylase, propionyl-CoA carboxylase, and pyruvate carboxylase. Hence biotinidase deficiency is one cause of multiple carboxylase deficiency.[39,102] These carboxylase reactions are involved in fatty acid biosynthesis, branched-chain amino acid metabolism, and gluconeogenesis.

Biotinidase deficiency is characterized by a variable clinical presentation but can lead to severe metabolic decompensation in the newborn period; features include ketoacidosis, hypotonia, seizures, and coma. Some children also have significant dermatologic findings (including rash and alopecia) and immunodeficiency. If untreated, older children could have significant developmental delay. This disorder can be treated successfully with biotin supplementation (5 to 20 mg/day PO). Some residual neurologic deficits could persist if treatment does not begin before the onset of symptoms.

Serum biotinidase activity is the gold standard for newborn screening of biotinidase deficiency.[39,102] The disorder can also be detected using MS/MS to measure the blood concentration of C5-OH (3-hydroxyisovalerylcarnitine), the acylcarnitine that is formed secondary to the deficiency of β-methylcrotonyl-CoA carboxylase. However, the sensitivity of the MS/MS approach is unknown, and it might not provide a reliable method for newborn screening. A positive screening result should be confirmed by quantitative serum biotinidase analysis and by performing plasma carnitine analysis and urine organic acid analysis, looking for the characteristic plasma acylcarnitine pattern and organic aciduria that is present in a small percentage of affected patients.

Care must be exercised in collecting and processing the serum specimen used for biotinidase analysis because biotinidase is quite labile at room temperature. It is best to obtain a concurrent control from one or both parents to establish that the sample has been processed properly (i.e., eliminate the chance of a false-positive result).

GALACTOSEMIA

Classic galactosemia is the consequence of galactose-1-phosphate uridyltransferase (GALT) deficiency. Classic galactosemia can manifest in the newborn period with lethargy, poor feeding, jaundice, cataracts, and in some cases, *Escherichia coli* sepsis.[19,39] If unrecognized, this disorder can lead to early death or a chronic course characterized by cirrhosis, cataracts, seizures, and mental retardation. The mainstay of therapy for classic galactosemia is strict dietary lactose restriction.[19,39,98] Diet therapy is difficult to sustain because lactose is a ubiquitous food additive. Dietary galactose restriction should be started as early as possible (preferably within the first few days after birth) to have the best chance of precluding the development of speech and learning problems. However, even children treated early often have mild growth failure, learning disabilities, and verbal dyspraxia. Affected girls almost invariably develop premature ovarian failure.[32,82] This observation serves as a caution to those caring for children with galactosemia that long-term follow-up is mandatory and further improvements in treatment are required.

There are two other forms of galactosemia: uridine diphosphate galactose-4′-epimerase deficiency and galactokinase deficiency. In most cases, epimerase deficiency is a benign condition that does not require treatment. The rarer, systemic form of epimerase deficiency produces a clinical picture similar to classic galactosemia. Galactokinase deficiency is also rare, and produces nuclear cataracts but none of the other manifestations of classic galactosemia. Early recognition and treatment of this disorder is generally successful.

One approach to screening measures GALT activity. This assay can detect transferase deficiency without regard to prior dietary intake of galactose. It does not evaluate for either epimerase deficiency or galactokinase deficiency. Another approach is to measure galactose and galactose-1-phosphate (the substrate for GALT), which depend on prior dietary galactose intake, and evaluate for all three enzyme deficiencies. Most U.S. states use a combination of these approaches. Because of the rapid onset of symptoms of classic galactosemia and the presence of lactose in breast milk and most artificial formulas, screening programs for galactosemia must provide rapid results. Often, however, the screening results are not available before the affected neonate becomes ill; initial evaluation of a sick newborn should therefore include testing for the presence of urinary reducing substances (see "Specialized Biochemical Testing"). A newborn identified by newborn screen as possibly having classic galactosemia should have definitive biochemical testing by measuring whole blood or erythrocyte GALT activity and erythrocyte red cell galactose-1-phosphate. In addition, genetic analysis for the common GALT mutations is often helpful in interpreting the results of the GALT activity measurements and making treatment decisions. Following initiation of these studies, lactose should be withdrawn from the diet pending results of the laboratory investigations.

Widespread neonatal testing of erythrocyte transferase activity in various populations has revealed considerable genetic heterogeneity of this enzyme deficiency.[19] Some individuals have a partial enzyme deficiency that does not result in significant impairment of galactose metabolism or any discernible clinical disorder; there is no evidence of a need for dietary treatment of these cases. In other cases with partial enzyme activity, erythrocyte galactose-1-phosphate concentrations are increased, and minimal symptoms can develop. These cases can be managed with less-severe restriction of dietary lactose intake.

HOMOCYSTINURIA

Several inborn errors of metabolism produce homocystinuria.[39,65] The most common of these disorders is caused by cystathionine β-synthase deficiency, an autosomal recessive trait. Cystathionine β-synthase is a pyridoxine (vitamin B_6)-dependent enzyme. Rare disorders that also lead to homocystinuria include defects in folate or cobalamin metabolism. Screening programs for homocystinuria are based on detection of elevated blood levels of methionine, the precursor of cystathionine. Hypermethioninemia is characteristic of cystathionine β-synthase deficiency, but may not be associated with other causes of homocystinuria.

False-positive and false-negative results do occur in screening programs for homocystinuria.[39,65] False-positive results are generally the consequence of artifacts (e.g., poor quality of sample), but they may also result from nongenetic causes of hypermethioninemia, such as parenteral administration of amino acids or generalized liver disease or, rarely, from a genetic cause such as hereditary tyrosinemia, galactosemia, or citrin deficiency (see "Hepatic Dysfunction"). False-negative results are produced by the milder variants of cystathionine β-synthase deficiency, especially the pyridoxine-responsive form, which might not exhibit hypermethioninemia in the neonatal period.

The diagnosis of homocystinuria should be confirmed in patients with a positive newborn screening test by measuring total plasma homocysteine, plasma amino acids including free homocysteine, and urine amino acids including homocysteine. The diagnosis of cystathionine β-synthase deficiency can be confirmed by measuring the enzyme activity in cultured skin fibroblasts or genetic testing.

Cystathionine β-synthase deficiency rarely manifests in the neonatal period, but it can cause lethargy, poor feeding, and thromboembolic phenomena when it does.[39,65] If untreated, the disorder can lead to musculoskeletal anomalies suggestive of a marfanoid habitus, ectopia lentis, thromboembolic vascular disease, behavioral or psychiatric problems, and mental retardation. Patients with pyridoxine-responsive defects tend to have milder disease than do patients with pyridoxine-nonresponsive defects. All patients should undergo a pyridoxine challenge test to determine whether they are pyridoxine responsive.

Patients with pyridoxine-responsive forms of homocystinuria might require only daily vitamin B_6 supplementation and mild methionine restriction, whereas nonresponders probably require a strict low-methionine diet with cysteine supplementation (cysteine is the product of the cystathionine β-synthase reaction). Patients might also benefit from folate, vitamin B_{12}, and betaine supplementation, which augment the remethylation of homocysteine to methionine, thereby reducing the toxic effects of excessive homocysteine. The outcome for vitamin B_6-responsive patients appears to be good, but the outcome for nonresponders has often been less satisfactory because of the irreversible damage caused by the presenting episode, the therapeutic inadequacy of the present dietary management, or both.

MAPLE SYRUP URINE DISEASE

MSUD is an inborn error of branched-chain amino acid metabolism caused by deficiency of branched-chain α-ketoacid dehydrogenase, which is involved in isoleucine, leucine, and valine metabolism.[39] The classic clinical variant of this disorder manifests in the neonatal period and can lead to serious consequences if it is not recognized and treated within the first week of life. Untreated, the severe neonatal form leads to ketoacidosis and hypoglycemia, lethargy, seizures, and often death. If the patient recovers from this initial episode, the disorder can lead to growth failure and mental retardation.

Treatment requires intensive management of the presenting and subsequent acute episodes and meticulous long-term management that entails a diet containing reduced amounts of the branched-chain amino acids (i.e., isoleucine, leucine, and valine) and, in some cases, supplementation with pharmacologic amounts of thiamine. Thiamine is a cofactor for the branched-chain α-ketoacid dehydrogenase complex; a minority of patients have thiamine-responsive defects.

Screening programs for MSUD are based on the presence of hyperleucinemia. There are relatively few false-positive results. However, there was a relatively high frequency of false-negative results in the traditional screening programs. The rate of false-negative results has been reduced by the use of MS/MS technology because it is more sensitive and can concurrently measure isoleucine, leucine, and valine, thereby permitting the use of amino acid ratios to identify at-risk newborns.

The response to a positive screening result must be rapid because onset of this disease is often within the first week of life. Positive screening results might not be received from the newborn screening program until after the patient is in the neonatal intensive care unit. Bedside detection of the characteristic odor of maple syrup by an alert parent or nurse might be the first evidence of this disorder. The diagnosis should be established by specific blood and urine testing for the characteristic aminoacidopathy (i.e., increased plasma concentrations of allo-isoleucine, isoleucine, leucine, and valine) and the characteristic urinary organic acid pattern (see "Specialized Biochemical Testing"). Definitive enzyme analysis can be performed with leukocytes or cultured skin fibroblasts, but institution of treatment should not be delayed pending definitive analysis.[39,58] Treatment should be started immediately and should include vigorous correction of metabolic acidosis and hypoglycemia. Hemodialysis may be required. Once the infant is stable, the offending amino acids should be carefully reintroduced, either parenterally or orally (see "Metabolic Acidosis").

Treatment has prolonged the life expectancy and the quality of life for patients with MSUD, but the prognosis for intellectual outcome remains guarded because most patients experience recurrent episodes of ketoacidosis.[58] The key factor that correlates with ultimate intellectual outcome is the age of initiation of therapy; initiation of therapy after 10 days of age is rarely associated with normal intellectual outcome.

MEDIUM-CHAIN ACYL-CoA DEHYDROGENASE DEFICIENCY

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common inherited disorder of fatty acid oxidation, with an incidence of approximately 1 in 15,000.[34,39,50,78] It has a highly variable clinical presentation, even within families. It appears only rarely in the newborn period. Most patients present between 3 and 24 months of age, but others remain asymptomatic until they are much older, even in adulthood. The initial retrospective studies on MCAD deficiency found that in almost one fourth of patients, the diagnosis followed sudden, unexplained death.

The typical presentation is that of an infant who has unexplained progressive vomiting, hepatomegaly, lethargy leading to coma, and seizures associated with an infectious illness or a period of prolonged fasting. The characteristic laboratory finding is nonketotic or hypoketotic hypoglycemia; signs of liver dysfunction may also be present. Older patients could have a more indolent course that is associated with failure to thrive, developmental delay, or chronic muscle weakness. A significant proportion of patients are asymptomatic. MCAD deficiency is not infrequently diagnosed in an "unaffected" older sibling after his or her younger sibling comes to medical attention for an acute metabolic crisis or a positive newborn screening result for MCAD deficiency.

The diagnosis of MCAD deficiency is confirmed by plasma carnitine analysis with an acylcarnitine profile, urine organic acid analysis, and urine acylglycine analysis.[39,50] The plasma total and free carnitine concentration can vary with the phase of the illness. The plasma acylcarnitine profile typically shows increased amounts of C6, C8, and C10 acylcarnitines, with the greatest elevation being C8-acylcarnitine (octanoylcarnitine). However, patients with secondary carnitine deficiency could have a relative increase, but not an absolute increase, in these acylcarnitines. Urine organic acid analysis generally shows a typical medium-chain dicarboxylic aciduria (C6-C10) in symptomatic patients, but it could be normal in asymptomatic patients. Urinary acylglycine analysis can be useful in detecting the characteristic metabolite (suberylglycine) in asymptomatic patients. Thus it is especially important that all three complementary studies be performed for asymptomatic patients.

Genetic testing is useful for confirming the diagnosis. It used to be thought that at least 90% of patients carried at least one copy of the same abnormal allele, the A985G mutation, but the frequency of this particular allele is lower in patients identified by newborn screening programs.

Patients with MCAD deficiency should avoid fasting. Infants require frequent feedings: every 3 to 4 hours. The older infant or child may be allowed to fast for progressively longer periods of time, but not for more than 8 to 12 hours. The period of nocturnal fasting should be alleviated by providing uncooked cornstarch as a source of slow-release sugar with the last bottle or meal of the day. A low-fat diet ($<30\%$) may be beneficial, as may oral carnitine supplementation for patients with secondary carnitine deficiency. Carnitine supplementation should be monitored with periodic plasma carnitine analysis. Acute metabolic crises should be treated with intravenous glucose and carnitine. The prognosis for patients who are identified before the onset of irreversible neurologic damage is generally excellent.

PHENYLKETONURIA

Several genetic disorders produce hyperphenylalaninemia. Classic PKU and non-PKU hyperphenylalaninemia are caused by defects in phenylalanine hydroxylase, and variant PKU is caused by one of several defects in tetrahydrobiopterin (BH_4) metabolism.[39] Several nongenetic factors also produce hyperphenylalaninemia in the newborn, but this hyperphenylalaninemia disappears in the first year of life. The most common causes of transient hyperphenylalaninemia are prematurity and high protein intake. Newborn screening programs identify infants with genetic and nongenetic hyperphenylalaninemia. It is imperative that patients identified by the screening program receive a rapid, accurate, and definitive diagnosis because the clinical implications and therapies for the various forms of hyperphenylalaninemia are different.

All genetic forms of hyperphenylalaninemia are caused by defects that directly or indirectly affect the activity of the enzyme phenylalanine hydroxylase. This enzyme catalyzes the conversion of phenylalanine to tyrosine and requires BH_4 as a cofactor. Classic PKU and non-PKU hyperphenylalaninemia are caused by allelic defects of phenylalanine hydroxylase itself, whereas variant PKU is caused by defects of BH_4 biosynthesis or reutilization. BH_4 is also a cofactor for tyrosine hydroxylase and tryptophan hydroxylase, which are enzymes involved in neurotransmitter biosynthesis. Approximately 98% of patients with hyperphenylalanemia have a defect in phenylalanine hydroxylase, whereas 2% have a defect in BH_4 metabolism.

Patients with milder deficiencies of phenylalanine hydroxylase, i.e., patients with transient hyperphenylalaninemia or non-PKU hyperphenylalaninemia, usually do not require dietary treatment. However, patients with more severe deficiencies, that is, patients with classic PKU, require lifelong phenylalanine restriction. Treatment should start within the first month of life to avoid irreversible neurologic damage. When started early, treatment is generally effective in preventing the long-term neurologic sequelae of this disease. However, standard treatment appears unable to prevent more subtle intellectual and behavioral disabilities.[39] Dietary restriction should be lifelong. Women with PKU who fail to maintain the appropriate diet are at risk for having neurologically impaired offspring (maternal PKU syndrome; see "Maternal Diseases Affecting the Fetus").

In recent years, clinical trials have demonstrated that some patients with milder forms of classic PKU respond to oral supplementation with a BH_4 homologue. They appear to tolerate a higher dietary protein intake while maintaining acceptable serum phenylalanine concentrations. Further studies are needed to define better which patients are suitable candidates for this form of therapy.

Defects of BH_4 metabolism cause defective neurotransmitter synthesis as well as hyperphenylalaninemia, and lead to a more generalized neurologic syndrome known as *variant PKU,* characterized by convulsions, abnormal tone and posture, abnormal movements, hyperthermia, hypersalivation and swallowing difficulties, drowsiness, irritability, and developmental delay. Standard dietary management corrects the hyperphenylalaninemia that these patients have, but does not improve the neurologic problems related to their neurotransmitter deficiencies. Only a small percentage of patients with hyperphenylalaninemia have BH_4-related defects, and these patients must be identified early in order to initiate appropriate therapy. A variety of approaches are being used to treat these patients with some success.[39]

Newborn screening for hyperphenylalaninemia is based on measuring the concentration of phenylalanine in the blood while the newborn infant is receiving a phenylalanine-containing diet.[39,56] In the past, blood samples were obtained before discharge from the hospital, typically on the third or fourth day of life. Many newborn infants now go home from the hospital before 24 hours of age, thereby creating problems for screening programs. Screening before 24 hours increases the risk of a false-negative result, whereas delaying screening until after discharge increases the risk of poor compliance.

The rate of false-negative results is less a problem with MS/MS screening than the traditional approaches, partly because it is possible to measure the concentrations of phenylalanine and tyrosine (the product of the phenylalanine hydroxylase reaction) concurrently. Those who have a positive screening result require prompt attention, including plasma amino acid analysis. If the plasma phenylalanine concentration and the plasma phenylalanine-to-tyrosine ratio is increased, the patient should be placed on a low-phenylalanine diet. Breast feeding should be stopped. In all cases of confirmed hyperphenylalaninemia, the patient should be evaluated by a metabolic disorders specialist to rule out a defect in BH_4 metabolism.

THE ABNORMAL NEWBORN INFANT: CLINICAL PHENOTYPES

On the whole, newborn infants with inborn errors of metabolism have relatively few types of presentation. The most common clinical presentations are listed in Table 50-3, along with a differential diagnosis of the categories of metabolic disorders that may be associated with each presentation. A more detailed discussion of each presentation follows.

Prenatal Onset

Most inborn errors of metabolism do not affect the developing fetus and do not affect the woman who is carrying an affected fetus until after the birth of the baby. Similarly, most maternal illnesses, including inborn errors, do not affect the developing fetus. There are, however, several notable exceptions.[98]

MATERNAL DISEASES AFFECTING THE FETUS

The prototype of a maternal disease affecting the fetus is maternal PKU.[72] A pregnant woman who has PKU is at increased risk for spontaneous abortion. She also has an increased risk of having a child with major birth anomalies, including intrauterine growth restriction, microcephaly, mental retardation, and a congenital heart defect, as well as a broad range of minor anomalies. The risk of birth defects is proportional to the mother's serum phenylalanine concentration. There is no safe level below which the fetus is not at risk. Women with PKU should be placed on a strict low-phenylalanine diet before conception. This has proved difficult to do in practice, however, and maternal PKU syndrome remains a significant problem for women with PKU.

FETAL DISEASES AFFECTING THE MOTHER

As a rule, inborn errors of metabolism of the fetus do not affect the developing fetus or pregnant mother. However, reports began to appear in the 1990s describing mothers who had experienced *a*cute *f*atty *l*iver of *p*regnancy (AFLP) while carrying a fetus who subsequently manifested evidence of a fatty acid oxidation defect after birth.[100] AFLP is the most extreme end of a clinical spectrum of maternal complications of pregnancy that includes HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, and a *l*ow *p*latelet count) and AFLP. HELLP syndrome and AFLP are potentially serious complications of pregnancy (see Chapter 15).

TABLE 50–3 Clinical Findings Helpful in the Differential Diagnosis of Suspected Metabolic Disease in Neonates

Diagnostic Finding	Considerations
Prenatal Onset	
Maternal diseases affecting fetus	Phenylketonuria
Fetal diseases affecting mother	Fatty acid oxidation defects
Fetal diseases affecting fetus	Lysosomal storage disorders
The "sick" neonate	Amino acid disorders Carbohydrate defects Fatty acid oxidation defects Organic acidemias Respiratory chain defects Urea cycle defects Other
Cardiomegaly and/or cardiomyopathy (see Table 50-4)	Fatty acid oxidation defects Glycogen storage diseases Lysosomal storage diseases Peroxisomal disorders Respiratory chain defects
Eye Anomalies	
Cataracts	Carbohydrate defects Lysosomal storage disease Respiratory chain defects
Cornea	Lysosomal storage disorders
Retinal anomalies	Fatty acid oxidation defects Lysosomal storage disorders Peroxisomal disorders
Gastrointestinal abnormalities	Carbohydrate defects Intestinal transport defects Lysosomal storage disorders Organic acidemias
Hair or skin abnormalities	Amino acid disorders Menkes disease Organic acidemias
Hematologic abnormalities	Organic acidemias Respiratory chain defect
Hepatic dysfunction (see Table 50-5)	Amino acid defects Bile acid biosynthetic defects Carbohydrate defects Congenital disorders of glycosylation Fatty acid oxidation defects Peroxisomal disorders Respiratory chain defects
Hepatomegaly/ splenomegaly	Carbohydrate defects Fatty acid oxidation defects Glycogen storage diseases Lysosomal storage disorders Peroxisomal disorders
Sepsis	Galactosemia Respiratory chain defects
Unusual odor (see Table 50-7)	Amino acid disorders Organic acidemias
Dysmorphic syndromes (see Table 50-8)	Large-molecule disorders Small-molecule disorders

Clinical, biochemical, and histologic evidence of hepatic dysfunction mark both disorders. Patients with HELLP syndrome commonly develop epigastric pain, nausea, vomiting, headache, and biochemical findings of elevated serum liver enzymes, and they occasionally develop disseminated intravascular coagulation. AFLP is less common than HELLP syndrome and shows a greater degree of hepatic dysfunction. It often produces a severe coagulopathy, hypoglycemia, and fulminant hepatic failure. Microvesicular fatty deposits in the liver characterize both disorders. Both disorders can have life-threatening consequences for the fetus and mother. Women with either of these disorders improve remarkably after delivery, suggesting that the fetus is causing a toxic effect that resembles that seen in patients with inborn errors of fatty acid oxidation.

There is convincing evidence that a specific defect of fatty acid oxidation, long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency, is associated with the HELLP syndrome and AFLP spectrum.[6,35] LCHAD is part of a trifunctional multimeric enzyme complex that performs the three terminal steps in the fatty acid β-oxidation cycle: long-chain 2,3-enoyl-CoA hydratase, LCHAD, and long-chain 3-ketoacyl-CoA thiolase. LCHAD deficiency can be seen as an isolated deficiency or as part of trifunctional protein deficiency that affects all three enzyme activities. Both disorders are inherited as autosomal recessive traits.

Isolated LCHAD deficiency is marked by relative genetic homogeneity. More than 50% of the mutant alleles found in patients who have this disease carry the same mutation: a G1528C change in the gene that encodes for the α-subunit of LCHAD. Other mutations in the same gene that predispose a heterozygous mother to AFLP have also been identified. A relatively large number of at-risk pregnancies have now been identified and reviewed after the birth of a child with LCHAD deficiency.[6] These studies show that a woman who is heterozygous for LCHAD deficiency is at risk for developing HELLP syndrome or AFLP during a pregnancy in which she is carrying a fetus who is homozygous for the same deficiency. Thus a heterozygous mother is only at risk if her fetus inherits a second LCHAD mutation from the father. The baby, in turn, is at risk for significant postnatal problems associated with his or her enzyme deficiency. The diagnosis and care of a child with LCHAD deficiency is discussed later under Hypoglycemia.

The fraction of women who develop AFLP as a consequence of LCHAD deficiency is greater than 50%. The current recommendation is to evaluate all pregnant women who develop AFLP for LCHAD deficiency by biochemical and genetic testing. This recommendation does not extend to women who develop HELLP syndrome because it is more common than AFLP and less likely to be associated with LCHAD deficiency. Rarely, other inborn errors of fatty acid β-oxidation can also produce AFLP.

FETAL DISEASES AFFECTING THE FETUS

The fetus does not generally suffer prenatally detectable consequences of its own inborn error of metabolism until after birth because the abnormal metabolites that it produces are removed by the maternal circulation, or conversely, deficiency states caused by the inborn error are replenished by the maternal circulation. The primary exceptions to this rule are disorders of large-molecule metabolism in which macromolecules are not degraded appropriately and therefore accumulate in fetal organs (see "Dysmorphic Syndromes").

The most common of these inborn errors are the lysosomal storage disorders, which can produce congenital ascites or hydrops fetalis.[89] The lysosomal storage disorders that can lead to these problems include β-glucuronidase deficiency and Morquio syndrome (i.e., mucopolysaccharidoses); Farber disease and G_{M1}-gangliosidosis (glycolipidoses); galactosialidosis and sialidosis (oligosaccharidoses); and free sialic storage disease, a lysosomal transport defect. Several other disorders can also cause hydrops, including carbohydrate-deficient glycoprotein syndrome (known as *congenital disorder of glycosylation*), glycogen storage disease IV, Niemann-Pick disease type C (i.e., a defect of intracellular cholesterol transport), and several inborn errors of red cell glycolytic enzymes (see Chapter 22).

The Sick Newborn Infant

Newborn infants have a limited number of ways to respond to an acute illness such as an inborn error of metabolism.[11,45] These responses generally include cardiorespiratory, feeding, and neurologic difficulties. Symptoms generally do not appear on the first day of life but usually begin later in the first week. The initial symptoms are often poor feeding associated with a poor suck and irritability. Muscle tone is decreased, sometimes marked by a fluctuating pattern of decreased and increased tone. Reflexes are often abnormal, and seizures can develop. The poor feeding is sometimes accompanied by vomiting. Diarrhea is uncommon.

Disorders accompanied by a metabolic acidosis (i.e., the lactic acidemias or organic acidemias) can lead to a compensatory increase in respiratory rate. In the case of urea cycle defects, hyperammonemia increases the respiratory drive, leading to hyperpnea. The neonate shows lethargy, which can progress to coma and death. These symptoms often progress rapidly, sometimes within a matter of hours but more often during the course of a few days. It is important to suspect a metabolic disorder as early as possible in its course to interrupt the progression of symptoms, because many of these disorders are life threatening.

Many inborn errors of metabolism are associated with what appears to be a cascade of effects. A number of specific metabolites are overproduced as a result of a specific enzymatic deficiency. In excess, these normal metabolites serve as endogenous toxins that impair a relatively narrow range of metabolic or physiologic processes. When disrupted, these other processes lead to production of additional metabolites, which impair other cellular processes. Early interruption of the cascade through such relatively simple measures as fluid and caloric support might abort episodes of metabolic decompensation. Physicians who care for older children with metabolic disorders often receive a retrospective history of "sepsis" in the neonatal period that was never confirmed by culture and that resolved spontaneously; these episodes might have represented an interrupted metabolic intoxication syndrome. Early nonspecific supportive treatment can abort the pathologic cascade or delay the onset of a more fulminant course until a provisional metabolic diagnosis, upon which more specific treatment can be based, becomes available.

So-called sick newborns should be evaluated for a defect in amino acid metabolism, carbohydrate metabolism, fatty acid β-oxidation, organic acid metabolism, the mitochondrial respiratory chain, and the urea cycle (see Table 50-3). As a rule, the differential diagnosis for these patients can be narrowed by the presence of other clinical findings or by a characteristic laboratory finding, such as acidosis, hyperammonemia, hypoglycemia, ketosis, or lactic acidemia (see "The Abnormal Newborn Infant: Laboratory Phenotypes").

ERRORS OF METABOLISM NOT DETECTABLE BY STANDARD SCREENING

There is a limited but ever-growing number of inborn errors of metabolism that might not be identified by the standard laboratory approach presented later in this chapter. These disorders must, therefore, be considered and pursued independently and specifically. They include the carbohydrate-deficient glycoprotein syndromes (known as *congenital disorders of glycosylation*), folinic acid–responsive seizures, glucose transporter type 1 (GLUT-1) deficiency, Menkes disease, nonketotic hyperglycinemia, the peroxisomal disorders, pyridoxine-dependent seizures, and sulfite oxidase deficiency. The congenital disorders of glycosylation and the peroxisomal disorders are diverse groups of conditions and are discussed later under Dysmorphic Syndromes. Menkes disease is discussed under Hair and Skin Abnormalities.

Folinic Acid–Responsive Seizures

Folinic acid–responsive seizures is a poorly understood disorder or group of disorders that appear to be related to defects in neurotransmitter metabolism.[33,64] The diagnosis can be facilitated by biochemical analysis of cerebrospinal fluid (CSF). Practically, the patient can be evaluated for the possibility of folinic acid–responsive seizures by monitoring the response to a challenge of intravenous folinic acid (5 mg per day). It can take several weeks to see a response.

Glucose Transporter Type 1 Deficiency

GLUT-1 deficiency sometimes manifests in the neonatal period with seizures that are refractory to standard anticonvulsants, opsoclonus, and intermittent hemiplegic episodes.[43,57] With time, affected children develop ataxia, apraxia, and developmental delay. The disorder is caused by deficiency of the protein that facilitates glucose transport across the blood-brain barrier.

Once considered, the diagnosis can be readily established by concurrently measuring glucose, lactate, and pyruvate in the blood and CSF. The characteristic finding is a low CSF glucose concentration (less than 40 mg/dL) (hypoglycorrhachia) and a decreased CSF glucose-to-blood glucose concentration ratio (less than 0.35; normal, 0.65). The blood and CSF lactate and pyruvate concentrations are normal. The diagnosis can be confirmed by measuring erythrocyte uptake of a nonmetabolizable glucose homologue, 3-methylglucose, or by mutational analysis of the *GLUT-1* gene.

GLUT-1 deficiency can be treated successfully with a low-carbohydrate, high-fat diet (a ketogenic diet), which provides ketones as an alternative fuel source for the brain. It is important that the diagnosis be made as early as possible in order to initiate treatment before irreversible neurologic damage occurs.

Nonketotic Hyperglycinemia

Nonketotic hyperglycinemia is an autosomal recessive disorder caused by a defect in the glycine cleavage enzyme.[27,30] In the first few days of life, the infant has profound hypotonia, poor feeding, hiccupping, lethargy often leading to coma, and severe (generally myoclonic) seizures. Electroencephalographic analysis initially shows a burst-suppression pattern, which evolves with time into hypsarrhythmia. The disorder often leads to early death.

Standard laboratory analysis of plasma amino acids might not suffice to establish the diagnosis because the plasma glycine concentration might only be minimally elevated. Diagnosis of this disorder requires amino acid analysis on concurrently collected plasma and CSF samples; the biochemical hallmark of nonketotic hyperglycemia is an elevated CSF glycine-to-plasma glycine ratio. In addition, patients with nonketotic hyperglycinemia must be distinguished from those with ketotic hyperglycinemia, which accompanies many of the organic acidemias. Thus urinary organic acid analysis should be performed to determine whether the patient has characteristic organic aciduria (see "Specialized Biochemical Testing").

Treatment for nonketotic hyperglycinemia is poor, although efforts to block the action of glycine on the N-methyl-D-aspartate receptor are being evaluated.

Pyridoxine-Dependent Seizures

Another disorder that should be considered in the evaluation of a newborn infant with unexplained seizures accompanied by negative findings on a standard metabolic evaluation is pyridoxine-dependent seizures.[25,64] This disorder typically begins in the neonatal period, although in some cases, the seizures begin in utero.

The biochemical basis of this disorder was thought to be an inborn error in glutamic acid decarboxylase, which is the rate-limiting step in the synthesis of γ-aminobutyric acid (GABA). GABA is a critical neurotransmitter. Patients with this disorder have a decreased CSF GABA concentration. Pyridoxine (vitamin B_6) is a cofactor for the decarboxylase and was thought to augment the activity of the deficient enzyme. However, recent studies have shown that the mechanism of action is more complicated. It now appears that pyridoxine-dependent seizures are due to a genetic defect in the *ALDH7A1* gene, which encodes for a protein called *antiquitin*. Antiquitin is an enzyme involved in the lysine (a dibasic amino acid) degradation pathway. Antiquitin deficiency leads to accumulation of pipecolic acid and Δ^1-piperidine 6-carboxylic acid, which react with and inactivate the active form of pyridoxine in brain, pyridoxal phosphate. Thus patients with pyridoxine-dependent seizures have an autosomal recessive disorder in lysine metabolism that inactivates pyridoxal phosphate, which is required for GABA synthesis. Pyridoxine supplementation compensates for the increased loss of pyridoxal phosphate.

The disorder is generally diagnosed by demonstrating clinical and electroencephalographic responses to a pharmacologic challenge dose of pyridoxine rather than by biochemical analysis of lysine metabolites in the CSF or genetic analysis of the *ALDH7A1* gene, because the clinical approach is more easily performed and provides a more rapid answer. The response to parenteral pyridoxine (50 to 100 mg) is often dramatic, with normalization of the electroencephalographic pattern within minutes. This pyridoxine challenge test must, however, be done with caution because patients can experience apnea, hypotonia, and hypotension. The test should be done in an intensive care setting with electroencephalographic monitoring (see Chapter 40, Part 5). Once the diagnosis is established, daily oral pyridoxine supplementation (5 to 10 mg/kg) is effective treatment for this disorder. The prognosis for this disorder, once recognized and treated, is favorable.

A variant of pyridoxine-dependent seizures has been recognized in which the patient does not respond (or responds partially) to parenteral or oral pyridoxine, but responds to oral pyridoxal 5′-phosphate (pyridoxal phosphate).[25,64] Pyridoxal phosphate is the "active" form of vitamin B_6; that is, it serves as the cofactor for the enzymes involved in neurotransmitter biosynthesis. The patients who respond to pyridoxal phosphate have a clinical presentation similar to that of patients with pyridoxine-dependent seizures. However, they have a number of unique biochemical findings: decreased CSF concentrations of homovanillic acid (an L-dopa metabolite) and 5-hydroxyindoleacetic acid (a serotonin metabolite), increased CSF concentrations of two other L-dopa metabolites (3-O-methyldopa and vanillactic acid), and increased CSF concentrations of two amino acids (glycine and threonine). These changes are thought to be secondary to a generalized dysfunction of three vitamin B_6-dependent enzymes, aromatic L-amino acid decarboxylase, glycine cleavage enzyme, and threonine dehydratase. The underlying genetic defect is a deficiency of pyridox(am)ine 5′-phosphate oxidase (PNPO), which is required for the conversion of dietary pyridoxine and pyridoxamine phosphate to pyridoxal 5′-phosphate.

A patient suspected of having this disorder can be evaluated biochemically for the CSF abnormalities enumerated above or, more simply, by using pyridoxal phosphate in place of pyridoxine in an oral challenge test (pyridoxal phosphate is not available in a parenteral form). The patient should receive 50 mg of pyridoxal phosphate by nasogastric tube, while in an intensive care unit with EEG monitoring because of the risk of apnea, hypotonia, and hypotension. In some cases, the EEG response was relatively rapid (within an hour), but the patient remained unresponsive for several days following administration of pyridoxal phosphate. If the challenge test is successful, the patient should continue to receive pyridoxal phosphate (10 mg/kg every 6 hours). See Chapter 40 for further details on evaluating and managing patients with this disorder.

Sulfite Oxidase Deficiency

Sulfite oxidase deficiency exists in two forms: (1) an isolated genetic deficiency of sulfite oxidase and (2) a genetic defect in the molybdenum cofactor, which is required for the function of sulfite oxidase and xanthine dehydrogenase/aldehyde oxidase. Sulfite oxidase is involved in the degradation of the sulfur-containing amino acids, methionine, homocysteine, and cysteine to sulfate, whereas xanthine dehydrogenase and aldehyde oxidase are involved in the purine degradation pathway leading to uric acid.[3] Both disorders are characterized clinically by early onset, refractory seizures, hypotonia leading to hypertonia, and if the patients survive long enough, microcephaly, lens dislocation, and severe psychomotor delay. Many affected infants die in the first year of life. There is no proven treatment for this disorder, although a low-methionine, low-cystine diet has been tried and may have been beneficial in a few patients with mild disease.

The key biochemical findings of sulfite oxidase deficiency, either in cases of isolated deficiency or in cases of molybdenum cofactor deficiency, are increased excretion of urinary sulfite and thiosulfate, increased plasma and urinary S-sulfocysteine, and decreased plasma cystine. In addition, the plasma homocysteine concentration is very low in these patients and provides a unique biochemical marker that can be obtained rapidly. Patients with molybdenum cofactor deficiency produce the same set of metabolites as patients with the isolated deficiency, plus they excrete increased amounts of xanthine and hypoxanthine and decreased amounts of uric acid. As in the case of homocysteine, the serum uric acid is sometimes very low in patients with molybdenum cofactor deficiency and provides an easily measured marker for this form of the disease.

Cardiomegaly and Cardiomyopathy

See also Chapter 45.

Inborn errors of metabolism that are manifested by cardiomegaly, cardiomyopathy, or both in the neonatal period can be divided into five diagnostic categories: fatty acid β-oxidation defects, glycogen storage disorders, lysosomal storage disorders, mitochondrial oxidative defects, and other defects (Table 50-4). The pathogenesis for cardiac disease differs among these different diagnostic categories. The glycogen storage disorders and the lysosomal storage disorders are infiltrative processes resulting from the accumulation of partial breakdown products of glycogen and complex carbohydrates, respectively, whereas the fatty acid β-oxidation defects and the mitochondrial oxidative defects compromise energy production in the heart or lead to production of toxic metabolites.[21,24,75]

GLYCOGEN STORAGE DISORDERS

The glycogen storage disorder that most commonly causes cardiomyopathy in early infancy is Pompe disease, also known as *acid maltase deficiency* or *glycogen storage disease type II*. Acid maltase is the only enzyme involved in glycogen metabolism that is located within the lysosome. Pompe disease can also be considered a lysosomal storage disorder, and it is probably helpful to consider its pathogenesis from this perspective. Acid maltase is a key enzyme responsible for degrading glycogen; it cleaves the α-1,4-glucoside linkages of the glycogen polymer, converting glycogen to glucose.

Generalized hypotonia, failure to thrive, and cardiomyopathy characterize the neonatal form of Pompe disease. Hepatomegaly does not develop in patients with Pompe disease (except as a consequence to heart failure), as it does in patients with some other glycogen storage disorders. The diagnosis can be confirmed by specific enzyme analysis using skeletal muscle, cardiac muscle, or more conveniently, cultured skin fibroblasts, or by genetic testing. Enzyme replacement therapy for Pompe disease appears promising.

TABLE 50–4 Disorders Associated with Cardiomegaly or Cardiomyopathy

Category of Disorder	Disorder
Fatty acid oxidation	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency Multiple acyl-CoA dehydrogenase deficiency Very-long-chain acyl-CoA dehydrogenase deficiency
Glycogen storage	GSD type II (Pompe disease) GSD type IX (phosphorylase bkinase deficiency)
Lysosomal storage	Glycolipidoses Mucopolysaccharidoses Oligosaccharidoses
Respiratory chain	nDNA defects Complex I Complex III Complex IV Barth syndrome Leigh syndrome mtDNA defects Leigh syndrome mtDNA depletion syndromes $tRNA^{Ile}$, $tRNA^{Leu}$
Other	Congenital disorders of glycosylation

GSD, glycogen storage disease; mtDNA, mitochondrial DNA; nDNA, nuclear DNA; $tRNA^{Ile}$, transfer RNA for isoleucine; $tRNA^{Leu}$, transfer RNA for leucine.

Cardiomyopathy is not generally seen in the neonatal period in association with the other glycogen storage disorders, except in rare cases of cardiac-specific phosphorylase b kinase deficiency.[21,24]

LYSOSOMAL STORAGE DISORDERS

The lysosomal storage disorders produce cardiomegaly, valvular disease, or cardiomyopathy (dilated or hypertrophic).[21,24,89] Lysosomal storage disorders should be considered in the differential diagnosis of the newborn infant with cardiac disease who also has physical findings suggestive of a lysosomal storage disorder, such as craniofacial dysmorphism, corneal clouding or retinal abnormalities, hepatosplenomegaly, or skeletal anomalies (see "Dysmorphic Syndromes"). The lysosomal storage disorders that may be associated with cardiomyopathy in the newborn period include glycolipidoses (e.g., G_{M1}-gangliosidosis and G_{M2}-gangliosidosis), mucopolysaccharidoses (e.g., Hurler disease and Sandhoff disease), and oligosaccharidoses (e.g., I-cell disease and fucosidosis).

FATTY ACID β-OXIDATION AND MITOCHONDRIAL RESPIRATORY CHAIN DEFECTS

The myocardium derives a significant fraction of its energy from the mitochondrial oxidative metabolism of fatty acids, especially long-chain fatty acids.[21,44] The oxidation of these fatty acids requires a carnitine-mediated system to transport long-chain fatty acids into the mitochondrion, a β-oxidation pathway to break down the fatty acids, and the mitochondrial oxidation phosphorylation system to extract energy from the breakdown products. Cardiomyopathy would be expected to develop in the context of a defect in carnitine-mediated transport of long-chain fatty acids into the mitochondrion, defects of the fatty acid β-oxidation pathway, and defects of the respiratory chain itself. Studies have demonstrated that defects of long-chain fatty acid oxidation are a significant cause of cardiac disease, whereas defects affecting primarily medium-chain or short-chain fatty acid oxidation are less so.

Two defects of carnitine transport have been found to cause cardiomyopathy in the neonatal period: carnitine-acylcarnitine translocase deficiency and carnitine palmitoyltransferase II deficiency. A third defect of carnitine transport, deficiency of the plasma membrane carnitine transporter, does not commonly cause cardiomyopathy in the neonatal period, although it often produces cardiomyopathy in infancy and childhood.

Several defects of the β-oxidation pathway can cause cardiomyopathy: LCHAD deficiency, trifunctional protein deficiency, and very-long-chain acyl-CoA dehydrogenase deficiency.[21] These disorders can also cause life-threatening cardiac arrhythmias, presumably because of the accumulation of toxic long-chain acylcarnitines in the myocardial cells. Multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type II), a defect in the transfer of reducing equivalents from the enzymes of the β-oxidation pathway to the respiratory chain, can produce also cardiomyopathy (see "Dysmorphic Syndromes").

Several respiratory chain defects are associated with cardiomyopathy in the neonatal period.[38,75,80,90] These disorders may be classified according to whether they are the consequence of an error in a nuclear-encoded component (nDNA) or in a mitochondrial-encoded component (mtDNA) of the respiratory chain, or a nuclear-encoded gene involved in the synthesis, structural integrity or function of the mitochondrion (see “Lactic Acidemia”). These disorders can produce isolated cardiomyopathy or a highly diverse multisystem disease.

Nuclear-encoded defects that produce cardiomyopathy include defects of complex I (NADH-coenzyme Q reductase), complex III (reduced ubiquinone cytochrome c reductase), and complex IV (cytochrome c oxidase), as well as nuclear-encoded defects that affect protein required for the assembly of the oxidative phosphorylation complexes, such as SCO2, which is involved in the assembly of complex IV.[62,91] Barth syndrome is an X-linked disorder that impairs production of the lipid membrane required for normal mitochondrial function. This disorder is characterized by cardiomyopathy, cataracts, deafness, and neutropenia.[5] Leigh syndrome is characterized by a broad and variable clinical pattern that can include hypotonia, optic atrophy, nystagmus, developmental delay, myopathy, cardiomyopathy, and hepatic dysfunction. It is also a genetically heterogeneous disorder that can be caused by several different mutations, some involving nDNA and others involving mtDNA.

Lastly, several mtDNA defects can cause cardiomyopathy, including mutations affecting the mitochondrially encoded components of the oxidative phosphorylation complexes, as well as the transfer ribonucleic acids for glycine ($tRNA^{Gly}$), isoleucine ($tRNA^{Ile}$), and leucine ($tRNA^{Leu}$) (see “Lactic Acidemia”).[9,75,80]

OTHER DISORDERS

The main consideration in the miscellaneous category of inborn errors that may be associated with cardiomyopathy is the congenital disorders of glycosylation (CDG). The CDG syndrome is a highly pleiotropic disorder that can result in pericardial effusions, cardiomyopathy, or both, in addition to a broad range of other abnormalities, including neurologic abnormalities, hepatic dysfunction and, in some cases, a characteristic pattern of malformation (see “Dysmorphic Syndromes”).

Eye Anomalies

Many inborn errors of metabolism manifest with unusual ophthalmologic findings (see Table 50-3). A careful ophthalmologic examination is a crucial part of the clinical evaluation for a suspected inborn error of metabolism; conversely, patients with unusual ophthalmologic findings might require a metabolic evaluation (see Chapter 53).

Inborn errors of metabolism can affect any of the structural components of the eye.[66] Cataracts are classically associated with carbohydrate disorders (e.g., galactosemia) and lysosomal storage disorders, but they are also associated with Lowe syndrome (oculocerebrorenal syndrome), peroxisomal defects (e.g., Zellweger syndrome, neonatal adrenoleukodystrophy), and respiratory chain defects (e.g., Barth syndrome, Senger syndrome).[5,66] The cornea is often affected by lysosomal storage diseases, which can cause corneal clouding, as in G_{M1}-gangliosidosis, β-glucuronidase deficiency, I-cell disease, and sialidosis. Lens dislocation does not generally occur during the neonatal period in patients with homocystinuria or sulfite oxidase deficiency.

Several inborn errors of metabolism affect retinal development.[66] The so-called cherry-red spot found in several of the lysosomal storage disorders (Farber disease, galactosialidosis, G_{M1}-gangliosidosis, and sialidosis) is the best known of these retinal anomalies. Abnormal deposits in the retinal pigment epithelial layer can be found in older patients who have an unusual defect of mitochondrial fatty acid oxidation (LCHAD deficiency) and in patients with CDG syndrome, peroxisomal disorders, and respiratory chain defects.

Gastrointestinal Abnormalities

Newborn infants with inborn errors of metabolism might have various gastrointestinal abnormalities. Common findings include poor feeding, jaundice, and hepatomegaly (see “Hepatomegaly and Splenomegaly”). Many of the organic acidurias and urea cycle disorders are associated with vomiting. A number of patients with an organic acidemia have undergone surgery for and been found to have pyloric stenosis. Researchers hypothesize that the organic acidemias produce toxic metabolites that affect pyloric sphincter tone. Similarly, pancreatitis is a well-documented problem in a minority of patients with several organic acidemias, fatty acid oxidation disorders, or respiratory chain defects.[37]

Diarrhea is a relatively uncommon finding, but it can occur in patients who have defects of bile acid synthesis (see “Hepatic Dysfunction”), respiratory chain defects (see “Lactic Acidemias”), CDG syndrome (see “Dysmorphic Syndromes”), deficiencies of the intestinal disaccharidases or monosaccharide transport systems, congenital chloride diarrhea, and Wolman disease, a lysosomal storage disorder (see “Hepatomegaly and Splenomegaly”). Several lysosomal storage disorders can also produce congenital ascites and hydrops fetalis (see “Prenatal Onset”).

Hair and Skin Abnormalities

See also Chapter 52.

Abnormalities of the skin and hair are characteristic of several inborn errors of metabolism. Menkes disease, an X-linked disorder involving intracellular copper metabolism, leads to defects in a number of copper-dependent enzymes. Menkes disease is a highly pleiotropic disorder characterized by sparse and kinky scalp hair—hence the name kinky-hair disease. The disorder causes hypotonia, hypothermia, intractable seizures, profound developmental delay, and early death. The disorder may be associated with lactic acidosis caused by impaired activity of cytochrome c oxidase, a copper-dependent enzyme. The hair is also brittle and coarse in the childhood-onset forms of argininosuccinic aciduria, a urea cycle defect, but this is not seen in neonates with this disease (see “Hyperammonemia”).

A number of disorders include abnormalities of skin pigmentation. PKU may be associated with fair hair and skin pigmentation in affected white neonates. Similarly, newborn infants with cystinosis also have fairer hair and skin than their unaffected siblings. However, cystinosis, an autosomal recessive defect affecting lysosomal transport of cystine, a sulfur-containing amino acid, does not produce symptoms until several months of age, when it results in renal Fanconi syndrome and, ultimately, renal failure caused by cystine crystal deposits in the kidney.

Rash and partial alopecia may be associated with multiple carboxylase deficiency, an organic aciduria caused by defects in biotin metabolism: holocarboxylase synthetase deficiency and biotinidase deficiency (see "Newborn Screening").[102] Both defects can produce severe ketoacidosis, feeding difficulties, apnea, lethargy, hypotonia, and coma in the newborn period. Holocarboxylase synthetase and, in some cases, biotinidase deficiency can be detected by urinary organic acid analysis. Both conditions respond to biotin therapy, biotinidase deficiency more so than holocarboxylase synthase deficiency.

Hematologic Abnormalities

Several organic acidemias, including isovaleric acidemia, propionic acidemia, and methylmalonic acidemia, are characterized by neutropenia, thrombocytopenia, anemia, or pancytopenia.[40,93] The thrombocytopenia may be severe enough to lead to clinically significant bleeding. The precise pathophysiologic basis of these findings is not well understood, but is thought to be caused by direct bone marrow suppression of the metabolic imbalance associated with these disorders.

Hematologic abnormalities may be associated with respiratory chain defects, including Barth syndrome[5] (see "Cardiomegaly and Cardiomyopathy") and Pearson syndrome.[80] In contrast to the neutropenia and cardiomyopathy found in Barth syndrome, Pearson syndrome is characterized by sideroblastic anemia, pancreatic exocrine insufficiency, and lactic acidosis. Pearson syndrome is the consequence of a heteroplasmic mutation (deletion) of the mtDNA (see "Lactic Acidemia"). Neutropenia is a characteristic feature of glycogen storage disease type Ib, and this diagnosis should be considered in the patient who presents with hypoglycemia, hepatomegaly, triglyceridemia, neutropenia, and recurrent infections (see "Hypoglycemia").[96]

Hepatic Dysfunction

A number of inborn errors of metabolism are associated with hepatic disease. Excluding disorders that are associated primarily with defects in bilirubin metabolism (see Chapter 48), several groups of disorders lead to hepatic dysfunction and some degree of hepatomegaly. One approach to categorizing these disorders is to divide them into those that impair one or more aspects of hepatic function to a more significant degree than they produce liver enlargement and those for which the reverse is true. The former group of disorders is discussed in this section; the latter group, composed primarily of lysosomal storage disorders, is discussed under Hepatomegaly and Splenomegaly.

The inborn errors of metabolism that cause hepatic dysfunction can be categorized further according to the function or functions that they impair: defects that cause hypoglycemia, defects that cause hepatocellular damage leading to liver failure and cirrhosis, and defects that cause cholestatic disease. Although this approach is useful from a physiologic perspective, many inborn errors affect more than one of these hepatic functions, and an alternative scheme based on biochemical classification may be applied more practically. The biochemically based approach has been adopted in organizing this section. It is recommended that defects of the following biochemical categories be considered in evaluating patients with hepatic dysfunction: amino acid metabolism, bile acid metabolism, carbohydrate metabolism, fatty acid β-oxidation, peroxisomal disorders, respiratory chain defects, and a miscellaneous group of disorders (Table 50-5).[14] The clinical aspects of these disorders are presented in greater detail in Chapter 48.

AMINOACIDOPATHY

Tyrosinemia Type I

Tyrosinemia type I, also known as hepatorenal tyrosinemia, is the classic aminoacidopathy that can produce a fulminant disorder characterized by progressive hepatocellular damage leading to cirrhosis, proximal renal tubular dysfunction, and peripheral neuropathy.[83] The biochemical basis of this disorder is a defect in fumarylacetoacetate hydratase, an enzyme

TABLE 50–5 Disorders Associated with Abnormal Liver Function

Category of Disorder	Defect
Amino acid metabolism	Tyrosinemia type I Citrin deficiency Urea cycle defects
Bile acid biosynthesis	See text for specific disorders
Carbohydrate metabolism	Galactosemia Hereditary fructose intolerance
Fatty acid oxidation	Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency Multiple acyl-CoA dehydrogenase deficiency Very-long-chain acyl-CoA dehydrogenase deficiency
Peroxisomal disorders	Neonatal adrenoleukodystrophy Zellweger syndrome
Respiratory chain	Complex I, III, or IV, or combined deficiencies mtDNA depletion syndromes
Other	α_1-Antitrypsin deficiency Congenital disorders of glycosylation Glycogen storage disease type IV Niemann-Pick disease type C

mtDNA, mitochondrial DNA.

acting late in the tyrosine degradative pathway. Fumarylacetoacetate accumulates secondary to this enzyme deficiency and is nonenzymatically converted to succinylacetone, which is the characteristic urinary metabolite identified in patients with this disorder. Succinylacetone can be identified by urine organic acid analysis.

Until recently, the only treatment for this disorder that appeared to be effective was liver transplantation. A new treatment based on pharmacologic inhibition of 4-hydroxyphenylpyruvate dioxygenase (an enzyme upstream of the hydratase in the tyrosine catabolic pathway) with 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) appears to be effective, especially when therapy is begun before the onset of acute liver failure.

Citrin Deficiency

Urea cycle defects are generally associated with mild hepatocellular dysfunction during their acute presentation, but the neurologic manifestations of these disorders are the predominant signs (see "Hyperammonemia"). The degree of hepatocellular disease can become more significant later in the course of these diseases, especially in argininosuccinic aciduria. There is, however, a urea cycle defect, citrin deficiency, that produces neonatal intrahepatic cholestasis.[60]

Citrin deficiency is a genetic disorder caused by deficiency of the mitochondrial aspartate glutamate carrier, which plays a key role in the urea cycle, gluconeogenesis, and the malate shuttle (which moves NADH between intracellular compartments). Impaired citrin function would limit the conversion of citrulline and aspartate to argininosuccinic acid, a key component of the urea cycle. Absent aspartate, citrulline accumulates and urea production is impaired. Hence, citrin deficiency is also known as citrullinemia type II. Citrullinemia type II was previously thought to be a relatively mild adult-onset form of hyperammonemia, whereas citrullinemia type I was a serious neonatal or pediatric disorder associated with argininosuccinic acid synthetase deficiency (see the discussion under "Hyperammonemia" in "Approaches to Specific Abnormal Laboratory Findings").

Subsequently, citrin deficiency was identified as a self-limited disorder that resolves by 1 year of age and can be treated successfully with a low-lactose diet and support for the hepatic dysfunction. However, more severe, progressive cases were also identified that produced neonatal intrahepatic cholestasis.[60] Patients with this form of citrin deficiency had increased serum concentrations of citrulline, methionine, and phenylalanine, as well as galactose. These patients were often ascertained by newborn screening that identified the increased amino acid concentrations and by programs that measure serum galactose as their screen for galactosemia (but not by programs that measure GALT activity) (see "Newborn Screening"). Neonatal citrin deficiency is primarily a cause of cholestatic liver disease rather than hyperammonemia. It is a treatable disease.

BILE ACID BIOSYNTHESIS DEFECTS

Heritable defects in bile acid biosynthesis can cause severe hepatobiliary disease (cholestatic jaundice and intestinal malabsorption) in the newborn infant.[14,28] These defects are probably underdiagnosed because they are not ascertained by the standard methods of metabolic screening of the sick neonate. However, once considered, they can be diagnosed with relative ease. Recognition of these disorders is especially important because effective treatment exists for many of these defects.

In simple terms, bile acid biosynthesis involves conversion of cholesterol to two bile acids, cholic acid and chenodeoxycholic acid. The first steps in this conversion involve transformation of the cholesterol nucleus, and the last few steps involve transformation of the cholesterol side chains. Several defects in conversion of the cholesterol nucleus to bile acids have been described including: 3β-hydroxy-Δ^5-C_{27}-steroid dehydrogenase deficiency and 3-oxo-Δ^4-steroid-5β-reductase deficiency.[14,28] Both of these disorders can result in severe cholestatic disease in the newborn period and can lead in later months to steatorrhea, clinically significant malabsorption of fat-soluble vitamins D and K, failure to thrive, and chronic hepatitis. The patients generally have no or relatively mild hepatomegaly, mildly elevated hepatic aminotransferase values, and nonspecific findings on liver biopsy. If untreated, many patients progress to irreversible liver disease and die in early childhood. Early recognition is crucial because it permits institution of bile acid replacement therapy using a combination of cholic and chenodeoxycholic acids, which is effective in reversing the hepatotoxic manifestations of these enzyme deficiencies.

Several of the peroxisomal disorders also impair bile acid biosynthesis because they affect enzymes required for the final steps of cholesterol side-chain oxidation.[28,99] These enzymes (i.e., the bifunctional enzyme and the thiolase) are also involved in peroxisomal oxidation of very-long-chain fatty acids, and their deficiency leads to a highly pleiotropic dysmorphic syndrome associated with severe neurologic consequences. Bile acid replacement therapy does not ameliorate the neurologic consequences of these disorders. The peroxisomal disorders, including those that produce cholestatic disease, are discussed further under "Dysmorphic Syndromes".

CARBOHYDRATE METABOLISM DISORDERS

Two disorders of carbohydrate metabolism, galactosemia (see "Newborn Screening") and hereditary fructose intolerance, are associated with hepatocellular disease. These disorders manifest only when the newborn's diet contains the monosaccharide to which the newborn is intolerant, such as galactose in the case of galactosemia and fructose in the case of hereditary fructose intolerance. Similarly, these disorders are detectable by urinary screening tests only when the affected newborn is receiving a diet containing the offending monosaccharide. Because fructose is not a component of breast milk and is a component of only the infant formulas that contain sucrose, hereditary fructose intolerance usually does not manifest in the neonatal period. Both disorders can be detected by the presence of reducing substances other than glucose in urine (see "Specialized Biochemical Testing"). The diagnosis of galactosemia[19] or hereditary fructose intolerance must be confirmed by specific biochemical analysis or genetic testing.

Treatment of these disorders consists of dietary restriction of the hepatotoxic monosaccharide. Such restriction is not easily managed because of the nearly ubiquitous presence of galactose (in the form of lactose) and fructose (in the form of sucrose) in many processed foods. Nevertheless, dietary restriction can be successful and is associated with improved long-term outcomes.

Other disorders of carbohydrate metabolism can also cause hepatic dysfunction, including the glycogen storage diseases (especially types I and III), fructose-1,6-diphosphatase deficiency, and pyruvate carboxylase deficiency. These disorders affect gluconeogenesis and, in contrast to galactosemia and hereditary fructose intolerance, result primarily in hypoglycemia rather than generalized hepatocellular dysfunction (see "Hypoglycemia").

FATTY ACID OXIDATION DEFECTS

Several defects of fatty acid oxidation are associated with fat accumulation in the liver and with hepatocellular dysfunction (see Table 50-5). A defect of fatty acid oxidation should be suspected in patients with unexplained hepatocellular disease that is accompanied by nonketotic or hypoketotic hypoglycemia.

One defect of fatty acid oxidation that is a well-established cause of hepatic dysfunction is multiple acyl-CoA dehydrogenase deficiency. This deficiency is a genetically heterogeneous disorder caused by deficiency of one of two proteins that serve as intermediates between several acyl-CoA dehydrogenases that are involved in fatty acid β-oxidation or amino acid degradation, and the mitochondrial respiratory chain. This disorder can also be classified as an organic aciduria and is also called glutaric aciduria type II because glutaric acid is often the principal metabolite observed on urinary organic acid analysis (see "Specialized Biochemical Testing"). Some forms of this disorder are associated with dysmorphic features (see "Dysmorphic Syndromes").

PEROXISOMAL DISORDERS

Several of the peroxisomal disorders cause significant hepatocellular disease in the neonatal period. These syndromes can also produce dysmorphic manifestations and are discussed later.

RESPIRATORY CHAIN DEFECTS

Several respiratory chain defects are associated with hepatocellular disease, but there is no simple rule for predicting which defects cause hepatocellular disease and which do not. The respiratory chain defects that cause hepatic dysfunction in the neonatal period can involve a nuclear-encoded component (nDNA) or a mitochondrial-encoded component (mtDNA) of the respiratory chain (see "Lactic Acidemia"). Respiratory chain defects may be manifested as isolated hepatopathies, in which generalized hepatic dysfunction is the main feature, or as highly diverse multisystem disease, in which hepatic dysfunction occurs with encephalopathy, cardiomyopathy, skeletal myopathy, renal tubular dysfunction, or hematologic abnormalities (see "Lactic Acidemia").[15,88]

A particular group of nuclear-encoded defects has received increasing attention as a cause of hepatic dysfunction—the mitochondrial DNA depletion syndromes.[53,76,80] This is a group of autosomal recessive disorders characterized by reduced mtDNA copy number. Several nuclear genes have been identified as the cause of these disorders including two genes that encode for proteins involved in the mitochondrial nucleotide salvage pathway, deoxyguanosine kinase (DGUOK) and thymidine kinase (TK2), or mitochondrial DNA replication, polymerase γ (POLG), or encode for an inner mitochondrial membrane protein (MPV17). DGUOK, POLG, and MPV17 mutations have been identified as a cause of neonatal liver disease. In some cases, the patients also had encephalopathy. Mutations in the TK2 gene are associated with severe neonatal skeletal myopathy rather than liver dysfunction. The relative contribution of the mitochondrial depletion syndromes to neonatal liver disease, as well as other phenotypes, remains to be established.

OTHER DISORDERS

Three disorders must be considered in the miscellaneous category of inborn errors of metabolism that cause hepatic dysfunction in the newborn period: congenital disorders of glycosylation (CDG), glycogen storage disease type IV, and Niemann-Pick disease type C. The CDG syndromes are discussed under "Dysmorphic Syndromes". Another disorder, neonatal hemochromatosis, can produce severe liver dysfunction, but is not understood to be an inborn error of metabolism.

Glycogen storage disease type IV is a rare disorder that can cause isolated hepatic dysfunction. Niemann-Pick disease type C is a disorder of intracellular cholesterol trafficking that generally causes benign transient neonatal jaundice although it occasionally causes fulminant hepatic failure. The disease subsequently manifests in adolescence or adulthood as a progressive neurodegenerative disorder.

Hepatomegaly and Splenomegaly

Several inborn errors of metabolism are associated with hepatomegaly in the newborn period. In many of these disorders, liver enlargement develops as a result of primary hepatocellular disease. Another group of disorders, the lysosomal storage disorders, result in hepatomegaly because of excessive storage of incompletely metabolized macromolecules in the liver.

Lysosomes contain a large number of enzymes involved in degrading macromolecules. In the absence of one or more of these enzymes, the macromolecules are only partially degraded. Depending on the origin and nature of the macromolecules, the partially degraded products accumulate in one or more tissues or organs and produce a range of clinical phenotypes. The lysosomal storage disorders can be classified according to the types of macromolecules that accumulate in the lysosome: glycogen, glycolipids or other complex lipids, mucopolysaccharides, or oligosaccharides (Table 50-6). Another group of lysosomal storage diseases is associated with defects of lysosomal transport (e.g., cystinosis), but these disorders generally do not manifest in the neonatal period.

Several lysosomal storage disorders manifest in the neonatal period and should be considered in the differential diagnosis of patients who present with hepatomegaly, with or without other signs of storage disease (see Table 50-6).[11,89] Type II glycogen storage disease (Pompe disease) is the only glycogen storage disease caused by a defect in a lysosomal enzyme, but it generally is associated with hypotonia or cardiomyopathy rather than hepatomegaly (see "Cardiomegaly and Cardiomyopathy"). Other glycogenoses, such as glycogen storage disease types I, III, IV, and VI, may be associated with hepatomegaly and, especially in the case of type I disease (von Gierke disease), with hypoglycemia.

TABLE 50–6 Lysosomal Storage Disorders in Neonates

Category of Disorder	Substrate	Disorders
Glycogenoses	Glycogen	GSD type II (Pompe disease) GSD type IV
Lipidoses	Glycolipids or other complex lipids	Farber disease G_{M1}-gangliosidosis Gaucher disease Krabbe disease Niemann-Pick disease Wolman disease
Mucopolysaccharidoses	Mucopolysaccharides	β-Glucuronidase deficiency
Oligosaccharidoses	Glycoproteins Glycolipids	Fucosidosis I-cell disease Sialidosis

GSD, glycogen storage disease.

Several glycolipidoses or related disorders of complex lipid catabolism can manifest with hepatomegaly or splenomegaly in the newborn period.[11,89] Farber disease is an untreatable autosomal recessive defect of acid ceramidase. There are different clinical forms of this disorder, and patients can have joint swelling and pain, hoarseness, disturbance in swallowing, macular cherry-red spots, or central nervous system (CNS) dysfunction. An acute neuronopathic form of Gaucher disease results in hepatosplenomegaly during the first months of life. In these patients, the characteristic neurologic picture includes trismus, strabismus, and retroflexion of the head, followed by inexorable neurologic deterioration. This autosomal recessive disorder is caused by a deficiency of glucosylceramidase. Niemann-Pick disease (i.e., sphingomyelinase deficiency) can begin at birth with hepatosplenomegaly and progress with failure to thrive, psychomotor retardation, pulmonary infiltrates, macular cherry-red spots, and early death. One of the most striking of these disorders is Wolman disease, which is characterized by hepatomegaly, abdominal distention, vomiting, diarrhea, anemia, failure to thrive, and adrenal calcifications. This disorder, caused by lysosomal acid lipase deficiency, invariably leads to early death.

β-Glucuronidase deficiency (i.e., mucopolysaccharidosis type VII) occasionally manifests in the neonatal period, although it usually begins later. It occurs rarely with hydrops fetalis in addition to the more common signs of a mucopolysaccharidosis: hepatosplenomegaly, inguinal or umbilical hernias, skeletal dysplasia, corneal clouding, and coarse facial features.

Four oligosaccharidoses are manifested in the neonatal period. I-Cell disease is characterized by coarse facies and disproportionate craniofacial features, limitation of joint movement, hepatosplenomegaly, corneal clouding, and gingival hypertrophy. Severe forms of fucosidosis, galactosialidosis, and sialidosis may have a similar manifestation. Patients with these defects of mucopolysaccharide or oligosaccharide catabolism might also present with hydrops fetalis.

Two other lysosomal storage disorders can manifest in the neonatal period, but neither is associated with hepatomegaly in the first month of life. Patients with the infantile form of G_{M1}-gangliosidosis (i.e., β-galactosidase deficiency) have psychomotor delay and coarse facial features but do not develop hepatomegaly until later in the first year of life. These patients might also have cherry-red spots.[66] Rarely, Krabbe disease (i.e., galactosylceramidase deficiency) begins in the neonatal period with progressive psychomotor retardation, but hepatomegaly does not develop in affected patients.

Preliminary clinical assessment of a patient with a suspected lysosomal storage disease should include a careful eye examination to detect corneal clouding, cataracts, or abnormal retinal pigment changes; a cardiac evaluation, including an electrocardiogram and echocardiogram; a peripheral blood smear to detect leukocyte inclusions; and a radiologic study of the skeleton for identification of dysostosis multiplex. Leukocyte inclusions are characteristic of the oligosaccharidoses (i.e., fucosidosis, I-cell disease, α-mannosidosis, and sialidosis), are the exception in the glycolipidoses (e.g., Niemann-Pick disease), and are not found in glycogen storage disease type II. Laboratory evaluation of lysosomal disorders is presented in "Specialized Biochemical Testing".

Other than supportive care, organ transplantation appears to offer the only possibility for definitive treatment for lysosomal storage disorders. Bone marrow transplantation, and possibly cord blood transplantation, can arrest or even reverse some of the somatic disease and neurologic degeneration associated with some of these disorders.[61,89]

Sepsis

A newborn infant with a metabolic disease may be at greater risk for sepsis than other neonates, and the presence of documented sepsis does not exclude the possibility of an underlying metabolic disorder. Several inborn errors of metabolism predispose the newborn infant to infections. The best-documented of these associations is the risk of *E. coli* infection in patients with galactosemia. Infections with other bacteria can also develop, but an *E. coli* infection is relatively specific. The diagnosis of galactosemia should be suspected in all neonates with *E. coli* sepsis, and these infants might need a galactose-free formula until the diagnosis has been excluded.

Unusual Odor

Several inborn errors of metabolism are characterized by unusual odors (Table 50-7). In many of these disorders, the odor is an inconstant finding and can be detected only during episodes of acute metabolic decompensation. In some cases, the odor is difficult to appreciate during a bedside examination and can more easily be detected by smelling a urine specimen that has been kept at room temperature for several hours or a paper sheet that has been stained with urine and air dried.

TABLE 50–7 Characteristic Odors of Several Neonatal Inborn Errors of Metabolism

Disorder	Nature of Odor
Isovaleric acidemia	Sweaty feet
Maple syrup urine disease	Maple syrup
β-Methylcrotonyl-CoA carboxylase deficiency	Male cat urine
Multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type II)	Sweaty feet
Multiple carboxylase deficiency	Male cat urine
Phenylketonuria	Musty

Dysmorphic Syndromes

Newborn infants with inborn errors of metabolism usually are not dysmorphic, and therefore metabolic evaluations of dysmorphic patients are not likely to be fruitful (see Chapter 29). However, many inborn errors of metabolism cause dysmorphic syndromes. Most of these disorders affect large-molecule metabolism or organelle biogenesis and function, but increasing numbers of inborn errors of small-molecule metabolism are being identified that also produce dysmorphic syndromes.

DEFECTS IN LARGE-MOLECULE METABOLISM

Two groups of inborn errors of large-molecule metabolism produce dysmorphic syndromes: defects of glycoconjugate biosynthesis and the lysosomal storage disorders (Table 50-8). The defects of glycoconjugate biosynthesis are commonly referred to as the congenital disorders of glycosylation syndromes. From a pathogenetic perspective, the CDG syndromes represent the mirror image of the lysosomal storage disorders. The CDG syndromes are the consequence of enzyme deficiencies that impair the biosynthesis of glycoconjugates, whereas the lysosomal storage disorders are primarily the consequence of enzyme deficiencies that impair the biodegradation of glycoconjugates.

Congenital Disorders of Glycosylation

The CDG are a highly pleiotropic group of disorders, which are caused by genetic deficiencies in the biosynthesis of glycoconjugates. The prototypic form of this disorder, which is now referred to as *CDG type Ia* (CDG-Ia), has a characteristic pattern of dysmorphism plus multisystem disease.[36,48] Most patients with this form of CDG present in the neonatal period or in early infancy with neurologic abnormalities, including strabismus or other eye movement abnormalities, hypotonia, ataxia, and with time, developmental delay. Other problems at presentation can include failure to thrive (usually attributed to poor feeding, vomiting, or diarrhea), cardiac problems (cardiomegaly, cardiomyopathy, or pericardial effusion), hepatomegaly (associated with mild elevations in liver enzyme values and hypoalbuminemia), proteinuria, skeletal anomalies, and recurrent infections, especially of the pulmonary tree.

The dysmorphism characteristically associated with this disorder includes an abnormal pattern of fat distribution, with an especially prominent fat pad in the buttocks, doughy skin texture, and inverted nipples. This pattern of dysmorphism can be recognized in the neonatal period.

Cranial imaging demonstrates cerebellar or olivopontocerebellar hypoplasia and a milder degree of cerebral hypoplasia. Microscopic examination of liver biopsy specimens reveals a characteristic form of fibrosis, whereas ultrastructural studies demonstrate a characteristic pattern of lysosomal inclusions and changes in the endoplasmic reticulum.

About 20% of patients with neonatal onset of the disease die in the first year of life as a result of cardiac failure, liver failure, or infection. Those who survive the first year of life manifest severe mental retardation, ataxia, peripheral neuropathy, retinal pigmentary degeneration, and skeletal dysplasia.

The characteristic biochemical marker of this disease is a generalized abnormality of glycosylation of circulating and cell membrane glycoproteins. The diagnosis of CDG-Ia is made by isoelectric focusing of transferrin, a circulating glycoprotein that contains two carbohydrate side-chains attached by N-glycosidic linkage to the peptide backbone of the protein. Patients with CDG type Ia show an immunoisoelectric focusing pattern consistent with underglycosylation. The underlying cause of this syndrome is an autosomal recessive defect in phosphomannomutase, which is one of the enzymes required for biosynthesis of mannose-containing glycoconjugates. There is no effective treatment for type Ia disease.

Approximately two dozen forms of CDG have been described since type Ia was identified and the transferrin immunoisoelectric focusing analysis was developed.[36,48] The immunoisoelectric focusing test has provided a useful method for identifying additional forms of CDG with a remarkable range of clinical phenotypes. For example, CDG-Ib is one of the most distinctive of these variants, because it manifests with hepatic and intestinal problems rather than neurologic problems. This variant produces hypoglycemia, protein-losing enteropathy, failure to thrive, vomiting, diarrhea, hepatomegaly and hepatic dysfunction associated with congenital hepatic fibrosis, and thrombosis or an increased bleeding tendency. Type Ib is caused by deficiency of another enzyme involved in mannose metabolism, phosphomannose isomerase. Unlike the situation for CDG-Ia, patients with CDG-Ib can be treated effectively with oral mannose supplementation. The clinical problems of several patients with type Ib disease have been reversed with this form of therapy. The other CDG disorders are primarily neurologic disorders associated

TABLE 50–8 Inborn Errors of Metabolism That Cause Dysmorphic Syndromes

Category of Disorder	Syndrome
Large-Molecule Metabolism	
Disorder of glycoconjugate biosynthesis	Congenital disorders of glycosylation
Lysosomal storage diseases	Glycolipidoses Mucopolysaccharidoses Oligosaccharidoses
Small-Molecule Metabolism	
Cholesterol biosynthesis	Conradi-Hunermann syndrome Desmosterolosis Smith-Lemli-Opitz syndrome
Organic acidurias	3-Hydroxyisobutyryl-CoA deacylase deficiency Mevalonic aciduria* Multiple acyl-CoA dehydrogenase deficiency
Peroxisomal Disorders	
Biogenesis disorders	Chondrodysplasia punctata, rhizomelic type Zellweger syndrome and its variants Infantile Refsum disease Neonatal adrenoleukodystrophy
Single-enzyme defects	Acyl-CoA oxidase deficiency Bifunctional enzyme deficiency Thiolase deficiency

*Mevalonic aciduria has been classified as an organic acidemia on the basis of the method used for its diagnosis, but it can also be classified as a peroxisomal single enzyme disorder or as a defect in cholesterol biosynthesis because of its intracellular location and function, respectively.

with severe developmental delay and mental retardation, but many of them also have distinguishing features.

In addition to the forms of CDG that involve N-linked glycoconjugates, analogous defects in O-linked glycoconjugates have been identified. Patients with these defects cannot be ascertained by the transferrin isoelectric focusing test, because it only detects abnormalities of N-linked glycoconjugates. Several defects in O-linked glycoconjugation have been identified, including Walker-Warburg syndrome (a neuronal migration abnormality associated with malformations of the brain and eye, and congenital muscular dystrophy) and hereditary multiple exostosis (multiple osteochondromas). There is every reason to expect that additional disorders of N-linked and O-linked glycosylation will be identified in the future.

Lysosomal Storage Diseases

Several lysosomal storage disorders begin in the neonatal period with cardiomegaly, characteristic ocular abnormalities, or hepatomegaly (Staretz-Chacham). Many of the patients have dysmorphic features, including coarse facies, macroglossia, and skeletal dysplasia (dysostosis multiplex). At least one mucopolysaccharidosis (β-glucuronidase deficiency), four oligosaccharidoses (fucosidase deficiency, galactosialidosis, I-cell disease, and sialidase deficiency), and one glycolipidosis (G_{M1}-gangliosidosis) begin in this way. The laboratory evaluation of these disorders is presented under "Tests for Lysosomal Storage Disorders". Definitive diagnosis requires specific enzyme analysis.

DEFECTS IN SMALL-MOLECULE METABOLISM

The inborn errors of small-molecule metabolism that produce dysmorphic syndromes are a highly heterogeneous group of disorders (see Table 50-8). As a class, this group represents disorders of endogenous teratogenesis. The pathogenesis of each disorder appears to be unique. Further study of these disorders should enhance our understanding of the mechanisms of teratogenesis and development in general.

Cholesterol Biosynthesis

Several defects of cholesterol biosynthesis manifest in infancy. The best understood defects of steroid biosynthesis are those that lead to the congenital adrenal hyperplasia syndromes. The most common of these syndromes, 21-hydroxylase deficiency, is associated with dysmorphogenesis (i.e., ambiguous genitalia) and electrolyte imbalances. This class of disorders is discussed more fully in Chapter 49.

Inborn errors of cholesterol biosynthesis include defects in the early steps of the pathway and defects in the late steps. Mevalonic aciduria is caused by a defect in an early step in cholesterol biosynthesis (i.e., mevalonate kinase deficiency) and is discussed in the next section (see "Organic Acidurias").

Smith-Lemli-Opitz (SLO) syndrome is a prominent example of a recognizable malformation disorder that is caused by a defect in a late step in cholesterol biosynthesis.[41,67,95] SLO syndrome was recognized in the 1970s as a highly variable malformation syndrome. In its mild form the disorder is characterized by prenatal and postnatal growth restriction, microcephaly, characteristic craniofacial dysmorphism (including ptosis, low-set ears, epicanthal folds, and micrognathia), strabismus, syndactyly of the second and third toes, hypospadias, and mental retardation. In its most severe form, patients also exhibit postaxial polydactyly, cleft palate, eye malformations, holoprosencephaly, cardiac defects, and, in boys, pseudohermaphroditism ranging from hypospadias to sex reversal. At autopsy, a range of severe malformations of the brain, heart, and kidneys can be identified. The mild phenotypes are designated SLO syndrome type I, and the severe phenotypes are designated SLO syndrome type II; however, the distinction between the two types was arbitrary, and the pathogenetic relationship between the two types was unknown.

In 1994, the genetic basis of SLO syndrome was shown to be a heritable defect in cholesterol biosynthesis.[41,95] Patients were found to have an abnormally low plasma cholesterol concentration and a markedly increased concentration of 7-dehydrocholesterol and, to a lesser degree, 8-dehydrocholesterol in plasma and cultured skin fibroblasts. Further work established the enzymatic basis of this syndrome as an autosomal recessive defect affecting the synthesis of 7-dehydrocholesterol reductase. SLO types I and II appear to be allelic forms of this enzyme deficiency. After recognition of the underlying defect causing the SLO syndrome and development of specific methods for diagnosis, SLO syndrome has been recognized as a relatively common inborn error of metabolism, with a frequency of approximately one case in 20,000 persons.

The diagnosis of SLO syndrome should be investigated in patients with suggestive clinical phenotypes. Because the clinical phenotype is so variable and may be difficult to recognize in female patients without obvious genital anomalies, the diagnosis should also be pursued in patients with low plasma cholesterol concentrations. The diagnosis should also be pursued in patients who have a suggestive clinical phenotype but normal plasma cholesterol concentrations, because many of the methods in standard clinical use for measuring the plasma cholesterol concentration are relatively nonspecific and could yield false-negative results for patients with SLO syndrome. SLO syndrome can be diagnosed more specifically by measuring 7-dehydrocholesterol in plasma or cultured skin fibroblasts using gas chromatography or gas chromatography with mass spectrometry.

Efforts to treat SLO patients with supplemental cholesterol were begun immediately after recognition of the biochemical basis of the disease. Cholesterol supplementation could improve some aspects of the outcome, including the behavioral aspects of the disease, especially when treatment is begun very early in infancy.[41] As expected, the outcome appears to be better for patients with milder forms of the disease than for those with the severe forms (patients with significant defects in prenatal morphogenesis). However, the long-term intellectual outcome of this form of treatment remains poor.

Other defects of cholesterol biosynthesis have been identified subsequent to the discovery of the genetic basis of SLO syndrome, including Conradi-Hunermann syndrome, the rhizomelic form of chondrodysplasia punctata, lathosterolosis, desmosterolosis, Greenberg skeletal dysplasia, and CHILD (*c*ongenital *h*emidysplasia, *i*chthyosiform erythroderma, and *l*imb *d*efects) syndrome.[41,67]

Patients with Conradi-Hunermann syndrome have chondrodysplasia punctata and rhizomelic skeletal dysplasia. Chondrodysplasia punctata is a distinctive radiologic finding, which refers to the abnormal pattern of punctate calcification of epiphysial cartilage and related tissues. This finding can be seen in some of the neonatal forms of peroxisomal disease (e.g., Zellweger syndrome) as well as SLO syndrome.

Rhizomelic dysplasia is a pattern of proximal limb shortening that is found in several malformation syndromes. Using the same analytic methods required to diagnose and evaluate patients with SLO syndrome, a previously unrecognized defect in sterol biosynthesis was identified in a fraction of patients with the rhizomelic form of chondrodysplasia punctata and in patients with Conradi-Hunermann syndrome.

Desmosterolosis has an osteosclerotic form of skeletal dysplasia and malformations similar to SLO syndrome. It appears that defects of sterol biosynthesis will prove to be responsible for a family of recognizable malformation syndromes, including many characterized by unusual skeletal dysplasia.

Organic Acidurias

Three organic acidurias (or acidemias) are associated with dysmorphic syndromes: 3-hydroxyisobutyryl-CoA deacylase deficiency, mevalonate kinase deficiency (mevalonic aciduria), and multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type II).

3-HYDROXYISOBUTYRYL-CoA DEACYLASE DEFICIENCY

3-Hydroxyisobutyryl-CoA deacylase deficiency is a rare disorder that produces craniofacial dysmorphism, vertebral anomalies, tetralogy of Fallot, and agenesis of the corpus callosum.[8] The deficient enzyme plays a role in valine catabolism. In the absence of this enzyme, the precursor of 3-hydroxyisobutyryl-CoA, methacrylyl-CoA, accumulates and is conjugated with cysteine to form two unusual metabolites that are excreted in the urine. This disorder is detected by urinary amino acid analysis, which reveals the unusual cysteine conjugates.

This disorder appears to be caused by intracellular accumulation of methacrylyl-CoA or methacrylate, which is formed by nonenzymatic hydrolysis of methacrylyl-CoA. Methacrylate is a potent teratogen in various animal models. In addition to this defect, several patients with 3-hydroxyisobutyric aciduria did not have deacylase deficiency or another recognizable enzyme deficiency in the valine pathway. The clinical phenotype of these patients was similar to that of the patient with deacylase deficiency, including significant craniofacial and cerebral dysmorphism, which was accompanied in some cases by intracerebral calcifications. Although the underlying defect has not been identified in these patients, the presumption is that a defect in the metabolism of 3-hydroxyisobutyric acid led to the intracellular accumulation of methacrylate or a related teratogen.

MEVALONATE KINASE DEFICIENCY

Mevalonic aciduria is caused by a rare defect, mevalonate kinase deficiency, in an early step in cholesterol biosynthesis.[29] It is classified as an organic aciduria because it is diagnosed by urine organic acid analysis. It can also be classified as a peroxisomal single enzyme disorder because mevalonate kinase is located within the peroxisome (see “Peroxisomal Disorders”).

The pathogenesis of this disorder is complex because mevalonic acid has a role in several key pathways. In addition to its role as a precursor of cholesterol, mevalonic acid is a precursor of dolichol, which is required for complex carbohydrate biosynthesis; heme, which plays a key role in oxygen transport; and ubiquinone, a component of the respiratory chain (see “Lactic Acidemia”).

Mevalonate kinase deficiency is a highly pleiotropic disorder associated in the newborn period with dysmorphic features (e.g., nonspecific craniofacial anomalies, cataracts), hepatosplenomegaly, lymphadenopathy, diarrhea, hypotonia, and anemia. In severe cases, it leads to profound failure to thrive, developmental delay, and early death. Although the defect would be expected to lead to lactic acidosis because of decreased synthesis of ubiquinone and malfunctioning of the respiratory chain, lactic acidosis is not a common feature of the disorder. The hypocholesterolemia seen in these patients is generally mild. Alternatively, mevalonate kinase deficiency can produce a very different clinical phenotype, hyper IgD syndrome, which is one of the periodic fever disorders. Mevalonic aciduria and hyper IgD syndrome appear to be allelic forms of mevalonate kinase deficiency.

The characteristic diagnostic feature is mevalonic aciduria, which can be documented by urinary organic acid analysis. No effective treatment exists for this disorder, although corticosteroids might be of some benefit.

MULTIPLE ACYL-CoA DEHYDROGENASE DEFICIENCY

Multiple acyl-CoA dehydrogenase deficiency was originally known as glutaric aciduria type II because of the very large urinary excretion of glutaric acid, a product of amino acid catabolism (lysine, hydroxylysine, and tryptophan) (see “Newborn Screening”). The organic acid pattern also shows many other metabolites, and the disorder came to be called multiple acyl-CoA dehydrogenase deficiency when it was recognized that the pattern reflected deficient activity of several flavin-dependent acyl-CoA dehydrogenases. These dehydrogenases are required for amino acid catabolism and fatty acid oxidation. The biochemical defect affects one of two proteins (electron-transfer flavoprotein [ETF] or ETF dehydrogenase) involved in transferring electrons generated by flavin-dependent acyl-CoA dehydrogenases to the respiratory chain.

Multiple acyl-CoA dehydrogenase deficiency is a clinically heterogeneous disorder; the most severe form is associated with metabolic consequences (e.g., acidosis, hypoglycemia, ketosis) and dysmorphic consequences (e.g., craniofacial dysmorphism, polycystic kidneys, cerebral cortical dysplasia, intrahepatic biliary hypoplasia). A less-severe form is associated with similar metabolic consequences but no dysmorphism. The dysmorphic form of the disease is found in some patients with ETF dehydrogenase deficiency, and the nondysmorphic form is associated with ETF deficiency. It is unclear how ETF dehydrogenase deficiency leads to dysmorphism.

Peroxisomal Disorders

Many of the peroxisomal disorders produce dysmorphic syndromes. The peroxisomal disorders are a highly diverse group of disorders, reflecting the metabolic diversity of the enzymes contained within this small organelle.[99] In contrast to the lysosome, which primarily contains a large number of degradative enzymes, the peroxisome contains biosynthetic and catabolic enzymes. Many of these enzymes are involved in unusual oxidation reactions; the name of this organelle was derived from one such reaction involving hydrogen peroxide.

The peroxisomal disorders are classified into two groups: defects of peroxisome biogenesis and defects affecting a single enzyme (see Table 50-8; see “Test for Peroxisomal Disorders”).[99]

BIOGENESIS DISORDERS

The first group consists of disorders associated with absent or severely reduced numbers of peroxisomes and multiple enzyme deficiencies. These disorders are caused by defects in peroxisomal biogenesis, which lead to impaired import of proteins and enzymes into the peroxisome.[54] The paradigm of this group of disorders is Zellweger syndrome, an autosomal recessive trait characterized by craniofacial dysmorphism, severe psychomotor retardation, renal cortical cysts, epiphyseal stippling, failure to thrive, and early death. Epiphyseal stippling is an unusual radiographic finding of ectopic calcification found most characteristically in the ankle, patella, vertebrae, hips, and trachea (see “Cholesterol Biosynthesis” earlier). Other peroxisomal assembly disorders include neonatal adrenoleukodystrophy, infantile Refsum disease, and rhizomelic chondrodysplasia punctata.

Genetic studies have identified approximately 20 different genetic loci associated with peroxisomal biogenesis defects. Genetic complementation studies have shown that Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease represent allelic variants at many of these loci. Zellweger syndrome is the most severe variant, and infantile Refsum disease is the least severe variant. There is no cure or effective treatment for this group of disorders.

Rhizomelic chondrodysplasia punctata is the consequence of mutations at one of the other loci involved in peroxisomal biogenesis. Peroxisomal deficiencies have been found only in the rhizomelic form of chondrodysplasia punctata, which is an autosomal recessive disorder characterized by severe shortening of the proximal extremities (hence the term *rhizomelic*), craniofacial dysmorphism, congenital cataracts, joint contractures, and severe psychomotor retardation. The skeletal abnormalities of this form of dwarfism are evident in the neonatal period. There is no treatment for this disorder.

SINGLE-ENZYME DEFECTS

The second group of peroxisomal disorders includes defects associated with a normal number of peroxisomes and a single enzyme deficiency. The best-known disorder in this group is X-linked adrenoleukodystrophy, which does not produce dysmorphism and does not manifest in the neonatal period, and it therefore is not discussed further. However, several other peroxisomal monoenzymopathies with onset in the neonatal period have been recognized.[99] Several of these disorders have been identified in patients who appear to have the physical stigmata of Zellweger syndrome or its variants but have normal numbers of peroxisomes. The best characterized of these disorders are acyl-CoA oxidase deficiency, bifunctional enzyme deficiency, and thiolase deficiency. These three enzymes share a common biochemical role in peroxisomal (rather than mitochondrial) fatty acid oxidation and bile acid biosynthesis. The predominantly dysmorphic abnormalities and many of the laboratory abnormalities associated with Zellweger syndrome and its variants therefore can be attributed to abnormal fatty acid metabolism or abnormal bile acid metabolism. Similarly, defects affecting the enzymes that catalyze plasmalogen biosynthesis produce a clinical phenotype that resembles rhizomelic chondrodysplasia punctata.

Several other single-enzyme deficiencies have been described that do not involve the peroxisomal pathways of fatty acid oxidation or plasmalogen biosynthesis. One of these disorders, mevalonic aciduria, is a defect in cholesterol biosynthesis and is described under "Organic Acidurias."

VITAMIN K METABOLISM

Vitamin K epoxide reductase deficiency is an autosomal recessive disorder that produces a phenocopy of the fetal warfarin embryopathy syndrome.[63] The enzyme deficiency is characterized by persistent coagulopathy, stippled epiphyses, nasal hypoplasia, brachydactyly with distal digital hypoplasia, and conductive hearing loss. Vitamin K epoxide reductase is the site of warfarin's pharmacologic action. The various dysmorphic features of fetal warfarin syndrome and vitamin K epoxide reductase deficiency are consequences of impaired activity of the vitamin K-mediated carboxylation reactions, which include proteins of the bone matrix and circulating coagulation factors. Vitamin K supplementation is an effective therapy for the coagulopathy associated with this disorder but might not be effective for the other manifestations because of their prenatal onset.

THE ABNORMAL NEWBORN INFANT: LABORATORY PHENOTYPES

Biochemical Testing

The laboratory evaluation plays a key role in the differential diagnosis of the metabolic disorders of infancy. The laboratory investigation of these patients should be staged. It should begin with broadly focused screening tests, which are then followed by more specialized examinations. Laboratory findings helpful in the differential diagnosis of suspected metabolic disease are listed in Table 50-9. A complete discussion of each of these findings is provided in the next section.

SCREENING STUDIES

The precise composition of the metabolic screen varies from one institution to another. There should be, however, a core of tests available at all institutions that care for sick neonates.[2,11] A suggested list of tests is presented in Table 50-10. These laboratory tests are chosen because they provide a relatively rapid, inexpensive evaluation for a wide range of disorders. It is strongly recommended that the specific details of collection and handling of all samples be clearly understood before samples are obtained and that there be collaboration with laboratory personnel throughout the process.

Blood Studies

A number of blood studies are indicated, many of which are routinely performed during the care of sick neonates. The complete blood cell count should include examination of cell morphology and a differential cell count. Neutropenia and thrombocytopenia may be associated with a number of the organic acidemias, including isovaleric acidemia, methylmalonic acidemia, and propionic acidemia (see "Hematologic Abnormalities").[40] Neutropenia may be found with glycogen storage disease type Ib, an uncommon variant of glucose-6-phosphatase deficiency.[96] This variant is caused by a defect of the glucose-6-phosphate translocase associated with the phosphatase rather than the phosphatase itself (see "Hypoglycemia"). Barth syndrome can also be a cause of neonatal neutropenia (see "Cardiomegaly and Cardiomyopathy").[5] Pearson syndrome, a respiratory chain defect, can cause pancytopenia (see "Lactic Acidemia"). Megaloblastosis may be found in disorders of purine biosynthesis, such as some rare forms of homocystinuria or orotic aciduria.

TABLE 50–9 Laboratory Findings Helpful in the Differential Diagnosis of Suspected Metabolic Disease in Neonates

Finding	Diagnostic Considerations
Acidosis (see Figs. 50-1 and 50-2)	Fatty acid oxidation defects Gluconeogenesis defects Glycogen storage diseases Ketogenesis defects Ketolytic defects Krebs cycle defects Organic acidemias Respiratory chain defects
Alkalosis: respiratory	Urea cycle defects
Alkalosis: metabolic	Steroid biosynthetic defects
Hepatic dysfunction (see Table 50-5)	Amino acid defects Bile acid biosynthesis defects Carbohydrate defects Fatty acid oxidation defects Peroxisomal disorders Respiratory chain defects Other
Hyperammonemia (see Box 50-2 and Fig. 50-4)	Amino acid disorders Fatty acid oxidation defects Organic acidemias Urea cycle defects
Hypoglycemia (see Table 50-17 and Fig. 50-3)	Fatty acid oxidation defects Gluconeogenesis defects Glycogen storage disease Ketogenesis defects Organic acidemias
Ketosis/ketonuria	Amino acid defects Gluconeogenic defects Glycogen storage diseases Ketolytic defects Organic acidemias
Pancytopenia	Organic acidemias Respiratory chain defects
Proximal renal tubular dysfunction (see Table 50-14)	Amino acid defects Carbohydrate defects Respiratory chain defects

TABLE 50–10 Initial Laboratory Screening of Neonates with Suspected Metabolic Disease

Body Fluid	Laboratory Studies
Blood	Blood cell count Electrolytes Blood gases Lactate and pyruvate Glucose Ketones (β-hydroxybutyrate and acetoacetate) Ammonia Uric acid
Urine	Smell Crystalluria Reducing substances pH Acetone α-Ketoacids (diphenylhydrazone) Ferric chloride
Cerebrospinal fluid	Glucose Lactate and pyruvate

Electrolytes and blood gases are required to determine whether acidosis or alkalosis exists and, if so, whether the abnormality is associated with an increased anion gap. Lactate and pyruvate analysis should be measured to identify the nature of any excess anions (see "Lactate and Pyruvate Analysis"). Lactic acidemia may be present without frank acidosis.

Hypoglycemia is a frequent finding in sick neonates, especially premature infants, but is also a critical finding in some metabolic disorders. Hypoglycemia should be investigated further when it is severe, when accompanied by other signs of metabolic disease, or when it proves refractory to conventional therapy.

Ketones (i.e., β-hydroxybutyrate and acetoacetate) are useful in developing a differential diagnosis for newborns with hypoglycemia. In particular, nonketotic or hypoketotic hypoglycemia is the hallmark of defects of fatty acid oxidation.

The blood ammonia concentration should be determined in all neonates with evidence of unexplained lethargy and neurologic intoxication. Early recognition of the congenital hyperammonemias is crucial because they are a rapidly progressive group of disorders that can quickly lead to irreversible damage after hours rather than days. Effective treatment is available for many of these disorders, but it must be instituted early in the course of the disease.

A blood uric acid test is a convenient screen for the few inborn errors of metabolism that are associated with hypouricemia or hyperuricemia. Type I glycogen storage disease is probably the most common inherited disorder associated with hyperuricemia (see "Hypoglycemia"), whereas xanthine dehydrogenase deficiency caused by molybdenum cofactor deficiency causes hypouricemia (see "The Sick Newborn Infant").

Urine Studies

A urine sample should be sent for metabolic screening using simple colorimetric agents or strips, if such testing is still available at one's institution (Table 50-11).[2,11] However, this approach to testing has been abandoned or replaced by more specialized forms of testing in most institutions, and it is no longer possible to obtain. In this event, a urine specimen should be sent directly for the more specialized testing. In any event, an aliquot of urine should be collected, covered, and set aside by the infant's incubator when possible. After a few hours at room temperature, the specimen should be smelled for evidence of an unusual odor. Several inborn errors of metabolism, especially the organic acidurias, are associated with characteristic odors (see Table 50-7).

Urine specimens should be tested for reducing substances, which include principally the monosaccharides (i.e., simple sugar molecules). The Clinitest reaction detects excess excretion of galactose and glucose but not fructose. False-positive reactions are found with ampicillin and related penicillin derivatives and with some other drugs that are excreted as their glucuronide conjugates. A specimen that shows a positive reaction with the Clinitest reaction should be investigated further by means of the Clinistix reaction (i.e., glucose oxidase), which is specific for the monosaccharide glucose. A specimen with positive Clinitest and negative Clinistix results should be analyzed specifically for galactose.

The urine pH should be determined in order to characterize the renal response to an alteration in blood pH. In the face of a significant acidemia, the kidneys should produce an acidic urine (pH less than 5). A renal acidification disorder should be considered in the absence of an appropriate urine pH.

Spot tests may be used to detect excessive urinary excretion of ketones, α-ketoacids, or other metabolites. Ketonuria should be investigated, especially in patients with hypoglycemia. The Acetest or Ketostix reactions are used for acetone and acetoacetate, and the 2,4-dinitrophenylhydrazone (DNP) reaction is used for α-ketoacids.

TABLE 50–11 Characteristic Urinary Findings in Inborn Errors of Metabolism

Finding	Disorder
Reducing substance	Hereditary fructose intolerance Galactosemia Hereditary tyrosinemia
Acetonuria	Organic acidemias
DNP (α-ketoacids)	Maple syrup urine disease Phenylketonuria Tyrosinemia type I
Ferric chloride	Phenylketonuria Tyrosinemia type I
Nitrosonaphthol	Tyrosinemia type I
p-Nitroaniline	Methylmalonic acidemia
Sulfitest	Sulfite oxidase deficiency

DNP, 2,4-dinitrophenylhydrazone.

The ferric chloride reaction is also a useful test, although it is relatively insensitive and subject to potentially misleading false-positive reactions with several drugs. It is helpful when used in conjunction with other screening studies, such as in detecting PKU and tyrosinemia.

Several other screening studies are recommended for use in special circumstances. These studies include the nitrosonaphthol reaction, which detects certain tyrosine metabolites; the *p*-nitroaniline reaction, which is relatively specific for methylmalonic aciduria; and the Sulfitest, which detects excess sulfite excretion in patients with sulfite oxidase deficiency.

Cerebrospinal Fluid Studies

Many sick infants undergo lumbar puncture for CSF analysis as part of a sepsis evaluation. In addition to obtaining the standard samples for CSF glucose and protein analysis, additional samples for more specialized testing, such as lactate and pyruvate analysis or amino acid analysis, should also be obtained if clinically indicated. When possible, appropriate blood samples should be collected at the same time as the lumbar puncture is performed to permit comparison of blood and CSF concentrations. For example, concurrent plasma and CSF glycine measurements are required for the diagnosis of nonketotic hyperglycinemia (see "The Sick Newborn Infant").

SPECIALIZED BIOCHEMICAL TESTING

Screening studies help determine whether further metabolic testing is indicated and, if so, what testing should be done next (Table 50-12). In general, the more specialized tests require relatively sophisticated equipment and personnel to perform and interpret, take longer to perform (sometimes days to weeks), are more expensive, and are usually available in only a few centers. All physicians who might care for a sick neonate with a suspected inborn error of metabolism should develop their own referral system for patients with various metabolic abnormalities. It is a good idea to set up a referral system in advance of a specific emergency so that appropriate referral can be obtained more easily when the time comes.

Because not all patients require transfer or tolerate transfer to a tertiary care center, plans should also be on hand for collecting samples for various specialized tests. It is truly unfortunate when the often extraordinary and well-intentioned efforts of those caring for a sick newborn infant are subverted by improper collection or handling of samples. Detailed requirements for collection and handling of samples for various metabolic analysis should be available in the nursery, and they should be kept in a place where they can be found in an emergency.

The distinction between a screening study and a specialized follow-up test is not always clear. In some circumstances, the physician would proceed directly to performing a specialized study. For example, a urinary organic acid analysis should be performed as soon as a neonate is thought to have a metabolic acidosis or has an unusual odor typical of one of the neonatal organic acid disorders. Similarly, it is generally best to perform some of the specialized studies during an episode of acute metabolic decompensation, such as hypoglycemia, when they are most likely to be informative, rather than waiting until the results of the screening tests become available. As a rule, the sequence of ordering tests should be compressed in an acutely ill patient.

TABLE 50–12 Specialized Laboratory Tests That May Be Required for the Care of Neonates with Suspected Metabolic Disease

Body Fluid or Tissue	Laboratory Tests
Blood	Amino acids Carnitine (total, free, and acylcarnitine profile) Lactate and pyruvate Tests for congenital disorders of glycosylation: Transferrin immunoelectrophoresis or mass spectrometry Tests for peroxisomal disorders: Very-long-chain fatty acids Phytanic acid
Urine	Amino acids Carnitine (total, free, and acylcarnitine profile) Organic acids Tests for lysosomal storage disorders: Glycolipids Mucopolysaccharides Oligosaccharides
Cerebrospinal fluid	Amino acids Lactate and pyruvate
Other	
Cultured skin fibroblasts	Enzyme studies Genetic studies Metabolite analysis
White blood cells	Enzyme studies Genetic studies

Amino Acid Analysis

The most commonly performed of the specialized studies is probably quantitative plasma and urinary amino acid analysis.[2,10,11] Some laboratories provide a qualitative amino acid screening study performed by paper or thin-layer chromatography as part of their screening protocol. Although this study may be useful, it does not substitute for a quantitative determination when the clinical findings suggest a disorder that is reflected in an abnormal amino acid pattern (Table 50-13). In most cases, a complete quantitative analysis is required, whereas in other situations, specific amino acids should be the focus of attention.

It is important to provide the laboratory performing the quantitative analysis with all relevant clinical and laboratory data so that it can focus on specific amino acids as needed.

TABLE 50–13 Neonatal-Onset Inborn Errors of Metabolism Characterized by Abnormal Plasma Amino Acid Patterns

Disorder	Finding
Amino Acid Disorders	
Maple syrup urine disease	↑Isoleucine, leucine, valine
Nonketotic hyperglycinemia*	↑Glycine
Phenylketonuria	↑Phenylalanine
Sulfite oxidase deficiency	↑S-Sulfocysteine
Hereditary tyrosinemia	↑Tyrosine, methionine
Lactic Acid Disorders	
Respiratory chain defects	↑Alanine (± proline)
PC deficiency	↑Alanine, citrulline, lysine
Organic Acidemias	
Methylmalonic acidemia	↑Glycine
Isovaleric acidemia	↑Glycine
Propionic acidemia	↑Glycine
Urea Cycle Disorders	
Urea cycle defects	↑Glutamine, ↓arginine, plus . . .
Argininosuccinic aciduria†	↑ASA, ↓citrulline
Citrullinemia	↑↑Citrulline
CPS and OTC deficiency	↓Citrulline

*Glycine concentrations are elevated in plasma and, to an even greater extent, in the cerebrospinal fluid.

†ASA is present in very large amounts in urine but is only marginally increased in plasma because of efficient renal clearance.

ASA, argininosuccinic acid (including its two anhydrides); CPS, carbamyl phosphate synthetase; OTC, ornithine transcarbamylase; PC, pyruvate carboxylase; ↑, increased; ↑↑ very increased; ↓, decreased; ±, with or without ↑.

For example, when evaluating a patient with hyperammonemia, it is important to inform the laboratory personnel so that they will look for argininosuccinic acid and its anhydrides; otherwise, these metabolites could be overlooked or misinterpreted. This recommendation to inform the laboratory of the clinical context of the investigation applies equally to the other specialized studies discussed here.

Quantitative amino acid analysis of CSF is not indicated as a rule, but it should be performed when appropriate, such as in the context of a hypotonic newborn infant who has seizures and an elevated plasma glycine level that is not accompanied by acidosis or ketosis. These findings suggest the diagnosis of nonketotic hyperglycinemia (see "The Sick Newborn Infant"). The plasma glycine level may be only minimally elevated in some patients with nonketotic hyperglycinemia. The biochemical hallmark of this disorder is an elevated ratio of CSF glycine to plasma glycine.

Carnitine Analysis

Plasma and urinary carnitine analysis is indicated for patients who show evidence of unexplained acidosis, hyperammonemia, hypoglycemia, or ketonuria when there might be a disorder accompanied by an abnormal organic aciduria, defect in fatty acid oxidation, or respiratory chain defect. In these settings, carnitine insufficiency or frank carnitine deficiency can develop.

Many of the organic acidurias or fatty acid oxidation defects are associated with overproduction of intracellular acyl-CoAs (i.e., CoA esters of an acid molecule). As they accumulate, these acyl-CoAs are transesterified with free carnitine to form acylcarnitines and free CoA. Many of these acylcarnitines then leave the cell, circulate in the bloodstream, and are ultimately excreted in the urine. If the production of a particular acyl-CoA is very large, comparably large amounts of the corresponding acylcarnitines are excreted in the urine, resulting initially in intracellular carnitine insufficiency and ultimately in carnitine deficiency (i.e., secondary carnitine deficiency). Abnormal acylcarnitines can also inhibit renal reabsorption of carnitine. Carnitine analysis should be performed whenever possible on samples of plasma and urine obtained concurrently.

Carnitine analysis should include measurement of total carnitine, free carnitine, total acylcarnitines, as well as the individual acylcarnitine profile. Measurement of total carnitine, free carnitine, and total acylcarnitines will help determine whether the patient has carnitine insufficiency or deficiency, while a quantitative acylcarnitine profile will help identify which, if any, acyl-CoA are accumulating, and hence identify the locus of the patient's metabolic defect.

Lactate and Pyruvate Analysis

Blood lactate analysis is indicated when acidosis or an increased anion gap is found, and it is used to investigate the possibility of a defect in carbohydrate metabolism, fatty acid oxidation, organic acid metabolism, or the respiratory chain (see Lactic Acidemia).[2,11] Lactate should also be measured in patients who have skeletal myopathy, cardiomyopathy, encephalopathy, retinal pigmentary deposits, neutropenia, or thrombocytopenia and in patients with hypoglycemia or ketosis even if they do not have frank acidosis. Many inborn errors of metabolism result in lactic acidemia without lactic acidosis.

When possible, the concentration of lactate and pyruvate should both be determined. These metabolites should be measured concurrently in blood and CSF, when a lumbar puncture is being performed for other reasons or the patient's presentation suggests the possibility of a CNS-specific defect. Measuring CSF lactate and pyruvate concentrations does not generally add useful information when the blood lactate and pyruvate concentrations have already been found to be elevated. Lactic acid is the reduction product of pyruvic acid. The lactate-to-pyruvate (L:P) ratio is a useful measure of the intracellular redox potential and is useful in approaching the differential diagnosis of the lactic acidemias (see Lactic Acidemia). Lactic acidemia and pyruvic acidemia are often accompanied by lactic aciduria and pyruvic aciduria, which can be detected, but poorly quantitated, by urinary organic acid analysis.

The significance of the finding of lactic acidemia can be investigated further by reviewing a quantitative plasma amino acid analysis for evidence of an increased alanine concentration, because alanine is the transamination product of pyruvate. The evaluation for lactic acidemia should include measurement of lactate, pyruvate, and alanine.

Urine Organic Acid Analysis

Urinary organic acid analysis was originally used to document defects in amino acid metabolism distal to the removal of the amino group from the amino acid. As currently performed, urinary organic acid analysis detects and quantitates a large number of metabolites that represent intermediates of carbohydrate and fatty acid oxidation, as well as those of amino acid catabolism.[2,10,11] Accordingly, urinary organic acid analysis is a highly useful study and is performed in a wide variety of clinical contexts. Urinary organic acid analysis is indicated for patients who have unexplained acidosis, lactic acidemia, hyperammonemia, hypoglycemia, or ketonuria.

A partial list of the organic acidurias with onset in the neonatal period is presented in Box 50-1. The organic acid disorders are called *-emias* or *-urias* for historical reasons. In most cases, abnormal metabolites accumulate in blood and urine in these disorders, and the terms *organic acidemia* and *organic aciduria* are used interchangeably in this chapter. Isovaleric acidemia, methylmalonic acidemia, and propionic acidemia appear to be the most common of the organic acid disorders that appear in the newborn period. The incidence of the organic acidemias that are detected by MS/MS newborn screening differs from the incidence of disorders that appear in the newborn period. Urinary organic acid analysis is generally performed by gas-liquid chromatography or, with increasing incidence, by combined gas-liquid chromatography and mass spectrometry.

Tests for Congenital Disorders of Glycosylation

The possibility of a CDG syndrome should be suspected in a newborn infant with the characteristic dysmorphism of CDG-Ia (e.g., abnormal fat pads of the buttocks and inner thighs, orange peel skin, inverted nipples) or a child with pericardial effusion or cardiomyopathy, hepatomegaly, diarrhea, an increased bleeding tendency or thrombosis, or neurologic abnormalities (e.g., strabismus, hypotonia, developmental delay). Several clinical forms of CDG syndrome have been described, each having a different genetic basis. Fortunately, most of the disorders described can be diagnosed using the transferrin immunoisoelectric focusing assay or the mass spectrometric adaption of this method to identify patients with an abnormal pattern of glycosylation.[36,48] Patients found to have a positive test result will require further testing to determine their particular disorder.

BOX 50–1 Organic Acidurias with Onset in the Neonatal Period

3-Hydroxyisobutyric aciduria
3-Hydroxy-3-methylglutaryl-CoA lyase deficiency
Isovaleric acidemia*
3-Ketothiolase deficiency
Maple syrup urine disease
3-Methylcrotonyl-CoA carboxylase deficiency
Methylmalonic aciduria*
Mevalonic aciduria
Multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type II)
Multiple carboxylase deficiency (biotinidase deficiency; holocarboxylase synthetase deficiency)
Propionic acidemia*
Pyroglutamic acidemia
Succinyl-CoA 3-ketoacid transferase deficiency

*Most commonly seen disorders.

Tests for Lysosomal Storage Disorders

Patients with coarse facial features, corneal clouding, cataracts, hepatomegaly, or dysostosis multiplex should be evaluated for a possible lysosomal storage disorder. Urine screening tests are available for quantitation of total mucopolysaccharides. The test results should be interpreted with caution since many of the tests have significant false-positive and false-negative rates. If the quantitative mucopolysaccharide screening test result is positive, chromatographic separation and identification of the individual mucopolysaccharides should be performed. Alternatively, selective analysis of the enzymes involved in mucopolysaccharide metabolism whose deficiency would be consistent with the patient's clinical phenotype can be performed as the next step. The enzyme analyses can be performed using white blood cells or cultured skin fibroblasts.[2]

Patients with clinical features suggestive of an oligosaccharidosis can be evaluated using one of the available chromatographic systems for separating and quantitating various oligosaccharides. A positive result can be investigated by performing a selective battery of enzyme assays using white blood cells or cultured skin fibroblasts.

Tests for Peroxisomal Disorders

Peroxisomal disorders include defects of biogenesis (group 1) and defects of individual enzymes (group 2). Almost all of the disorders in group 1 (Zellweger syndrome and its milder variants) and many of the disorders in group 2 (defects of peroxisomal fatty acid oxidation: acyl-CoA oxidase deficiency, bifunctional enzyme deficiency, and thiolase deficiency) have impaired very-long-chain fatty acid oxidation and are characterized by increased plasma concentrations of very-long-chain fatty acids (chain length longer than 22 carbons). In most cases, measurement of individual plasma very-long-chain fatty acids is the most useful single measure of peroxisomal function and serves as a useful initial test for these disorders.[99] Very-long-chain fatty acids can also be measured in cultured fibroblasts, thereby permitting premortem or postmortem diagnosis from a skin biopsy specimen established in culture.

Other measurements are required to diagnosis some forms of peroxisomal disease, such as rhizomelic chondrodysplasia punctata, and to distinguish between the various forms of peroxisomal disease. These additional tests include plasma phytanic acid analysis, erythrocyte plasmalogen analysis, and plasma dihydroxycholestanoic and trihydroxycholestanoic acid analysis. Mevalonic aciduria is diagnosed with urinary organic acid analysis. More definitive testing, including complementation analysis or assays of peroxisomal fatty acid β-oxidation, is often required to establish a specific diagnosis.[99]

Definitive Biochemical Diagnosis

Judicious application of the various biochemical tests described above will in many cases, but not all, allow the physician to establish a diagnosis. However, it is important to remember that the diagnosis must be confirmed by definitive testing because the same metabolite pattern (i.e., biochemical phenotype) can be associated with more than one inborn error of metabolism, which might differ in their treatment, prognosis and inheritance pattern. Definitive diagnosis is generally done by specific enzyme analysis or genetic testing. Relatively few laboratories perform many of the enzyme studies that are required to confirm the diagnosis of a rare genetic disorder. As a rule, these enzyme analyses are time consuming, relatively difficult to perform, and expensive. Specific enzyme analysis can often be done using blood cells (most commonly, white blood cells), but often require cultured skin fibroblasts or other tissue specimens.

It is therefore not surprising that laboratories performing these studies prefer (or require) evidence that there is a significant likelihood that the test being performed will demonstrate an abnormality. It behooves the physician caring for a sick neonate to obtain the preliminary evidence suggesting that a specific defect is likely before proceeding to specific enzyme analysis. This is often done in consultation with local experts in metabolic disease, but when such expertise is not available, the laboratories performing such assays usually are willing to give advice that will ultimately maximize the benefit of their efforts.

Genetic Testing

The discussion in this chapter focuses almost exclusively on the classic methods of biochemical genetics, which include analysis of metabolites, structural macromolecules, and enzymes. For the most part, little consideration is given to the role that recent advances of molecular genetics are playing in facilitating the diagnosis, improving our understanding of the pathogenesis, and expanding the possibilities for treatment of inborn errors of metabolism. This has been an intentional omission, because a discussion of the tools of molecular genetics is presented in Chapter 8 and molecular diagnosis is generally performed after a clinical diagnosis has been confirmed biochemically or enzymatically. The reasons for this omission notwithstanding, there are five clinical circumstances in which molecular testing comes to the forefront, and the clinician should be aware of them.

First, diagnosis can be accomplished easily and rapidly by mutational analysis for diseases that are characterized by relative genetic homogeneity (i.e., a few mutations account for most cases of the disease). Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency provides an excellent example. Approximately 90% of the disease-causing alleles found in affected patients have the same mutation (i.e., an A to G change at nucleotide 985). Second, diagnosis can be provided by mutational analysis, but not by conventional biochemical studies. This is the situation for disorders caused by mutations of the mitochondrial DNA; DNA-based mutation analysis can provide a specific diagnosis, whereas classic metabolite or enzymatic studies cannot. Third, mutation analysis can provide useful prognostic information. For example, in cases of galactosemia ascertained by newborn screening, mutation analysis can assist the clinician in determining the patient's tolerance for galactose and the need to restrict dietary galactose intake. Fourth, mutation analysis of postmortem samples can be used to diagnose the condition in patients who have died without a diagnosis. Fifth, knowledge of a patient's mutation can facilitate evaluation of other family members and prenatal testing.

Postmortem Evaluation

Although the management of a very sick newborn who is at imminent risk of dying is a familiar issue in neonatal care, certain points must be considered in the case of a newborn infant with a suspected inborn error of metabolism. Samples of blood, urine, and, if possible, CSF should be obtained before death. Serum and plasma samples should be obtained; a total of 10 mL should be collected, aliquoted, and saved for metabolite studies and for preparation and storage of DNA. As much urine as possible should be saved. All samples should be frozen at −20°C and preferably at −70°C.

A thoughtful but direct discussion should be arranged before death with the parents, during which the reasons for a postmortem examination are presented. It should be explained that an autopsy performed for the purpose of investigating a suspected metabolic disorder is different from autopsies performed for other purposes in that the autopsy examination must be performed within hours of death, preferably within less than 4 hours. This urgency is dictated by the need to obtain tissue before postmortem changes compromise the integrity of enzyme systems.

If the performance of a complete autopsy is not acceptable to the parents, the option of a limited autopsy should be discussed.[20,71] The selection of tissues or organs requested in a limited postmortem examination vary with the clinical situation but in general should include specimens of liver and skeletal muscle and a skin biopsy specimen for establishing a fibroblast cell culture. These specimens can be obtained with minimal disfigurement. Several small (1 cm^3) specimens of liver and skeletal muscle should be obtained. Similar specimens of heart tissue should be obtained from patients with cardiomyopathy. If permission for a limited postmortem examination is refused, permission for premortem percutaneous liver and open skeletal muscle biopsies should be sought; these procedures can be performed at the bedside. All specimens should be stored at −70°C for future study.

Similar arrangements should also be made for neonates who die suddenly in the hospital or at home, because inborn errors have become a well-recognized cause of sudden death. Approximately 2% of sudden, unexpected deaths in the neonatal period are the consequence of a metabolic disorder.[16] It is understandably more difficult to make arrangements that comply with the recommendations for the sick infant, but experience has shown that a modified protocol can be successful.[7,71] These modifications are dictated in part by the logistics of arranging for a prompt autopsy after an unexpected death, but equally important are the requirements dictated by the differential diagnosis of inborn errors that cause sudden death of the neonate.

The diagnostic entities that have to be considered primarily include defects in energy metabolism: glycogen storage diseases, defects in fatty acid oxidation, and electron transport chain defects. The most common pathogenetic mechanism that leads to sudden death in these disorders is cardiomyopathy or cardiac arrhythmia, which is the consequence of myocardial energy deficiency or disruption of the electrical conduction system by toxic metabolites that accumulate in these disorders.

Practically, recommendations are that a full autopsy be done within 72 hours of death. The autopsy should include particular attention to examination of the heart, liver, and skeletal muscle for evidence of glycogen or lipid storage. The following specimens should be obtained and stored frozen: liver, urine from the bladder (no matter how small the sample size), and bile from the gallbladder.[7,71] A skin biopsy should be obtained for establishing a cell line of cultured fibroblasts.

The results of the metabolite studies are dictated in part by the results of the standard pathologic evaluation. For example, findings consistent with a possible fatty acid oxidation defect should include measurement of glucose, free fatty acids, and total and free acylcarnitines in the liver specimen; organic acids and an acylcarnitine profile in urine; and an acylcarnitine profile in bile. The possibility of two specific inborn errors of fatty acid oxidation, MCAD deficiency and LCHAD deficiency, can be evaluated by molecular techniques that identify the mutations most commonly associated with these disorders. The specific requirements for other diagnostic possibilities are outlined in the relevant sections of this chapter.

Approaches to Specific Abnormal Laboratory Findings

Most newborn infants with an inborn error of metabolism have one or more of only a handful of key laboratory findings: metabolic acidosis, lactic acidemia, hypoglycemia, and hyperammonemia. An approach to differential diagnosis of inborn errors with each of these findings will now be presented. As with all attempts to develop a useful approach to differential diagnosis, it is important to remember that the algorithm never quite fits all patients. Such probably will be the case for these algorithms as well because of the range of diagnostic possibilities and the considerable genetic heterogeneity that characterizes all inborn errors of metabolism. Nevertheless, the approaches presented should serve as useful first approximations.

METABOLIC ACIDOSIS

Metabolic acidosis is a common laboratory finding in sick neonates. It is most often a consequence of shock or severe organ failure of the kidney or liver. In other cases, acidosis is a discrete finding suggesting that the patient has an inborn error affecting acid production or renal acid excretion. It is important to determine the cause of the acidosis because many cellular functions rapidly deteriorate at reduced pH. The most common treatment of acidosis is to "correct" the acidosis with bicarbonate; however, the most effective treatment of acidosis is to correct the cause of the acidosis. It is often possible to correct the acidosis caused by an inborn error of metabolism by reducing endogenous overproduction of specific acids.

Differential Diagnosis

The evaluation of metabolic acidosis should begin with an investigation for systemic shock, renal failure, and generalized liver disease. In the case of shock, the patient should be reevaluated for recurrent acidosis after restoration of normal cardiopulmonary function. Shock might have been the consequence of an inborn error of metabolism. Similarly, patients with severe liver disease should be evaluated for an underlying inborn error of metabolism as the cause of their liver disease (see Table 50-5).

After assessing the patient's cardiopulmonary, renal, and hepatic status, the physician should initiate a diagnostic study for a possible inborn error of metabolism by measuring serum electrolytes, blood gases and pH, and urine pH. The anion gap should be calculated. Acidosis that is associated with a normal anion gap and an inappropriate renal response to systemic acidosis (urine pH greater than 5) implicates a renal tubular defect. The presence of a normal kidney response to the systemic acidosis (urine pH less than 5) and an increased anion gap suggests that the excess acid load is systemic in origin rather than renal (see Chapter 36, Part 2). However, an increased anion gap is not always present in disorders associated with excessive production of abnormal acidic metabolites, and additional studies should be performed before concluding that a patient with a normal anion-gap metabolic acidosis has a renal defect rather than another disorder.

Additional studies that should be performed include determinations of blood lactate and pyruvate, serum glucose, plasma amino acids, plasma and urinary ketones, blood ammonia, plasma and urinary carnitine, and urinary organic acids. The results of these studies can be used to develop the algorithm for the differential diagnosis of metabolic acidosis shown in Figure 50-1. This algorithm uses the blood lactate concentration as the discriminant at its first branch point, thereby dividing the causes of metabolic acidosis into the lactic acidemias and other acidemias. The advantage to this approach is that a discrete algorithm can then be used to evaluate patients with lactic acidemias. One disadvantage is that many categories of disease (e.g., the organic acidemias) include a subset of disorders that produce lactic acidemia and a subset that does not; another is that the same disease might produce lactic acidemia in some patients but not in others. On balance, the presence of lactic acidemia is a useful discriminant. The disorders associated with lactic acidemia are discussed later under "Lactic Acidemia".

The serum glucose concentration is then used in Figure 50-1 to differentiate among the disorders that cause metabolic acidosis without lactic acidemia. Several groups of disorders are associated with a normal or increased serum glucose concentration at onset, whereas other groups of disorders are associated with hypoglycemia. These groups of disorders can be divided further into those that exhibit ketosis and those that do not. Ketosis is a relatively uncommon finding in the neonate. The possibility of ketosis should be searched for carefully in blood and urine in the sick newborn infant. If present, ketosis should be taken as strong evidence that the neonate has a metabolic disorder.[2,11] However, if ketosis is not present, especially in the premature newborn infant, the possibility of an underlying ketotic metabolic disorder should not be dismissed, because the pathways of ketone synthesis might not have developed sufficiently.

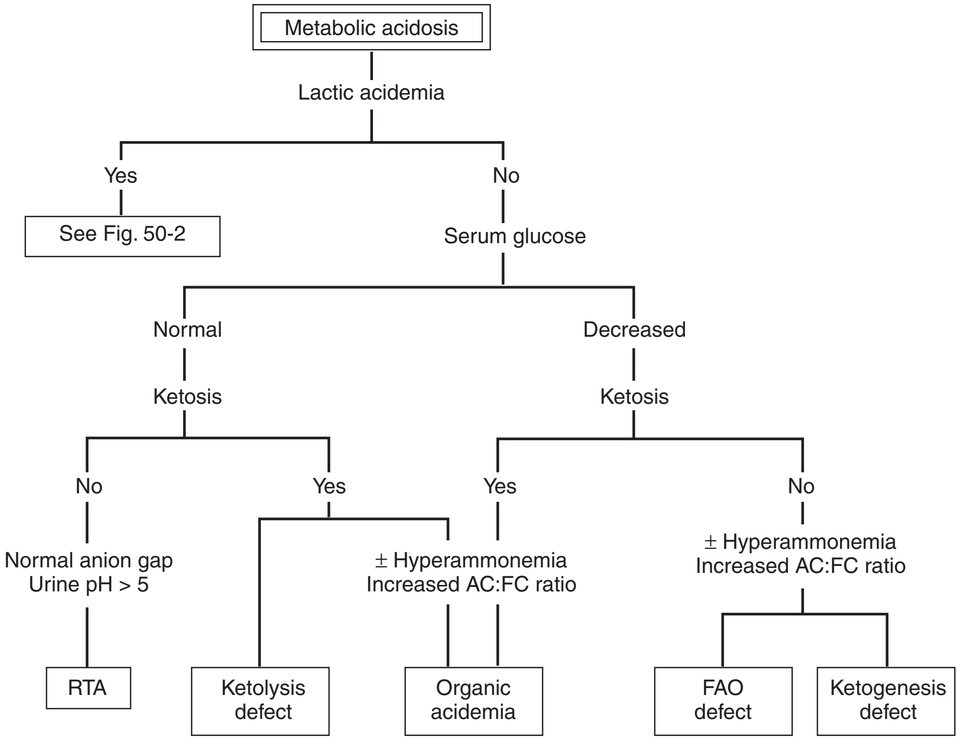

Figure 50–1. Approach to neonatal metabolic acidosis. AC:FC, ratio of acylcarnitine to free carnitine; FAO, fatty acid oxidation; RTA, renal tubular acidosis.

Other information from the initial screening studies should also be considered at this point. Serum electrolyte concentrations should be used to calculate the anion gap. The blood ammonia concentration should be assessed because it has diagnostic and therapeutic implications. Plasma amino acid analysis and plasma and urine carnitine analyses should be reviewed because they also might have diagnostic and therapeutic implications.

Patients who have a normal serum glucose concentration with ketosis might have an organic acidemia or a ketolytic defect. Approximately a dozen organic acidemias can have their onset in the neonatal period (see Box 50-1). Many of the organic acid disorders have a common set of features, including ketoacidosis, vomiting, convulsions, coma, and in some disorders, an unusual smell (see Table 50-7). Because the main diagnostic test for the organic acid disorders—urinary organic acid analysis—can detect essentially all of these defects, the physician need only consider this diagnostic category and order the appropriate analysis.

In general, analysis of a urine sample collected early in the course of an acute episode of metabolic decompensation has the best chance of revealing the characteristic pattern of organic aciduria. In other cases, the sample obtained during an acute episode contains too many metabolites, and the primary defect is obscured. Accordingly, it is advisable to send at least two samples to the laboratory, one obtained during and the other after an acute episode, when an organic acid disorder is suspected.

In addition to an abnormal urinary organic acid pattern, patients with many of the relatively common organic acidemias generally have an increased serum anion gap, reflecting the accumulation of abnormal organic acids, and hyperammonemia. The degree of hyperammonemia may be so great (500 to 1000 μmol/L)[85] that it generates concern and possibly confusion about whether the patient has a primary urea cycle defect (see "Hyperammonemia"). However, the organic acidemias can generally be distinguished from the urea cycle defects. The organic acidemias are associated with a more significant metabolic acidosis than is seen in the urea cycle defects, especially early in the course of the illness; an abnormal organic acid pattern; and an increased acylcarnitine-to-free carnitine ratio, which is often accompanied by a pathognomonic acylcarnitine profile. The clinical features of individual organic acidemias are discussed later.

Defects of Ketolysis

The other causes of ketotic normoglycemic acidosis are defects in ketolysis (i.e., the degradation of ketone bodies once they are formed). Ketolytic defects constitute a subset of organic acidemias. They are identified by urinary organic acid analysis but are considered separately here because their pathogenesis is unique. In normal individuals, ketone bodies are formed in the liver and then transported to peripheral tissues, where they are used as a glucose-sparing energy source.

Ketolytic defects are primarily defects in extrahepatic ketone use rather than ketone body synthesis by the liver. These defects are characterized by normoglycemia or even hyperglycemia. Ketolytic defects are relatively rare, especially in the neonate. Two ketolytic defects with onset in the newborn period are succinyl-CoA:3-ketoacid CoA-transferase deficiency and β-ketothiolase deficiency.[85] Both result in lethargy, hypotonia, a normal or increased serum glucose concentration, and marked ketosis during the fed state and the fasted state.

The diagnosis of succinyl-CoA:3-ketoacid CoA-transferase deficiency should be considered in a patient with negative findings on organic acid analysis except for markedly increased concentrations of β-hydroxybutyrate, acetoacetate, and β-hydroxyisovalerate. Confirmation of the diagnosis requires specific enzyme studies.

β-Ketothiolase deficiency impairs ketone body use and isoleucine metabolism because the enzyme is involved in both pathways. The urinary organic acid pattern seen in patients with this disorder shows increased amounts of 2-butanone, 2-methyl-3-hydroxybutyrate, and tiglylglycine, as well as increased excretion of acetoacetate and β-hydroxybutyrate. This disorder can be confused with diabetic ketoacidosis or salicylism when it occurs in the older child.

The treatment for both disorders is a low-protein diet and possibly a low-fat diet, especially during intercurrent illnesses. Carnitine supplementation might also be helpful.

Renal Tubular Defects

The most likely diagnosis when metabolic acidosis is associated with a normal serum glucose concentration, the absence of ketosis, a normal blood ammonia concentration, a normal anion gap, and an inappropriate renal response to systemic acidosis (urine pH greater than 5) is a renal tubular defect.

Renal tubular acidosis (RTA) is not discussed here because it is more appropriately considered in Chapter 51. However, certain inborn errors of metabolism are associated with RTA. In general, there are two forms of RTA that reflect the anatomic and functional locus of the defect: proximal RTA and distal RTA. The inborn errors of metabolism that are discussed in this chapter are associated with defects causing proximal RTA but not distal RTA. Most inborn errors of metabolism that cause proximal RTA also affect other components of proximal renal tubular function, producing the renal Fanconi syndrome (i.e., generalized aminoaciduria, glucosuria, phosphaturia, and RTA). Inborn errors of metabolism that cause renal Fanconi syndrome include defects of amino acid, carbohydrate metabolism, organic acid metabolism, and the respiratory chain (Table 50-14). The diagnostic approach and general treatment of these disorders are discussed in the respective parts of this chapter.

The next category to consider is the disorders that are associated with hypoglycemia (see Fig. 50-1), for which the presence or absence of ketosis provides the most discriminating laboratory clue. Patients who have hypoglycemia without ketosis (i.e., nonketotic or hypoketotic hypoglycemia) have a defect in mitochondrial fatty acid β-oxidation or in ketogenesis unless another cause is found. Patients with defects of mitochondrial fatty acid β-oxidation are unable to generate acetyl-CoA for ketone body synthesis, whereas patients with defects in ketogenesis are unable to use acetyl-CoA for ketone body synthesis. These disorders can also be associated with hyperammonemia, an increased anion gap, and disordered carnitine homeostasis. Defects in mitochondrial fatty acid β-oxidation are discussed in more detail under "Hypoglycemia".

TABLE 50–14 Disorders That Cause Renal Fanconi Syndrome

Category of Disorder	Disorder
Amino acid defects	Tyrosinemia type I
Carbohydrate defects	Galactosemia Glycogen storage disorder type I Hereditary fructose intolerance
Organic acidemia	Pyroglutamic aciduria
Respiratory chain defects	Complex I, II, or IV, or combined defects mtDNA depletion syndromes

mtDNA, mitochondrial DNA.

Defects of Ketogenesis

The most common ketogenesis defect is 3-hydroxy-3-methylglutaric aciduria, which is the result of an autosomal recessive deficiency of 3-hydroxy-3-methylglutaryl-CoA lyase.[85] This enzyme deficiency affects ketone body formation from fatty acid oxidation and leucine (a branched-chain amino acid) catabolism. This disorder, therefore, can be classified as an amino acid disorder or as a fatty acid oxidation defect. The defect interferes with the major pathways of ketone body formation and consequently is a cause of severe nonketotic acidosis and hypoglycemia in the newborn infant. Patients generally have vomiting, hypotonia, or lethargy at presentation, but others present with seizures caused by the profound hypoglycemia associated with this disorder. This disorder can be diagnosed by urinary organic acid analysis and is treated with a leucine-restricted, low-protein diet.

ORGANIC ACIDEMIAS

Patients who have hypoglycemia with ketosis should be evaluated for an organic acidemia. Methylmalonic acidemia and propionic acidemia, two of the most common organic acid disorders, are often associated with ketosis. This is also true of several other branched-chain organic acidemias. These common organic acidemias may be associated with hypoglycemia, an increased anion gap, hyperammonemia, hyperglycinemia, and an increased ratio of acylcarnitine to free carnitine with an abnormal pattern of specific acylcarnitines, but none of these findings is present invariably.[11,85] Definitive diagnosis can be accomplished by urinary organic acid analysis and plasma carnitine analysis with an acylcarnitine profile, followed by enzymatic or other specialized biochemical testing.

Defects in Branched-Chain Amino Acid Metabolism

The most common organic acidurias in the newborn period are isovaleric acidemia, methylmalonic acidemia, and propionic acidemia (see Box 50-1).[11,85] These three disorders share many of the same clinical and biochemical features. All three disorders are the consequence of defects in branched-chain amino acid metabolism, affecting the catabolism of isoleucine, leucine, or valine. The clinical phenotype fits the classic description of a newborn infant who is healthy at birth and then becomes inexplicably ill on the second or third day of life (see "The Sick Newborn Infant"). Standard supportive management might not halt the progression of the disease, and the neurologic status deteriorates until the patient becomes comatose and, in many cases, dies.

Biochemically, these disorders are characterized by a combination of many or all of the following features: severe ketoacidosis, hyperammonemia, lactic acidemia, hyperglycinemia, abnormal carnitine metabolism (i.e., relative carnitine insufficiency with an increased acylcarnitine-to-free carnitine ratio and abnormal acylcarnitine profile), hypocalcemia, and neutropenia, thrombocytopenia, or pancytopenia. Occasionally, patients with an organic acidemia do not present with acidosis. The blood sugar level may be decreased, normal, or increased.

Other relatively less common defects in branched-chain amino acid metabolism (e.g., 3-methylcrotonyl-CoA carboxylase deficiency) have similar clinical and biochemical phenotypes. MSUD also has a similar phenotype, except that hypoglycemia is not usually present (see "Newborn Screening"). Many of these patients are first ascertained by the alert nurse or parent who notices an abnormal odor emanating from the sick newborn infant's bed or diaper (see Table 50-7).

Ketone Body Metabolism Defects

The other organic acidurias with onset in the newborn period have certain clinical or biochemical features that distinguish them from the branched-chain organic acidurias. The defects in ketone body metabolism have already been discussed. The defects in ketolysis (i.e., succinyl-CoA:3-ketoacid CoA-transferase deficiency and β-ketothiolase deficiency) and the defects in ketogenesis (i.e., 3-hydroxy-3-methylglutaric aciduria) are diagnosed and subsequently treated as organic acidemias. Another organic aciduria, mevalonic aciduria, is associated with hepatosplenomegaly, diarrhea, anemia, hypocholesterolemia, and craniofacial dysmorphism. The underlying defect in this disorder is deficiency of mevalonate kinase, which is a peroxisomal enzyme that catalyzes the first committed step in the biosynthesis of cholesterol and nonsterol isoprenoids (see "Dysmorphic Syndromes").[29]

Pyroglutamic Acidemia

Pyroglutamic acidemia is caused by a defect in glutathione synthetase, an enzyme required for the biosynthesis of glutathione. Glutathione is a tripeptide involved in maintaining the redox status within the cell. This rare disorder produces acidosis but not ketosis or hypoglycemia in the newborn period. Clinically, it causes type I RTA (see Table 50-14), hemolysis, and hyperbilirubinemia in the newborn period. It leads to acidosis during intercurrent illnesses later in childhood and progressive neurologic abnormalities, including ataxia, spasticity, and mental retardation. The primary objective of treatment is to correct the acidosis and electrolyte imbalances associated with the disorder, especially during acute illnesses. In the neonatal period, it is also important to aggressively treat any anemia or hyperbilirubinemia that develops. Antioxidants, such as vitamin E and vitamin C, may be of long-term benefit.

Multiple Carboxylase Deficiency

Several organic acidurias represent compound phenotypes because the genetic defect affects the synthesis or functioning of several enzymes. The most common of these compound disorders is multiple carboxylase deficiency, which may be the consequence of either of two genetically distinct defects: biotinidase deficiency and holocarboxylase synthetase deficiency (see "Newborn Screening"). Both enzyme deficiencies lead to functional deficiencies of four enzymes, all carboxylases: acetyl-CoA carboxylase, which is involved in fatty acid synthesis; β-methylcrotonyl-CoA carboxylase deficiency, which is involved in branched-chain amino acid metabolism; propionyl-CoA carboxylase, which is also involved in branched-chain amino acid metabolism; and pyruvate carboxylase deficiency, which is involved in gluconeogenesis. Both forms of multiple carboxylase deficiency can cause lactic acidemia and a complex organic aciduria; both are also considered in the algorithm for lactic acidemia (see "Lactic Acidemia").

Both forms of multiple carboxylase deficiency can be diagnosed in the sick child by means of urinary organic acid analysis, although false-negative results may be obtained in biotinidase deficiency. Direct enzyme analysis of biotinidase deficiency is the best method of establishing this diagnosis.

Multiple Acyl-CoA Dehydrogenase Deficiency

Another disorder that represents a compound organic aciduria is multiple acyl-CoA dehydrogenase deficiency, or glutaric aciduria type II (see "Dysmorphic Syndromes").[85] This disorder is the consequence of a defect in ETF or ETF dehydrogenase, which are enzymatic components in the pathway that transfers reducing equivalents from the flavin-dependent dehydrogenases involved in mitochondrial fatty acid β-oxidation and the oxidation of several amino acids to the respiratory chain. This disorder is characterized by dysmorphogenesis of the brain, face, and kidneys, as well as the more expected clinical and biochemical phenotype of a fatty acid oxidation defect. This disorder is also associated in many cases with lactic acidosis, especially during acute phases of the illness.

MANAGEMENT

Management of a patient with an organic acidemia should include supportive care (i.e., administration of bicarbonate, mechanical ventilation, and reduced protein or fat intake with concomitantly increased glucose administration). If the patient has a severe neurologic intoxication, hemodialysis should be considered.[31,73,79,85] Centers unable to provide hemodialysis to newborn infants should consider transferring such patients because exchange transfusion, peritoneal dialysis, and hemofiltration are considerably less efficient than hemodialysis for managing many of these disorders.

Treatment should be modified as soon as a provisional diagnosis is available. For example, branched-chain amino acid–free parenteral nutrition and specially designed enteral formulas have been used to manage acutely ill patients with MSUD. Insulin can be used to augment the anabolic state, starting at 0.05 to 0.10 units/kg per hour.

Carnitine is used in many of these disorders to remove toxic metabolites during the acute phase. Carnitine can be given orally or intravenously. During an acute crisis, it is probably best to provide intravenous carnitine at 100 to 200 mg/kg per day (larger doses are sometimes given) as a continuous drip or in four divided doses. If parenteral carnitine is unavailable, carnitine should be given PO at comparable amounts in three or four divided doses. Glycine has been given for similar reasons to patients with isovaleric acidemia and related disorders.[85] Glycine should be given PO at a dosage of 250 to 500 mg/kg per day in three divided doses during the acute crisis. Intralipid can be started after carnitine supplementation has begun and once it is certain that the patient does not have a defect of fatty acid β-oxidation.

After the patient's condition is stabilized, oral feedings should be initiated. In the absence of a specific diagnosis, a high-carbohydrate formula that contains proportionately reduced amounts of protein and fat should be started. The diet should be modified after the neonate's diagnosis has been established. As a rule, it is necessary to limit only protein intake or, more correctly, the intake of certain amino acids, but restriction of protein and fat intake may be required for some disorders. A range of special formulas are commercially available for these patients, but specialized diets should always be designed with the assistance of a dietitian experienced in managing patients with inborn errors of metabolism.

Efforts to reduce the endogenous production of toxic metabolites could also include antibiotic suppression of gut flora that produce metabolites that enter the patient's bloodstream (e.g., long-term metronidazole in patients with methylmalonic and propionic acidemias).[94] Specific vitamins may be provided as cofactors for certain enzyme deficiencies, possibly including biotin (10 mg PO), hydroxycobalamin (1 mg/day IM), pyridoxine (10 mg/day PO), riboflavin (20 mg/day PO), or thiamine (10 mg/day PO). Carnitine (100 mg/kg per day) and glycine (250 mg/kg per day) are also used during the maintenance phase of treatment.

The various approaches to the acute and long-term management of organic acidemias have led to improved survival and outcome. However, the prognosis for patients with these disorders still varies widely for different disorders and for patients with the same disorder.[85] Efforts to establish correlations of genotype and phenotype for these disorders are underway and may soon provide a rational basis for providing prognostic information.

LACTIC ACIDEMIA

The lactic acidemias are a complex group of inborn errors of metabolism. The classification, diagnosis, and treatment of these disorders will almost certainly change as understanding of their pathogenesis improves. In particular, current understanding of the pathogenesis of defects of the respiratory or electron transport chain is evolving rapidly.

Lactic acidemia may be the consequence of overproduction of lactate, underuse of lactate, or both. A prerequisite for evaluating a patient with lactic acidemia is to assess the adequacy of tissue oxygenation. After it has been established that tissue oxygenation is adequate, several laboratory studies should be performed to determine the cause of the lactic acidemia, including those for blood lactate and pyruvate, blood gases and electrolytes, serum glucose, blood ammonia, plasma amino acids, plasma and urinary ketones, plasma and urinary carnitine, and urinary organic acids. If a lumbar puncture is planned to investigate the possibility of sepsis, a sample of CSF should be obtained for lactate and pyruvate analysis, along with samples for the more routine studies; a blood sample should be obtained concurrently for blood lactate and pyruvate analysis. The results of these studies can be used to generate an algorithm for establishing the diagnosis for a neonate with lactic acidemia (Fig. 50-2).

Differential Diagnosis

The differential diagnosis of the primary genetic lactic acidemias with onset in the neonatal period includes defects of gluconeogenesis, glycogenolysis, or pyruvate metabolism; defects of the Krebs (or tricarboxylic acid) cycle; and defects of the respiratory chain (Table 50-15). Many defects of fatty acid oxidation, organic acid metabolism, and the urea cycle are associated with lactic acidemia because of relationships

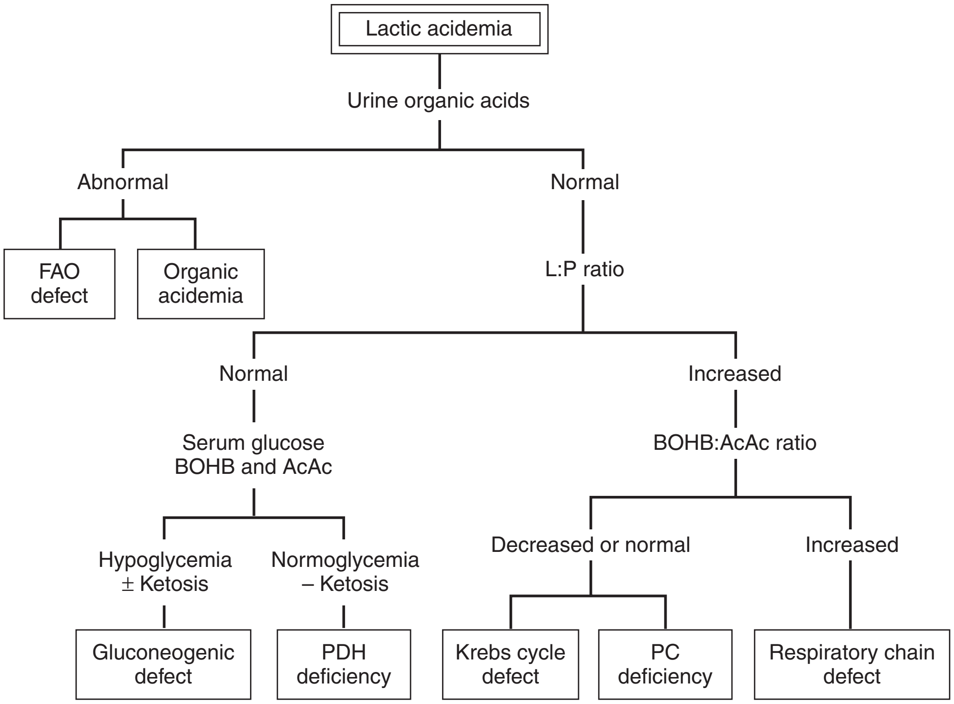

Figure 50–2. Approach to neonatal lactic acidemia. AcAc, acetoacetate; BOHB, β-hydroxybutyrate; BOHB:AcAc, β-hydroxybutyrate-to-acetoacetate ratio; FAO, fatty acid oxidation; L:P, lactate-to-pyruvate ratio; PC, pyruvate carboxylase; PDH, pyruvate dehydrogenase complex.

TABLE 50–15 Disorders Associated with Lactic Acidemia in Neonates

Category of Disorder	Disorder
Defects in gluconeogenesis, glycogenolysis, or pyruvate metabolism	Fructose-1,6-diphosphatase deficiency GSD type I (glucose-6-phosphatase deficiency) GSD type III (debrancher deficiency) Phosphoenolpyruvate carboxykinase deficiency Pyruvate carboxylase deficiency Pyruvate dehydrogenase complex deficiency
Krebs cycle defects	Dihydrolipoamide dehydrogenase deficiency Fumarase deficiency α-Ketoglutarate dehydrogenase deficiency
Organic acidemias	See Box 50-1
Respiratory chain (RC) defects	
mtDNA mutations	
Point mutations	
mRNA	Maternally inherited Leigh syndrome (ATPase 6)
rRNA	Aminoglycoside-induced nonsyndromic deafness
tRNA	Isolated cardiomyopathy ($tRNA^{Leu}$, $tRNA^{Ile}$)
Large deletions/duplications	Pearson syndrome
nDNA mutations	
Mutations that directly affect subunits of the RC complexes	Complex I, II, III, IV and V, or combined deficiencies
Mutations that affect nuclear genes required for transport, assembly or stabilization of the RC complexes	Complex III (BCS1L) Complex IV (SURF, SCO1, SCO2, COX10, COX15)
Mutations that affect nuclear genes required for replication or maintenance of the mitochondrial genome	Mitochondrial DNA depletion syndromes Mitochondrial polymerase γ deficiency Deoxyguanosine kinase deficiency Thymidine kinase 2 deficiency
Mutations that affect genes involved in other mitochondrial processes required for normal RC function	Barth syndrome (tafazzin)

ATPase 6, subunit 6 of ATP synthase; COX, cytochrome oxidase; GSD, glycogen storage disorder; nDNA, nuclear DNA; mtDNA, mitochondrial DNA; RC, respiratory chain; $tRNA^{Leu}$, transfer RNA for leucine (UUR); $tRNA^{Ile}$, transfer RNA for isoleucine.

among the various pathways of intermediary metabolism. These disorders are more properly considered secondary lactic acidemias and are discussed elsewhere in this chapter. Multiple carboxylase deficiency is an exception to this rule because the underlying defect impairs biotin metabolism, which may produce pyruvate carboxylase deficiency and lactic acidemia.

The urinary organic acid pattern, along with the blood ammonia concentration and plasma and urine carnitine analyses, provides a practical means for discriminating between the primary and secondary lactic acidemias. The urinary organic acid pattern is by definition abnormal in patients with an organic acidemia and is abnormal in many of the disorders of fatty acid β-oxidation. Patients with fatty acid oxidation defects often excrete increased amounts of dicarboxylic acids, 3-hydroxydicarboxylic acids, or both. In contrast, the primary lactic acidemias are associated with a normal organic acid pattern or a nonspecific pattern of increased excretion of lactate and pyruvate, various Krebs cycle intermediates, dicarboxylic and 3-hydroxydicarboxylic acids, or 3-methylglutaconic acid. The dicarboxylic and 3-hydroxydicarboxylic acids are the consequence of secondarily impaired mitochondrial fatty acid β-oxidation.

Despite the potential overlap between the patterns of urinary organic acids produced by these disorders, urinary organic acid analysis generally provides a useful means of discriminating between the primary and secondary lactic acidemias because qualitative and quantitative differences exist between the patterns seen in the two groups of disorders. The concentrations of urinary metabolites excreted in the primary lactic acidemias are generally less than that produced by the organic acidurias and fatty acid oxidation defects.

The plasma ammonia concentration and the plasma and urine carnitine analyses also provide useful information for distinguishing between the primary and secondary lactic acidemias. Patients with an organic aciduria or a fatty acid β-oxidation defect often have hyperammonemia and relative carnitine insufficiency, with an increased acylcarnitine-to-free carnitine ratio and specific acylcarnitine abnormalities.[59,70]

In contrast, patients with one of the primary lactic acidemias generally have a normal plasma ammonia concentration and relatively mild and nonspecific changes in their plasma and urinary carnitine values.

The exception to this rule is the severe neonatal form of pyruvate carboxylase deficiency, because these patients can have hyperammonemia. Similarly, patients with a primary urea cycle defect could have lactic acidosis, but the degree of acidosis is relatively mild, especially early in the course of the disease, when respiratory alkalosis rather than metabolic acidosis is generally present (see "Hyperammonemia").

Primary Lactic Acidemias

In practical terms, the first step in discriminating among the primary lactic acidemias is to examine the results of the lactate (L) and pyruvate (P) analyses in terms of the absolute and relative values of this pair of metabolites. The L:P ratio is a reflection of the redox state of the cytoplasm. The L:P ratio is normally between 10:1 and 20:1. Defects of gluconeogenesis or the pyruvate dehydrogenase complex are generally associated with a normal L:P ratio, whereas defects of the Krebs cycle, pyruvate carboxylase, or the respiratory chain are often associated with an increased L:P ratio.[55]

Pyruvate carboxylase (PC) is an exceptional case because it is a gluconeogenic enzyme, but its metabolic deficiency has different consequences than other gluconeogenic enzymes. The pathophysiology of PC deficiency is reviewed in the next section. The second exception to this rule is that many respiratory chain defects are associated with normal blood lactate and pyruvate concentrations and a normal L:P ratio. The reasons for this are not well understood, although the normal L:P ratio is considered to be the consequence of partial deficiencies or tissue-specific defects that exist in many patients. The possibility of a respiratory chain defect should not be ignored in patients with a normal blood lactate concentration or a normal L:P ratio when the patient's clinical picture otherwise suggests a respiratory chain disorder.

Further differentiation of the primary lactic acidemias can be made with the results of the plasma β-hydroxybutyrate (BOHB) and acetoacetate (AcAc) analysis and the serum glucose analysis. As discussed in regard to the results of the blood lactate and pyruvate analyses, the results of plasma BOHB and AcAc analyses should be evaluated in terms of the absolute and relative values of this pair of metabolites. Whereas the L:P ratio is a reflection of the redox state of the cytoplasm, the BOHB:AcAc ratio is a reflection of the redox state within the mitochondrion. Both ratios must be examined to appreciate the redox state within the cell.

The presence of different redox states in these two cellular compartments is the consequence of impaired production of reducing equivalents (i.e., in Krebs cycle defects), impaired shuttling of reducing equivalents between the cytosolic and the mitochondrial compartments (i.e., in PC deficiency and the Krebs cycle defects), or impaired oxidation of reducing equivalents within the mitochondrion (i.e., in respiratory chain defects). Normally, shuttling of reducing equivalents between the cytosolic and mitochondrial compartments is mediated by an oxaloacetate-dependent pathway. Shuttling of reducing equivalents is impaired in PC deficiency and Krebs cycle defects because these disorders lead to oxaloacetate deficiency. In the case of PC deficiency, the role of this enzyme is to form oxaloacetate from pyruvate and carbon dioxide; in the case of the Krebs cycle defects, oxaloacetate is the last step in each turn of the tricarboxylic acid cycle, and oxaloacetate deficiency develops when enzymes earlier in the cycle do not function normally.

The primary lactic acidemias associated with a normal L:P ratio include defects of gluconeogenesis and defects of the pyruvate dehydrogenase complex (see Fig. 50-2). These two groups of disorders can be distinguished from each other by the presence or absence of hypoglycemia and ketosis. Defects of gluconeogenesis are generally associated with hypoglycemia and ketosis, whereas patients with pyruvate dehydrogenase complex deficiency are generally normoglycemic and do not have ketosis (see "Hypoglycemia").

PYRUVATE DEHYDROGENASE DEFICIENCY

Patients with pyruvate dehydrogenase complex deficiency can present in the neonatal period with severe lactic acidosis and rapidly progressive deterioration. Less severe deficiencies are compatible with survival but lead to psychomotor retardation. Most patients with pyruvate dehydrogenase complex deficiency have an X-linked form of the disease, in which male patients are more severely affected than female patients. In many cases, patients with pyruvate dehydrogenase complex deficiency are born with structural CNS malformations, including agenesis of the corpus callosum and cystic lesions of cerebral cortex; in other patients, lesions of the basal ganglia and brainstem that are consistent with Leigh disease are present or develop later in infancy. However, the Leigh disease phenotype is not pathognomonic for pyruvate dehydrogenase deficiency because Leigh disease is genetically heterogeneous; it can also be the consequence of PC deficiency or defects of nuclear- or mitochondrial-encoded subunits of the respiratory chain.[17,80]

Efforts to treat patients with pyruvate dehydrogenase complex deficiency have included a high-fat, low-carbohydrate diet with thiamine and lipoic acid supplementation. The rationale for this therapy is that glucose is catabolized through the glycolytic pathway to pyruvate and then requires the action of the pyruvate dehydrogenase complex before it can enter the Krebs cycle, whereas fatty acids enter the Krebs cycle without passing through the pyruvate dehydrogenase complex. Thiamine and lipoic acid are cofactors for the first and second components of the pyruvate dehydrogenase complex, respectively. Some patients have been treated with dichloroacetate, a drug that maintains the pyruvate dehydrogenase complex in its activated state. These treatment efforts have met with mixed success.

As shown in Figure 50-2, the primary lactic acidemias associated with an increased L:P ratio can be distinguished by considering the absolute and relative concentrations of BOHB and AcAc. Patients with PC deficiency, a Krebs cycle defect, or a respiratory chain defect all exhibit postprandial ketosis. However, for the reasons explained previously, severe PC deficiency and Krebs cycle defects are accompanied by a decreased or a normal BOHB:AcAc ratio, whereas respiratory chain defects are accompanied by an increased BOHB:AcAc ratio.

KREBS CYCLE DEFECTS

Krebs cycle defects are rare. Four defects affecting the Krebs cycle have been described: α-ketoglutarate dehydrogenase complex deficiency, fumarase deficiency, succinate dehydrogenase deficiency, and dihydrolipoamide dehydrogenase deficiency. The clinical presentations of α-ketoglutarate dehydrogenase deficiency and fumarase deficiency are variable but always affect neurologic function. They can cause hypotonia, ataxia, and, in some cases, CNS malformations. Succinate dehydrogenase deficiency behaves clinically and biochemically as a respiratory chain defect, which is not surprising because succinate dehydrogenase forms part of complex II of the respiratory chain.

Dihydrolipoamide dehydrogenase deficiency affects a protein that is a component of three different α-ketoacid dehydrogenase complexes: the α-ketoglutarate dehydrogenase complex (i.e., Krebs cycle component), the pyruvate dehydrogenase complex (i.e., the enzyme that converts pyruvate to acetyl-CoA and thereby permits its entry into the Krebs cycle), and the branched-chain α-ketoacid dehydrogenase complex (i.e., the enzyme that is deficient in MSUD). Dihydrolipoamide dehydrogenase deficiency is therefore a compound deficiency of these three α-ketoacid dehydrogenase complexes and is associated with severe ketoacidosis and a pathognomonic organic aciduria. The Krebs cycle defects can be detected by urinary organic acid analysis.

Effective treatment does not exist for these Krebs cycle disorders.

The severe neonatal form of PC deficiency is associated with acidosis, hyperammonemia, hypercitrullinemia (citrulline is an amino acid component of the urea cycle), and hyperlysinemia (lysine is a dibasic amino acid). This disorder is characterized by postprandial ketosis, a normal or decreased BOHB:AcAc ratio, and an increased L:P ratio. It has a fulminant course of progressive neurologic deterioration. Less severe forms of PC deficiency are not associated with hyperammonemia, hypercitrullinemia, or hyperlysinemia, and the L:P ratio and BOHB: AcAc ratios are normal. PC deficiency is discussed further under "Hypoglycemia."

DEFECTS OF THE RESPIRATORY CHAIN

Defects of the respiratory chain are a complex group of disorders reflecting the large number of genes involved in this metabolic system.[13,17,55,80] The respiratory chain is composed of five multimeric protein units: complex I, II, III, IV and V. The number of protein subunits in these complexes ranges from 4 to 43 proteins. An additional level of complexity is that some subunits are encoded by nuclear DNA (nDNA) and others are encoded by mitochondrial DNA (mtDNA). The nDNA encodes for approximately 85% of the subunits, while mtDNA encodes for approximately 15%. Complexes I, III, IV, and V contain subunits encoded by both genomes, while complex II contains only nuclear-encoded subunits. The common names, composition, and genetic origin of the subunits of the five respiratory chain complexes are listed in Table 50-16.

The mitochondrial genome differs in several key ways from the nuclear genome.[17,55,80] There are both structural and biologic differences between the two genomes. The structural differences include the following:

- mtDNA is much smaller than nDNA. It is a circular, double-stranded genome that contains about 16,500 basepairs (16.5 kb), which encode for 37 genes (compared with the 30,000 genes that are encoded by the nuclear genome). The mtDNA encodes for 13 mRNAs, two rRNAs, and 22 tRNAs. The mRNAs encode for the polypeptide subunits of the respiratory chain complexes. The two rRNAs and 22 tRNAs are necessary for translation of mtDNA.
- The genetic codes of the mtDNA and nDNA differ in several key codons, such that the two genomes require their own translational apparatus.
- Almost all regions of mtDNA are part of coding sequence, that is, the mtDNA has few introns. This is very different from the situation for nDNA, which contains a high proportion of noncoding regions.
- The mutation rate for mtDNA is approximately 10-fold greater than that of nDNA, in part because it does not have histones and in part because it has a poor mutation repair apparatus.

Combining the high mtDNA mutation rate with the high proportion of coding sequence in mtDNA, mtDNA mutations are thought to account for a disproportionate percentage (based on their relative size) of human disease compared with the nuclear genome. Conversely, the number of nuclear genes involved in mitochondrial structure and function is far greater than the number of mitochondrial encoded genes, supporting the clinical observation that nuclear mutations are also a significant cause of mitochondrial disease, especially in children.

TABLE 50–16 The Respiratory Chain Complexes

		COMPOSITION AND GENETIC ORIGIN		
Complex	**Name**	**nDNA**	**mtDNA**	**Total**
I	NADH-CoQ reductase	37	7	43
II	Succinate-CoQ reductase	4	0	4
III	$CoQH_2$-cytochrome c reductase	10	1	11
IV	Cytochrome c oxidase	10	3	13
V	ATP synthase	12	2	14

CoQ, coenzyme Q (ubiquinone); $CoQH_2$, reduced coenzyme Q (ubiquinol); nDNA, nuclear DNA-encoded subunits; mtDNA, mitochondrial DNA-encoded subunits; NADH, reduced nicotinamide adenine dinucleotide.

In addition to these structural differences, there are also several key biologic differences between the mitochondrial and nuclear genomes:

- mtDNA is inherited exclusively from the mother, leading to maternal or matrilineal inheritance of mitochondrial encoded disorders.
- Each mitochondrion contains multiple copies of mtDNA, varying between two and 10 copies per organelle. Each cell, in turn, contains a variable number of mitochondria, leading to hundreds to thousands of copies of mtDNA per cell. In contrast, each cell (except mature germ cells) contains two copies of nDNA.
- Each cell may contain only one form of mtDNA ("normal" or "abnormal") or more than one form of mtDNA ("normal" or "abnormal"). The presence of only one form of mtDNA is called *homoplasmy*; the presence of more than one form is called *heteroplasmy*. The cell can contain any proportion of abnormal mtDNA. The clinical consequences of abnormal mtDNA are proportional to the degree of heteroplasmy of that mutation. The phenomenon of mtDNA heteroplasmy differs sharply from that for nDNA, wherein an individual is either homozygous or heterozygous for a normal or abnormal allele.
- The proportion of normal and abnormal mtDNA in a cell can change over time because mtDNA replication is not synchronous with nuclear division. A shift in the degree of heteroplasmy can occur prenatally or postnatally, can lead to improvement or worsening of the clinical phenotype, or can produce a change in the pattern of tissue and organ involvement.
- The clinical consequences of a mtDNA defect (homoplasmic or heteroplasmic) vary in different tissues and organs, depending on the mitochondrial (aerobic) energy requirements of each tissue or organ. This phenomenon has been termed the *threshold effect*.

The unique biologic properties of mtDNA provide a rationale for the unusual mode of inheritance, pattern of clinical involvement, and sometimes evolving clinical picture of some respiratory chain disorders.

An extraordinarily broad range of clinical phenotypes has been described among patients with respiratory chain defects.[13,17,80] This is not surprising given the almost universal requirement that different cells, tissues, and organs have for mitochondrial energy production. The clinical abnormalities primarily observed in newborns with respiratory chain disorders involve the CNS (lethargy, apnea, hypotonia, near miss episodes, coma), skeletal muscle (decreased spontaneous movements, atrophy, hypertonia or hypotonia, recurrent myoglobinuria), heart (hypertrophic cardiomyopathy), liver (hepatomegaly, hepatic failure), kidney (proximal tubular dysfunction), exocrine pancreas, and hematopoietic system (sideroblastic anemia, neutropenia, thrombocytopenia). In some cases, other clinical abnormalities can be identified (e.g., ocular abnormalities), which often provide a clue that facilitates further diagnostic evaluation. Thus, all patients suspected of having a respiratory chain disorder should undergo a comprehensive clinical evaluation to delineate the full pattern of organ involvement.

Similarly, all patients suspected of having a respiratory chain disorder should undergo a metabolic evaluation for lactic acidemia and related biochemical abnormalities, as discussed in the beginning of this section (see "Lactic Acidemia"). These studies should be done in both the fasting and fed state (1 hour postprandial). The metabolic evaluation should include measurement of blood lactate and pyruvate, plasma and urine ketones (β-hydroxybutyrate and acetoacetate), plasma amino acids (focusing on alanine, the transamination product of pyruvate), plasma carnitine analysis (including total carnitine, free carnitine and the acylcarnitine profile), plasma coenzyme Q10 (which is required for normal functioning of the respiratory chain), and urine organic acid analysis. In addition to measuring the blood lactate and pyruvate concentrations, these metabolites should also be measured in the CSF (especially in patients with CNS symptoms) if they are normal in blood. Magnetic resonance spectroscopy (MRS) of the brain may also be helpful in identifying increased lactate. It is important to remember that the absence of lactic acidemia, or any of the other aforementioned biochemical findings, does not exclude the diagnosis of a respiratory chain disorder.

More specialized diagnostic evaluation for a suspected respiratory chain disorder entails a combination of enzyme and morphologic analysis of tissues, polarographic analysis of intact mitochondria, and genetic analysis of mtDNA or nDNA encoded genes.[17,26] Polarographic analysis measures oxygen consumption by intact mitochondria using a variety of substrates. It requires freshly isolated mitochondria and is available in only a few centers. Interpretation of the results of these diagnostic studies is complicated by the fact that many defects are tissue specific. In particular, many defects are not expressed biochemically in blood cells or cultured skin fibroblasts, which mandates the need for invasive studies to obtain a skeletal muscle, cardiac, or liver biopsy. Enzyme and polarographic analysis can implicate deficiency of one or more of the respiratory chain complexes, but they do not permit the clinician to determine whether the patient has a defect in a nuclear- or mitochondrial-encoded subunit. Genetic analysis of the mitochondrial genome is available, but many mtDNA defects are not detectable in all tissues because of heteroplasmy. In recent years, considerable progress has been made in identifying the nuclear genes that encode for the respiratory chain subunits and related mitochondrial processes, and genetic analysis is becoming increasingly available for many nuclear-encoded defects. Genetic analysis of nuclear defects is not limited by the tissue-specificity issue that plays a role in the genetic evaluation of mtDNA-encoded defects.

A general consensus seems to have developed about the diagnostic evaluation of patients with a suspected respiratory chain disorder.[13,17,26] As noted earlier, the first step is to perform a comprehensive clinical evaluation and a noninvasive metabolic evaluation to establish whether the patient is likely to have a respiratory chain disorder. If the patient appears likely to have a respiratory chain disorder and the clinical phenotype is characteristic of a specific, well-defined mitochondrial disorder that can be confirmed by genetic testing of a blood sample, then proceeding with such genetic testing is generally indicated. If, on the other hand, it appears that the patient has a mitochondrial respiratory chain disorder that does not have a recognizable clinical pattern, then performing additional, more specialized, invasive biochemical testing to define the underlying metabolic defect before initiating genetic testing is the preferred route to pursue. The choice of diagnostic pathway is also influenced by the patient's clinical status, including transfusion history, ability to tolerate anesthesia or an invasive procedure such as an open skeletal muscle biopsy, and expected survival.

The key to learning the well-characterized clinical phenotypes that can be diagnosed by focused genetic testing using blood samples is to acquire an understanding of the current classification scheme for respiratory chain disorders. The traditional approach to classifying mitochondrial disorders was based on clinical phenotypes, pathologic findings and biochemical findings. This approach is still useful. However, a clinically based classification system is limited by two well-established characteristics of mitochondrial respiratory chain disorders: a particular clinical phenotype can be caused by more than one genetic defect, and conversely, the same genetic defect can produce more than one clinical phenotype. Recognition of these limitations led to efforts to classify mitochondrial disorders according to their genetic bases. This approach to classification is also imperfect, but it is improving as current understanding of the genetic bases of these disorders becomes greater.

The genetic classification divides the mitochondrial disorders into two broad categories, mtDNA defects and nDNA defects (see Table 50-15). The mitochondrial encoded disorders can be classified into those caused by point mutations and those caused by large deletions or duplications that affect multiple genes of the mitochondrial genome. Mitochondrial point mutations can be suclassified into those that affect mRNA, rRNA or tRNA. The nuclear-encoded disorders can be divided further into mutations that directly affect the genes that encode for subunits of the respiratory chain complexes; genes required for transport, assembly, or stabilization of the respiratory chain complexes; genes required for replication or maintenance of the mitochondrial genome; and genes involved in other mitochondrial processes required for normal respiratory chain function.

The differential diagnosis of several respiratory chain disorders that produce recognizable clinical syndromes in the newborn period are listed in Table 50-15. Most patients whose respiratory chain disorder manifests in the newborn period have a nDNA defect; when the disorder manifests later in childhood or adulthood, mtDNA defects predominate. Many of the most common and best characterized respiratory chain disorders that manifest in late childhood or adulthood do not appear in early infancy or manifest as much more severe, markedly different clinical phenotypes. The list of disorders is not comprehensive; rather it includes disorders that are relatively well-characterized and illustrate the basic approaches to diagnosis of these disorders.

Maternally inherited Leigh syndrome (MILS) is an example of a point mutation that affects a mtDNA structural gene (an mRNA) that encodes for a subunit of a respiratory chain complex (see Table 50-15). MILS is associated with a point mutation (generallyT8993C, T8993G, or T9176C) in the gene that encodes for subunit 6 of complex V (ATPase 6). Leigh syndrome was originally defined as a subacute necrotizing encephalopathy that involves the thalamus, brainstem, and posterior columns of the spinal cord. Typically, it has a mean age of onset of 2 years of age and is characterized by psychomotor regression, tremor, dystonia, optic atrophy, ophthalmoplegia, and respiratory difficulty with apnea. Death usually occurs by 4 years of age. Some patients have a Leigh syndrome–like disorder that is associated with hypertrophic cardiomyopathy, skeletal myopathy, or renal proximal tubular dysfunction. The defects that produce Leigh syndrome or a Leigh syndrome–like disorder include (but are not limited to) nuclear-encoded subunits of complex I, II, or IV, nuclear-encoded assembly genes for complex I or complex IV, nuclear-encoded subunits of the pyruvate dehydrogenase complex, or mtDNA encoded tRNAs.[13,17,91] MILS is an early onset, severe form of Leigh syndrome that is caused by mutations in the mitochondrially encoded subunit 6 of complex V. Patients without the ATPase 6 mutations listed should be evaluated for the other causes of Leigh syndrome. Detailed biochemical studies might refine the diagnosis to a specific complex or protein and direct further genetic studies.

Aminoglycoside-induced nonsyndromic deafness is caused by the A1555G mutation in the mitochondrial rRNA gene that encodes for the 12S ribosomal complex component. The aminoglycoside-induced nonsyndromic deafness disorder is a pharmacogenetic disorder that physicians should be aware of when obtaining a family history of maternally inherited hearing loss thought to be attributable to aminoglycoside use. The use of aminoglycosides in neonates with this mutation may produce irreversible deafness. This mutation is not the cause of aminoglycoside associated renal toxicity, but it can cause cardiomyopathy.

Isolated hypertrophic cardiomyopathy has been found in association with several tRNA mutations, principally involving the tRNA for leucine (tRNA^{Leu}) and the tRNA for isoleucine (tRNA^{Ile}). The tRNA^{Leu} defects include the A3243G mutation and the C3305T mutation. The A3243G mutation is probably the most commonly identified mtDNA mutation, and is the most common cause of MELAS (*m*itochondrial *e*ncephalomyopathy, *l*actic *a*cidosis, and *s*trokelike episodes), which manifests rarely in the newborn period as a severe encephalopathy syndrome. The C3305T mutation generally produces an infantile-onset hypertrophic cardiomyopathy with or without skeletal myopathy. Three tRNA^{Ile} mutations, A4269G, A4295G, and A4300, can produce isolated cardiomyopathy and should be considered in the evaluation of patients with this finding (also see multiple mtDNA depletion syndromes in Table 50-15).

Pearson syndrome is an example of a mitochondrial encoded disorder associated with large deletions or duplications of mtDNA. Pearson syndrome is characterized clinically by refractory sideroblastic anemia, neutropenia, thrombocytopenia, exocrine pancreatic dysfunction, and lactic acidosis. Patients with Pearson syndrome who survive the neonatal period can subsequently have gradual regression of the symptoms and signs of Pearson syndrome, and then develop Kearns-Sayre syndrome, which is an encephalomyopathy associated with progressive external ophthalmoplegia, hearing loss, cardiac arrhythmias, diabetes mellitus, and renal dysfunction.[17] The Kearns-Sayre syndrome is an alternate expression of the same mtDNA mutation, and is an example of how the phenotypes of mtDNA-encoded disorders can evolve dramatically with time.

Nuclear-encoded defects that produce recognizable clinical phenotypes in the newborn period are also listed in

Table 50-15. The first group of such disorders involves genes that encode for a specific subunit of the respiratory chain complexes. These disorders are often characterized by severe ketoacidosis that is associated with seizures, apnea, severe hypotonia, hepatomegaly, and renal proximal tubular dysfunction. Detailed enzymatic and polarographic studies are required to identify the deficient respiratory chain complexes. The specific deficiency can then be investigated by genetic analysis. For example, genetic testing is now available clinically for 7 of the 37 nuclear-encoded subunits of complex I.

The second group of nuclear disorders involves genes that encode for proteins that are required for transport, assembly, or stabilization of the respiratory chain complexes. For example, defects of several genes involved in assembly of complex IV (cytochrome oxidase, COX) have been identified. These defects appear to produce distinctive clinical phenotypes. SURF1 mutations produce Leigh syndrome. As noted earlier, Leigh syndrome does not manifest until later in infancy, but Leigh syndrome–like disorders can manifest in the newborn period.[13,17,91] SCO1 mutations can lead to encephalomyopathy and hepatic failure. COX10 mutations also lead to a Leigh syndrome–like phenotype (or encephalopathy), which is sometimes accompanied by hypertrophic cardiomyopathy, renal proximal tubular dysfunction, or anemia. SCO2 mutations and COX 15 mutations lead to encephalopathy or hypertrophic cardiomyopathy. Mutations of the assembly factors required for the other respiratory chain complexes have also been described. GRACILE syndrome, an eponymic association of growth *r*estriction, *a*mino aciduria, *c*holestasis, *i*ron overload, *l*actic acidosis, and *e*arly death, is the best described of these disorders; it is caused by mutations of the *BCS1L* gene, which is required for assembly of complex III.[13]

The third group of nuclear-encoded disorders involves genes that are required for replication or maintenance of the mitochondrial genome. These disorders are characterized by a reduction in mtDNA copy number, a condition known as mitochondrial DNA depletion syndrome. This syndrome can result from a deficiency of the mitochondrial DNA polymerase γ (POLG), an enzyme responsible for mitochondrial replication. It can also be the consequence of deoxyguanosine kinase (dGK) deficiency or thymidine kinase 2 (TK2) deficiency; dGK and TK2 are enzymes required for synthesis or recycling of the deoxyribonucleotides necessary for DNA replication. In brief, mitochondrial DNA is wholly dependent on the nucleus for production of the enzymes and deoxyribonucleotides it requires for its own replication. Absent these materials, the mitochondrion cannot replicate and its numbers decline. POLG deficiency leads to isolated encephalopathy or seizures, or to liver failure, hepatoencephalopathy, or Alpers syndrome (hepatopathic poliodystrophy). dGK deficiency presents with encephalopathy and liver failure, whereas TK2 presents with encephalopathy and severe skeletal myopathy.[13,76]

The fourth group of nuclear-encoded disorders are caused by mutations in genes required for other mitochondrial processes that are necessary for normal respiratory chain function. Barth syndrome is an example of such a disorder.[5] The clinical features of Barth syndrome include hypertrophic cardiomyopathy, cyclic neutropenia, and cataracts. It is an X-linked recessive disorder caused by a mutation in the *tafazzin* gene, which encodes for a protein required for synthesis of the lipid milieu of the mitochondrial membranes. Mutations in the *tafazzin* gene can also produce an unusual form of cardiomyopathy known as left ventricle noncompaction.

Treatment of patients with a respiratory chain defect is largely supportive.[13,17,80] Therapy includes symptomatic management, such as treating acute or chronic acidosis with bicarbonate or citrate, and treating cardiac, renal, and other systemic disease with standard methods. It also includes avoiding certain drugs, such as valproate and barbiturates, which may be mitochondrial toxins. There is no dietary therapy of proven benefit for patients with respiratory chain disease, although vitamins or other nutritional supplements are generally tried using the rationale that they might stabilize or augment residual enzyme activity of the respiratory chain complexes, or serve as artificial electron acceptors or antioxidants. Coenzyme Q10 is administered because it is a structural homologue of ubiquinone, which accepts electrons from complex I and complex II and passes them on to complex III. Riboflavin is used based on the rationale that complexes I and II contain flavin. Vitamins C and K are used in combination based on the rationale that they could provide an electron transfer shuttle to bypass a complex III deficiency. Thiamine is a cofactor in the pyruvate dehydrogenase complex, which serves as the point of entry for glucose into the Krebs cycle. The daily dietary supplements in use for a neonate include coenzyme Q10 (20 mg), vitamin B_1 (thiamine, 20 mg), vitamin B_2 (riboflavin, 25 mg), vitamin C (250 mg), and vitamin K_3 (menadione, 5 mg). Carnitine may also be used, especially in patients with secondary carnitine deficiency (50 to 100 mg/kg per day). The doses cited are at the lower end of the range of doses recommended by various physicians; some investigators have recommended doses up to 10 times greater than these. However, none of these recommendations are based on controlled studies.

Dichloroacetate has been tried in patients with respiratory chain defects, and several groups are investigating its clinical use. The rationale for using dichloroacetate (50 mg per day) is that it maintains the pyruvate dehydrogenase complex in its activated state, thereby permitting entry of pyruvate, the final product of anaerobic oxidation of glucose, into the Krebs cycle and fueling the respiratory chain. It is unclear whether dichloroacetate is of any clinical benefit to patients with respiratory chain defects, and it can produce peripheral neuropathy in some patients.

Finally, all patients must receive a thorough clinical evaluation to determine whether they may have an organ-specific defect that would be amenable to organ transplantation. For example, heart transplantation was reportedly successful in a patient with cardiomyopathy caused by a tissue-specific mtDNA depletion syndrome.[74]

HYPOGLYCEMIA

See also Chapter 49, Part 1.

Recognizing hypoglycemia in the newborn may be difficult because the symptoms of hypoglycemia (i.e., lethargy, poor feeding, hypothermia, and seizures) are nonspecific. Frequent blood sugar determinations are often required to confirm the suspicion of hypoglycemia. Because inborn errors of metabolism are a relatively infrequent cause of neonatal hypoglycemia, other diagnostic possibilities should be investigated concurrently.[77]

The first possibility to consider is neonatal stress secondary to perinatal asphyxia, hypothermia, or intrauterine malnutrition (e.g., placental abnormalities, prematurity, multiple gestations). The second consideration is the possibility of a hormonal abnormality affecting insulin and cortisol production or regulation. Third, the possibility of a malformation syndrome, such as Beckwith-Wiedemann syndrome, should be considered. The endocrine disorders and malformation syndromes associated with hypoglycemia are discussed more fully in Chapter 49, Part 1, as is the treatment of hypoglycemia. The fourth possibility is that the patient has a severe hepatocellular or cirrhotic liver disease that leads nonspecifically to fasting hypoglycemia.

The inborn errors that can produce this degree of liver damage include hereditary tyrosinemia, galactosemia (if the patient is receiving a diet containing galactose), hereditary fructose intolerance (if the patient is receiving a diet containing fructose), glycogen storage disease type IV, and respiratory chain defects (see Table 50-5). If liver disease is present, evaluation for these disorders should be performed (see “Hepatic Dysfunction”).

Differential Diagnosis

Hypoglycemia may be associated with five categories of inborn errors of metabolism: fatty acid oxidation defects, gluconeogenesis defects, glycogen storage diseases, ketogenesis defects, and organic acidemias (Table 50-17). The diagnostic approach to hypoglycemia therefore must give consideration to entities belonging to each of these categories. Usually, Krebs cycle defects and respiratory chain defects do not produce hypoglycemia, but these defects should be considered when other evidence points in their direction. The diagnostic approach must quickly narrow the field of possible diagnoses so that specific treatment can be instituted.

The classic approaches to the differential diagnosis of hypoglycemic disorders in children are the fasting study and special challenge tests. These studies are, however, not feasible in newborn infants because of the significant risks and technical difficulties associated with performing such studies and because of the lack of control data derived from normal neonates. Alternatively, efforts to determine the cause of hypoglycemia in the newborn infant should include hormonal and biochemical studies before and after feeding and especially during an acute episode of hypoglycemia. Definitive diagnosis might have to be postponed several months until the child is old enough to tolerate a formal fasting study or specialized in vitro cell studies.

An algorithm (Fig. 50-3) for diagnosing the disorders that cause neonatal hypoglycemia can be generated from the results of the following studies: blood electrolytes and pH, plasma and urinary ketones, plasma free fatty acids, blood lactate and pyruvate, blood ammonia, liver function tests, plasma and urinary carnitine and acylcarnitine analysis, and urinary organic acids. A specific diagnosis might not be made by these studies, but they are necessary for providing a provisional diagnosis that can be confirmed by specific enzyme analysis.

The first laboratory finding that is used to discriminate between the disorders that cause hypoglycemia is the presence or absence of ketosis (see Fig. 50-3), because the physiologic response to fasting or hypoglycemia should be increased lipolysis, fatty acid oxidation, and ketone body formation. Defects of gluconeogenesis, glycogenolysis, and organic acid metabolism (especially the common branched-chain disorders) are generally accompanied by ketosis, whereas defects in fatty acid β-oxidation and ketogenesis are accompanied by increased plasma free fatty acids without a

TABLE 50–17 Metabolic Defects Associated with Neonatal Hypoglycemia

Category of Disorders	Disorder
Fatty acid oxidation	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency Short-chain acyl-CoA dehydrogenase deficiency Very-long-chain acyl-CoA dehydrogenase deficiency
Gluconeogenesis	Fructose-1,6-diphosphatase deficiency Hereditary fructose intolerance Phosphoenolpyruvate carboxykinase deficiency Pyruvate carboxylase deficiency
Glycogen storage disease (GSD)	GSD type I (glucose-6-phosphatase deficiency) GSD type III (debrancher deficiency)
Ketogenesis	3-Hydroxy-3-methylglutaryl-CoA lyase deficiency
Organic acidemias	Isovaleric acidemia Maple syrup urine disease Methylmalonic acidemia Multiple acyl-CoA dehydrogenase deficiency Multiple carboxylase deficiency Propionic acidemia

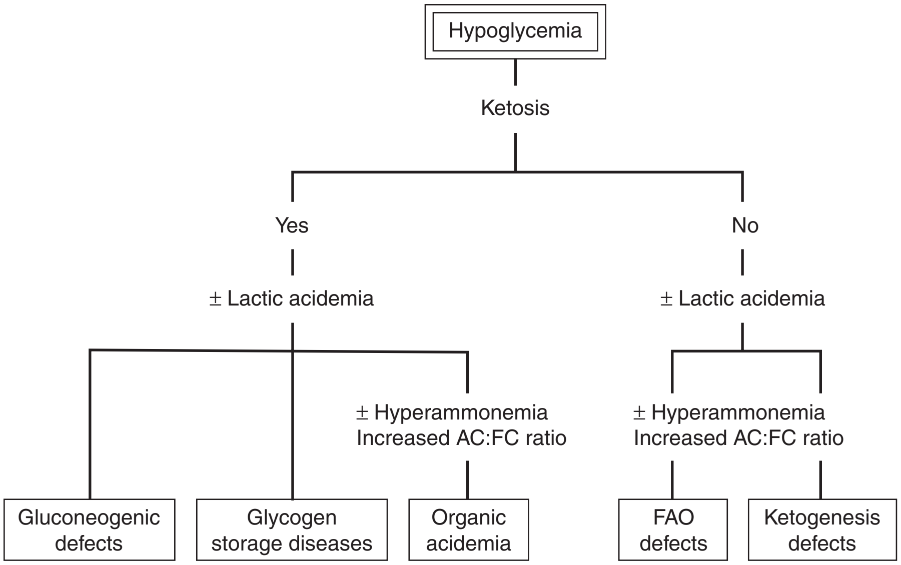

Figure 50–3. Approach to neonatal hypoglycemia. AC:FC, ratio of acylcarnitine to free carnitine; FAO, fatty acid oxidation.

concomitant increase in plasma β-hydroxybutyrate and acetoacetate concentrations.

The second laboratory finding used to distinguish among the neonatal hypoglycemias is lactic acidemia (see Fig. 50-3). Although the simple presence or absence of lactic acidemia is not useful for discriminating among these disorders because they all can exhibit some degree of lactic acidemia depending on the physiologic circumstances, the relative degree of lactic acidemia and its relationship to feeding are important discriminating factors. For example, the magnitude of the lactic acidemia seen in the organic acidemias is generally less than that seen in the gluconeogenesis defects and glycogen storage diseases. The lactate concentration decreases in the fed state for patients with glycogen storage disease type I, whereas it increases for patients with glycogen storage disease type III. Similarly, lactic acidemia becomes more pronounced with fasting in patients with fatty acid oxidation defects and organic acidemias but is greater in the fed state than in the fasted state for those with the glycogen storage disorders associated with hypoglycemia. Hyperammonemia often accompanies hypoglycemia in patients with fatty acid oxidation defects, ketogenesis defects, and organic acidemias, but it is not seen in defects of gluconeogenesis (except severe PC deficiency) or the glycogen storage diseases.

Glycogen Storage Disorders

Glycogen storage disease type I is the most common defect of gluconeogenesis or glycogenolysis.[12] This diagnosis should be considered if, in addition to increased plasma free fatty acid and ketone body concentrations, clinical examination demonstrates hepatomegaly and additional laboratory studies reveal lactic acidosis, hypertriglyceridemia, and hyperuricemia.

The most common form of glycogen storage disease type I is von Gierke disease, which is caused by deficiency of glucose-6-phosphatase. Von Gierke disease may be more accurately called *glycogen storage disease type Ia*, because there are several subtypes of this disorder. For example, the disorder caused by deficiency of glucose-6-phosphate translocase is type Ib. In addition to the clinical features of type Ia disease, glycogen storage disease type Ib is also characterized by neutropenia and neutrophil dysfunction, which lead to a propensity for serious bacterial infections. The long-term complications of both forms of type I glycogen storage disease include intellectual delay as a result of unrecognized or untreated hypoglycemia, short stature, gout, renal disease, and hepatic adenoma.

Type III glycogen storage disease may also occur in the neonatal period. Type III disease may be as severe as type I disease.

Definitive diagnosis of glycogen storage disease type I requires detailed enzymatic analysis of a liver biopsy specimen; the liver specimen must be fresh if studies for subtype Ib are to be done. Type III disease can be diagnosed by enzyme analysis of cultured skin fibroblasts. Alternatively, the diagnosis of glycogen storage disease Ia, Ib, and III can be established by genetic testing.

The mainstay of treatment for these forms of glycogen storage disease is to avoid prolonged fasting. Older affected patients should be provided with continuous nasogastric infusion or uncooked cornstarch at night. These treatments appear to be successful in controlling the hypoglycemia and other metabolic consequences associated with these disorders, but they might not eliminate the long-term sequelae (e.g., development of hepatic adenoma in glycogen storage disease type Ia).[12]

Gluconeogenesis Defects

Gluconeogenesis is the pathway by which glucose is synthesized from noncarbohydrate metabolites. The principal gluconeogenic precursors are pyruvate and lactate, certain gluconeogenic amino acids, and glycerol, which is derived mainly from fat metabolism. Several inborn errors of gluconeogenesis cause hypoglycemia (see Table 50-17).

Fructose-1,6-diphosphatase deficiency is an autosomal recessive disorder characterized by hyperventilation associated with severe ketoacidosis, hypoglycemia, seizures, and lethargy sometimes leading to coma. Hepatomegaly and the degree of liver dysfunction are generally mild. The defect in gluconeogenesis leads to lactic acidosis. Diagnosis requires a liver, intestine, or kidney biopsy for specific enzyme analysis. Acute episodes are treated with glucose administration, which is generally successful in correcting the hypoglycemia and ketoacidosis. Long-term treatment requires avoidance of fasting and removal of most fructose from the diet. As discussed for the glycogen storage diseases, patients with fructose-1,6-diphosphatase deficiency benefit from continuous nighttime feedings or the use of uncooked starch.

Pyruvate carboxylase (PC) deficiency can manifest in the neonatal period with hepatomegaly, lactic acidosis, citrullinemia, and hyperlysinemia, and structural CNS malformations. Patients who present in the newborn period might not survive beyond the first few months of life. Patients with less severe forms of PC deficiency may do well when they avoid fasting, have nighttime feedings, and receive supplementation with citrate, which yields oxaloacetate, the missing product of the PC enzyme reaction.

Phosphoenolpyruvate carboxykinase (PEPCK) deficiency is a rare disorder with an incompletely described phenotype.

Organic Acidemias

Several organic acidurias or acidemias cause neonatal hypoglycemia (see Table 50-17; see also "Metabolic Acidosis"). These disorders should be suspected when there is a metabolic acidosis, an anion gap, ketosis, abnormal results on urine spot tests for α-ketoacids, or an abnormal smell. Urinary organic acid analysis is the key diagnostic study. Many patients with an organic acid disorder have significant hyperammonemia. Plasma and urinary carnitine measurements are useful in diagnosing and possibly managing these disorders. Many of the organic acidurias are characterized by an increased acylcarnitine-to-free carnitine ratio in plasma and urine and overproduction of a particular acylcarnitine.

Fatty Acid Oxidation Disorders

Two groups of disorders cause neonatal hypoglycemia without ketosis: defects of fatty acid oxidation and defects of ketogenesis. It should be pointed out that inborn errors of metabolism that cause severe hepatocellular or cirrhotic liver disease also produce nonketotic or hypoketotic hypoglycemia associated with lactic acidosis. The disorders of fatty acid oxidation are discussed further in this section, whereas the defects of ketogenesis (e.g., 3-hydroxy-3-methylglutaryl-CoA lyase deficiency) are discussed in the preceding section on metabolic acidosis.

The primary pathway of fatty acid oxidation takes place within the mitochondrion.[44,70] Most forms of dietary fat contain primarily long-chain fatty acids (chain length of 14 to 20 carbons). For these long-chain fatty acids to be oxidized, they must be transported across the mitochondrial membranes into the mitochondrial matrix. The system for transporting these fatty acids across the mitochondrial membranes includes three components: carnitine palmitoyltransferase I (CPT I), carnitine-acylcarnitine translocase, and carnitine palmitoyltransferase II (CPT II). Medium-chain and short-chain fatty acids do not require this special system for transport across the mitochondrial membranes. Another transporter facilitates the uptake of free carnitine across the plasma membrane into the cytoplasm.

Inside the mitochondrion, fatty acids exist as their acyl-CoA derivatives. These fatty acid acyl-CoAs are degraded by the mitochondrial fatty acid β-oxidation system to form acetyl-CoA. The acyl-CoAs are degraded sequentially by a series of four enzymes: acyl-CoA dehydrogenase, enoyl-CoA hydratase, 3-hydroxyacyl-CoA dehydrogenase, and 3-ketothiolase. Different forms of these enzymes exist for fatty acid acyl-CoAs of different chain-lengths. These enzymes sequentially degrade the acyl-CoAs two carbon groups per turn of the β-oxidation cycle, from long-chain acyl-CoAs, to medium-chain acyl-CoAs, and finally to short-chain acyl-CoAs. An intact mitochondrial respiratory chain is required for normal functioning of the fatty acid β-oxidation pathway because it replenishes the oxidized forms of flavin adenine dinucleotide and nicotinamide adenine dinucleotide needed by the acyl-CoA dehydrogenases and the 3-hydroxyacyl-CoA dehydrogenases, respectively. Disorders caused by deficiency of almost all these enzymes have been described.[44,70,78]

As a rule, defects of long-chain fatty acid oxidation are more likely to manifest in the neonatal period and to cause serious problems than are defects of medium- or short-chain fatty acids.[70,78] Defects in long-chain fatty acid oxidation that manifest in the neonatal period include CPT II deficiency (but not CPT I deficiency), carnitine-acylcarnitine translocase deficiency, very-long-chain acyl-CoA dehydrogenase deficiency, long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency and the related disorder, mitochondrial trifunctional protein deficiency. Plasma membrane carnitine transporter deficiency (the cause of primary carnitine deficiency) does not generally manifest in the neonatal period.[6,35]

These disorders are a recognized cause of hypoglycemia, liver disease, cardiomyopathy, cardiac arrhythmias, and sudden death. The association of these defects with cardiomyopathy is consistent with the role of long-chain fatty acids as the chief energy source for the myocardium. The cause of the arrhythmias is less certain but may be a toxic effect of the long-chain acylcarnitines that accumulate in these disorders. Hyperammonemia may be seen in patients with the most severe forms of these deficiencies, for example, carnitine-acylcarnitine translocase deficiency and LCHAD deficiency. Neonatal CPT II deficiency is also associated with renal microcysts and CNS malformations. One of these defects, long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency, is gaining attention as a cause of acute fatty liver of pregnancy in pregnant women who are carrying a fetus that is homozygous for this deficiency (see "Prenatal Onset").[6,35]

Defects of medium-chain or short-chain fatty acid β-oxidation include medium-chain acyl-CoA dehydrogenase (MCAD) deficiency, short-chain acyl-CoA dehydrogenase (SCAD) deficiency, and short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD) deficiency.[70,78] MCAD deficiency is the most common of the fatty acid oxidation defects when all age groups are considered, but it does not generally appear in the neonatal period (see "Newborn Screening"). Similarly, SCHAD deficiency does not generally appear in newborns. SCAD deficiency, however, can manifest in the neonatal period with metabolic acidosis. Neonates with MCAD deficiency or SCAD deficiency do not develop cardiomyopathy.

Acute management of the newborn with a suspected fatty acid oxidation defect should begin with prompt infusion of high concentrations of glucose to correct the hypoglycemia and the underlying energy deficit. The patient should receive glucose at a rate of 10 mg/kg per minute or greater to maintain the serum glucose concentration above 100 mg/dL. The patient should not be given any formula that contains fat or parenteral intralipids until it is determined whether the patient has a defect of fatty acid oxidation.

A related consideration is the use of carnitine in patients with a suspected or proven fatty acid oxidation disorder. Carnitine has been used in patients with these disorders because they are often carnitine depleted. However, there is also concern that carnitine supplementation could increase the production of long-chain acylcarnitines, which can be arrhythmogenic.[44] The relative merits of using carnitine in the acute or chronic care of these patients with long-chain fatty acid β-oxidation defects are uncertain, but judicious use of a moderate carnitine dose (50 mg/kg per day) is often used until a diagnosis is established, and then adjusted depending on the diagnosis, the patient's clinical status, and the patient's plasma carnitine analysis.

Once the initial hypoglycemic episodes are controlled, the patient should be started on a high-carbohydrate, low-fat diet, while making certain to avoid fasting. Formulas enriched with medium-chain triglycerides should not be started before the infant's diagnosis has been established, because they can be dangerous to patients with defects in medium-chain fatty acid oxidation. Ultimately, a decision will have to be made regarding the infant's tolerance for fat. Riboflavin supplementation (50 mg/day) should be tried and its benefit evaluated. Long-term carnitine supplementation may be of benefit in some patients.

HYPERAMMONEMIA

The neonate with a hyperammonemia syndrome generally does well for the first few hours or days of life and then develops poor feeding, lethargy, vomiting, and tachypnea. If unrecognized and untreated, the illness generally progresses rapidly to coma, seizures, autonomic instability, and death. When hyperammonemia is suspected, the possibility should be investigated immediately because these illnesses are life threatening, and they can produce irreversible neurologic sequelae.

Differential Diagnosis

More than a dozen disorders can cause significant hyperammonemia in the newborn infant, and an attempt must be made to quickly reach a provisional diagnosis (Box 50-2). By convention, the primary hyperammonemias include deficiencies of the enzymes that make up the urea cycle itself plus N-acetylglutamine synthetase, which is required for activation of the first step in the urea cycle, carbamyl phosphate synthetase. The secondary hyperammonemias include enzyme or protein deficiencies that interfere with the normal functioning of the urea cycle: amino acid transport defects, fatty acid oxidation disorders, lactic acidemias, and organic acidurias.

A systematic approach to the differential diagnosis of these disorders is presented in Figure 50-4. It is imperative that the possibility of a primary hyperammonemia syndrome (a urea cycle defect) be distinguished from a secondary hyperammonemia syndrome (e.g., an organic aciduria), because the best way of treating the hyperammonemia in the latter would be to treat the underlying disorder.

BOX 50–2 Genetic Disorders Associated with Hyperammonemia in Neonates

AMINO ACID TRANSPORT DEFECTS
Hyperornithinemia-hyperammonemia-homocitrullinemia (HHH syndrome)
Lysinuric protein intolerance

FATTY ACID OXIDATION DEFECTS
Carnitine-acylcarnitine translocase deficiency
Carnitine palmitoyltransferase II deficiency
Long-chain acyl-CoA dehydrogenase deficiency
Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency

LACTIC ACIDEMIA
Pyruvate carboxylase deficiency

ORGANIC ACIDURIAS
3-Hydroxy-3-methylglutaryl-CoA lyase deficiency
Isovaleric acidemia
3-Ketothiolase deficiency
Methylmalonic acidemia
Multiple acyl-CoA dehydrogenase deficiency
Propionic acidemia

UREA CYCLE DEFECTS
Argininosuccinic acid lyase deficiency
Argininosuccinic acid synthetase deficiency
Carbamyl phosphate synthetase deficiency
Ornithine transcarbamylase deficiency
N-Acetylglutamate synthetase deficiency

The first step in evaluating a suspected hyperammonemia is to obtain an accurate plasma ammonia concentration. The plasma sample for ammonia determination must be collected and stored on ice and then rapidly analyzed. The plasma ammonia concentration may be as high as 150 μmol/L in a sick newborn. A plasma ammonia concentration greater than 150 μmol/L is the consequence of an inborn error of metabolism until proved otherwise.

Most primary disorders of the urea cycle do not begin in the first 24 hours of life. Hyperammonemia that develops within the first 24 hours of life is generally associated with prematurity or a secondary hyperammonemia, usually a disorder of organic acid metabolism or fatty acid oxidation.[11,45,92] The severe hyperammonemia associated with prematurity has been designated transient hyperammonemia of the newborn. It is a mistake to believe that transient means that this disorder is benign. The degree of hyperammonemia found in this disorder can be as great as that found in many of the primary hyperammonemia syndromes, sometimes exceeding 1000 μmol/L. This disorder therefore requires the same rapid and vigorous therapy as the other defects of the urea cycle.

The key to distinguishing between a primary and a secondary hyperammonemia syndrome is the presence or absence of acidosis, ketosis, or hypoglycemia. The urea cycle defects generally are associated with respiratory alkalosis in response to the increased ventilatory rate induced by the hyperammonemia itself. A urea cycle disorder such as argininosuccinic aciduria, which accumulates an acidic metabolite,

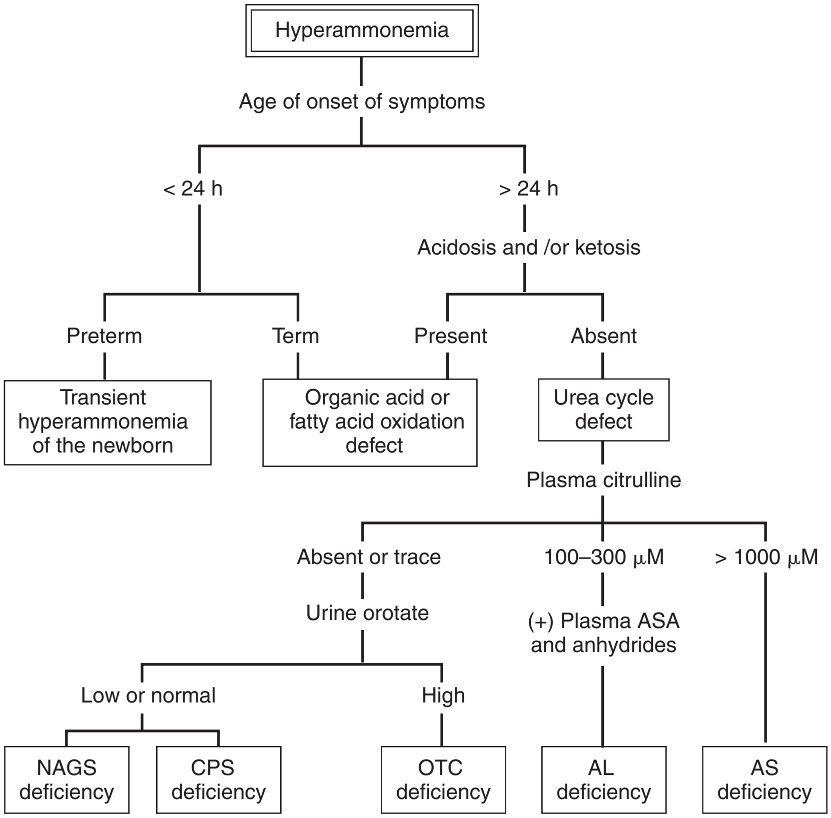

Figure 50–4. Approach to neonatal hyperammonemia. AL, argininosuccinic acid lyase; AS, argininosuccinic acid synthetase; ASA, argininosuccinic acid; CPS, carbamyl phosphate synthetase; NAGS, N-acetylglutamate synthetase; OTC, ornithine transcarbamylase. (*Adapted from Brusilow SW, Horwich AL: Urea cycle enzymes. In Scriver CR, et al, editors:* The metabolic and molecular bases of inherited disease, *8th ed. New York, 2001, McGraw-Hill, p 1909, reproduced with permission of The McGraw-Hill Companies.)*

can be associated with a mild acidosis, but the acidosis is rarely the predominant feature of presentation. Similarly, a component of metabolic acidosis can be superimposed on the respiratory alkalosis as the patient deteriorates. In contrast, the organic acidemias are generally associated with a metabolic acidosis of greater magnitude and an increased anion gap from their onset (see "Metabolic Acidosis"). Several fatty acid oxidation defects and the severe neonatal form of PC deficiency are also associated with a metabolic acidosis.

The second feature that distinguishes the organic acidemias from the urea cycle defects is the presence of ketosis in the organic acidemias. Ketosis can be detected rapidly by the screening studies outlined previously (see Tables 50-11 and 50-12). Definitive diagnosis of an organic acidemia requires quantitative urinary organic acid analysis. The distinguishing features of a fatty acid oxidation disorder are nonketotic or hypoketotic hypoglycemia. The presence of ketotic hypoglycemia and lactic acidosis, as well as the plasma amino acid pattern, distinguish PC deficiency from a urea cycle defect.

Urea Cycle Defects

In the absence of severe acidosis, ketosis, or hypoglycemia, a provisional diagnosis of a urea cycle defect should be made. The first step in the urea cycle is the formation of carbamyl phosphate from ammonia by carbamyl phosphate synthetase I (CPSI, but hereafter referred to simply as CPS). The next enzyme in the cycle, ornithine transcarbamylase (OTC), converts carbamyl phosphate and ornithine to citrulline. Citrulline is converted to argininosuccinate by argininosuccinate synthetase (ASS). Argininosuccinate is then cleaved by argininosuccinate lyase (ASL) to produce arginine. Finally, arginine is cleaved by arginase to form urea and ornithine. The urea is excreted in the urine, and the ornithine is available to restart the cycle. A fifth enzyme, N-acetylglutamate synthetase (NAGS), must be available to form N-acetylglutamine, which is required for the activation of CPS. Ornithine, citrulline, argininosuccinate, and arginine are all amino acids.

Urea cycle disorders can be differentiated from each other by performing amino acid analysis and urine orotic acid analysis (see also Specialized Biochemical Testing).[92] Typically, the amino acids proximal to the enzyme deficiency are increased, while the amino acids distal to the enzyme deficiency block are decreased. Except in the case of arginase deficiency, all of the urea cycle disorders are characterized by an increased plasma concentration of glutamine (a storage form for ammonia) and a decreased plasma arginine concentration.

The plasma citrulline and argininosuccinate concentrations provide the keys to distinguishing among the urea cycle defects that manifest with hyperammonemia in the neonatal period (see Fig. 50-4). The plasma citrulline concentration is generally low in NAGS deficiency, CPS deficiency, and OTC deficiency because citrulline synthesis requires the sequential action of these enzymes. Measurement of urinary orotic acid, which is formed from excessive amounts of carbamyl phosphate that leave the mitochondrion and enter the cytosolic pyrimidine biosynthetic pathway, can be used to distinguish among NAGS deficiency, CPS deficiency, and OTC deficiency. The urinary orotic acid concentration is low or normal in NAGS deficiency and CPS deficiency, but elevated in OTC deficiency.

Once formed, citrulline is converted to argininosuccinate by ASS. In the absence of ASS, citrulline produced by the earlier steps of the urea cycle accumulates in high concentration. For this reason, ASS deficiency is commonly called citrullinemia. ASL deficiency leads to increased excretion of argininosuccinate (and its anhydrides) and moderate elevation of plasma citrulline. Deficiency of the last step in the urea cycle, arginase, is not a cause of hyperammonemia in the neonatal period but is a cause of neurologic disease in later childhood. NAGS deficiency resembles CPS deficiency, and it requires enzyme analysis of a liver biopsy or genetic testing to distinguish between the two disorders.[92]

Treatment for the acute phase of the urea cycle defects includes stopping dietary protein intake, suppressing endogenous protein catabolism through parenteral administration of glucose, providing drugs that serve as alternate pathways for ammonia detoxification and excretion, and, in severe cases, hemodialysis.[46] Physicians who are unable to offer these forms of therapy should consider transferring their patients to centers that have such capability.

The protocols for detoxifying ammonia employ drugs that form excretable compounds with amino acids that accumulate during hyperammonemic crisis. The first drug to be developed was benzoate, which conjugates with glycine to form benzoylglycine (hippurate); formation and excretion of one molecule of hippurate eliminates one molecule of ammonia. The second drug to be developed was sodium phenylacetate, which conjugates with glutamine to form phenylacetylglutamine; formation and excretion of one molecule of phenylacetylglutamine eliminates two molecules of ammonia. Sodium phenylacetate is still available for intravenous use, but it has been replaced by sodium phenylbutyrate for oral use because sodium phenylbutyrate has a less offensive odor than sodium phenylacetate.

In addition to these drugs, arginine is provided to prime the urea cycle (i.e., regenerate ornithine), which is the precursor for the next turn of the cycle. N-carbamylglutamate is an analogue of N-acetylglutamate that can be taken orally and appears to be an effective treatment for N-acetylglutamate synthetase deficiency. Long-term management of these disorders after the acute illness entails modification of this basic plan.[92]

The prognosis for neonates who present with a urea cycle defect in the newborn period is guarded.[4,47] Without treatment, the mortality rate is high. With treatment, the mortality is reduced, but survivors are often left with significant neurologic impairments and a lifelong illness that predisposes them to recurrent life-threatening metabolic crises. The prognosis is particularly guarded for patients with defects affecting the early part of the cycle, namely NAGS deficiency, CPS deficiency, and OTC deficiency. The prognosis for patients with more distal defects in the urea cycle, ASS deficiency, and ASL deficiency, is better, although these patients also experience recurrent hyperammonemic crises. The guarded prognosis for all these patients has led many groups to perform early liver transplantation for these patients. The results of these efforts appear promising.[51]

Other Causes of Hyperammonemia

Four groups of disorders are associated with secondary hyperammonemia in neonates (see Box 50-2). We have already discussed fatty acid β-oxidation disorders, PC deficiency, and organic acidemias. The remaining group consists of two amino acid transport defects, the hyperornithinemia-hyperammonemia-homocitrullinuria (HHH) syndrome and lysinuric protein intolerance. The mechanism of the hyperammonemia in these disorders is impaired intracellular transport of one or more of the amino acids that make up the urea cycle. Treatment of these disorders is aimed at overcoming the defects in transport.[92,103]

TREATMENT

It is not possible in an overview of inborn errors of metabolism to discuss treatment of all the individual diseases that might be encountered. Treatments for some inborn errors of metabolism were discussed in the relevant sections of this chapter. General principles that are relevant to many of these diseases are discussed in the following section.

With few exceptions, the inborn errors of metabolism expressed in the newborn period are inherited as recessive traits. Disorders inherited in this manner generally have a common mechanism of pathogenesis, which is depicted in Figure 50-5. In simple terms, patients with these metabolic diseases are lacking a specific enzyme that converts substance B to substance C. In some cases, the enzyme requires one or more cofactors for its activity. Deficient enzyme activity may be caused by an error in apoenzyme function or cofactor availability.

The absence of enzyme activity can produce disease in a number of different ways. First, there is accumulation of substance B proximal to the enzyme block, leading to increased concentrations of substance B that might be toxic. The congenital hyperammonemias are a good example of this mechanism. Without one of the urea cycle enzymes, ammonia accumulates and causes significant neurotoxic effects. Second, there is overproduction of substance B, which is converted by alternate pathways to toxic metabolites E and F. It is thought that tyrosinemia type I, for example, produces its hepatotoxic and neurotoxic effects through overproduction of toxic secondary metabolites. Third, the disease state may be caused by deficiency of substance C or D, which is distal to the enzyme block. Defects of gluconeogenesis, such as pyruvate carboxylase deficiency, presumably work through this mechanism. Hypoglycemia results from impaired production of gluconeogenic precursors.

The disease state may be produced by a combination of these mechanisms. It is thought that many of the organic acidemias produce their toxic effects through a combination of mechanisms. In many of these disorders, acyl-CoA molecules accumulate proximal to the enzyme block and interfere

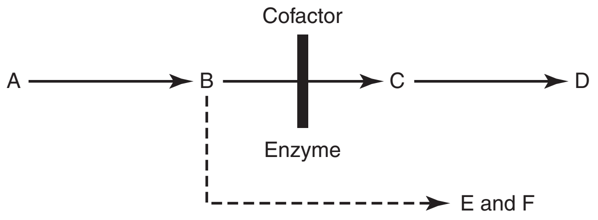

Figure 50–5. Schematic depiction of the pathogenesis of many inborn errors of metabolism. See text for details.

with a number of other metabolic pathways (e.g., the urea cycle), and there is underproduction of metabolites distal to the enzyme deficiency that are essential for other cellular processes.

Treatment at the Metabolite Level

Traditional approaches to treating inborn errors of metabolism have focused on this model of pathogenesis. The two general approaches in use are manipulation at the metabolite level and manipulation at the protein (or enzyme) level (Table 50-18).

The most common form of metabolite manipulation is dietary restriction, which decreases the amount of precursor A that the impaired enzyme must handle. The dietary management of PKU is an example of successful application of this approach. Dietary restriction is often combined with other treatment approaches, such as metabolite diversion.

The therapy for the urea cycle defects is perhaps the best studied of the metabolite diversion strategies. Two drugs, sodium phenylacetate and sodium benzoate, are provided to these patients to serve as ammonia traps (see also "Hyperammonemia"). Phenylacetate conjugates with glutamine to form phenylacetylglutamine, eliminating two ammonia molecules as the nitrogen component of glutamine; benzoate conjugates with glycine to form benzoylglycine (hippurate), eliminating one ammonia molecule as the nitrogen component of glycine. Arginine is also provided to prime the urea cycle because it is the last amino acid in the urea cycle and is split to release urea and ornithine, the precursor for the next turn of the cycle.

Other forms of diversion therapy include carnitine and glycine supplementation for the organic acidurias. Carnitine and glycine are transesterified with acyl-CoAs to form acylcarnitines and acylglycines, respectively. These transesterifications release free CoA, making it available for essential intracellular processes, while the potentially toxic acyl groups are excreted in the urine as acylcarnitines and acylglycines.

The deficiency of substances distal to the enzyme block (e.g., C or D) can be overcome by supplementing with exogenous C or D. An example of this approach is the feeding of uncooked cornstarch to patients with the hepatic forms of glycogen storage disease who cannot generate glucose from endogenous glycogen and are predisposed to fasting hypoglycemia.[12] The uncooked cornstarch is metabolized slowly to provide a steady source of glucose while these patients are sleeping.

TABLE 50–18 Approaches to Treatment of Inborn Errors of Metabolism

Approach	Examples
Metabolite manipulation	Dietary restriction Diversion Supplementation
Protein manipulation	Inhibition Replacement Stimulation of residual activity Transplantation
Gene manipulation	Somatic cell gene therapy

Treatment at the Protein Level

There are several approaches to treating at the protein level. Historically, the first example of this approach was to stimulate residual enzyme activity by providing pharmacologic amounts of cofactor required by the deficient enzyme. This approach has been used successfully to reduce the clinical severity of several vitamin-dependent enzymopathies, including vitamin B_6 and homocystinuria, vitamin B_{12} and methylmalonic acidemia, and thiamine and MSUD. It is important to understand that only a fraction of patients with any of these disorders respond to vitamin supplementation, for reasons that are still not completely understood.

The converse of the first approach is to inhibit enzyme activity and block production of toxic metabolites. The use of NTBC to treat tyrosinemia type I is an example of this approach. Tyrosinemia type I is a defect in the distal portion of the catabolic pathway for tyrosine. The enzyme deficiency that causes tyrosinemia type I leads to overproduction of toxic metabolites that produce the hepatic and neurologic complications of the disease. NTBC is a drug that inhibits an enzyme, *p*-hydroxyphenylpyruvate dioxygenase, which is proximal in the catabolic pathway to the enzyme deficiency that causes tyrosinemia type I. NTBC successfully suppresses overproduction of the toxic metabolites that produce the hepatic and neurologic complications of tyrosinemia type I.

A more direct approach to treating an enzyme deficiency is to replace the dysfunctional enzyme. This approach has been the focus of biochemical genetics for some time and has been tried from two directions: providing direct enzyme replacement and providing enzyme through organ transplantation. It has been very difficult to provide enzyme in a bottle for a number of reasons, including the need to produce large amounts of pure enzyme; the need to direct the enzyme to the organ, cell, or organelle where it is needed; the tendency of the body to reject foreign proteins; and the great expense of such efforts. The greatest success of this approach has been for some of the hematologic clotting disorders, such as factor VIII deficiency (see Chapter 46).

Direct enzyme replacement therapy has been available for several years for two inborn errors of metabolism, Gaucher disease and α_1-antitrypsin deficiency. In the case of Gaucher disease, enzyme replacement therapy has been successful in treating the hematologic and visceral manifestations and somewhat less successful in treating the skeletal manifestations of children and adults with the non-neuronopathic form of this disease. In the case of α_1-antitrypsin deficiency, enzyme replacement therapy is effective for the adult-onset pulmonary manifestations of the disease but not for the hepatic problems expressed in the neonatal period. The lessons learned in treating these diseases are being applied to other inborn errors of metabolism, especially the lysosomal storage disorders.

The second approach to enzyme replacement therapy is organ transplantation. This approach is being pursued vigorously for a number of inborn errors of metabolism (Table 50-19). Perhaps the best studied approach is liver transplantation, which has been performed successfully

TABLE 50–19 Experience with Organ Transplantation for Treating Inborn Errors of Metabolism

Organ	Disorder
Bone marrow	Lysosomal storage disorders Severe combined immunodeficiency
Heart	Dilated cardiomyopathy Familial hypercholesterolemia
Heart and lung	Cystic fibrosis
Kidney	Cystinosis Fabry disease
Liver	α_1-Antitrypsin deficiency Glycogen storage disorders Tyrosinemia type I Ornithine transcarbamylase deficiency

for about two dozen different inborn errors of metabolism.[51,86] This approach has been particularly successful for disorders in which the liver is the sole source of the enzyme and the only organ affected by the disease.

Many inborn errors of metabolism cannot be treated with liver transplantation or even multiple organ transplantation because the abnormal genotype produces a multisystem disease. This appears to be the case for many patients with a respiratory chain disorder, but not all.[74,87] Bone marrow transplantation is sometimes used to treat multiorgan disease because pluripotent bone marrow cells provide precursors for many related cell types in different organs. The benefit of bone marrow transplantation or stem cell transplantation for the lysosomal storage diseases appears promising and is an area of intense interest.[61,68]

Treatment at the Genetic Level

Treatment of inborn errors of metabolism has focused on modification of the phenotype rather than the genotype, but vigorous efforts are underway to develop methods for manipulating the genotype of somatic cells (i.e., cells other than germ cells). Efforts have focused on somatic cell gene therapy rather than altering germ cells for numerous ethical reasons. Additionally, there is the very practical reason that most children born with inborn errors of metabolism are not known to be at risk before they manifest symptoms of disease.

Somatic cell gene therapy requires insertion of a functional gene into a patient's somatic cells in such a way that they are introduced into the appropriate target organs, are functionally active, and are appropriately regulated. Somatic cell gene therapy has the goal of treating the affected patient's disease; it cannot correct the affected patient's germline. Successful somatic cell gene therapy has not been demonstrated conclusively for any inborn error of metabolism. The approaches to somatic cell gene therapy employ viral vectors or physicochemically modified DNA as a means of delivering a suitably tailored normal gene to its appropriate target. In vivo and ex vivo approaches also are being used to introduce the corrective gene. One source of concern with this approach has been that gene insertion into the patient's genome would be random and could lead to harmful mutagenesis. Homologous recombination is being explored as a means of circumventing this risk. In homologous recombination, a new gene (or DNA fragment) is inserted in exchange for the defective gene (or DNA fragment) rather than inserted randomly into the patient's genome. Homologous recombination could therefore provide a means of selectively excising the deleterious gene in exchange for the normal gene without the risk of producing harmful random insertional mutagenesis.

A novel pharmacogenetic approach for treating X-linked adrenoleukodystrophy was explored based on studies that showed genetic redundancy for many genes and many pathways.[42] In particular, the mammalian genome contains a gene that encodes for a protein that is functionally related to the protein that is abnormal in X-linked adrenoleukodystrophy. This protein is called adrenoleukodystrophy-related protein (ALDRP). Using sodium phenylbutyrate, which is known to activate a subgroup of latent genes, the investigators were able to activate the gene that encodes for the ALDRP protein in cultured cells from patients with X-linked adrenoleukodystrophy and in X-linked adrenoleukodystrophy knockout mice, and correct the biochemical lesion. Human trials with sodium phenylbutyrate or similar drugs are anticipated for the future. It is also anticipated that further studies will identify and capitalize on other instances of genetic redundancy for treating other inborn errors of metabolism.

Along with these efforts to develop somatic gene therapy, considerable effort is being expended to address the larger clinical, ethical, and societal issues of this form of treatment. These issues will undoubtedly prove to be as formidable a challenge as the technical issues, and they deserve the same attention.

CONCLUSION

Inborn errors of metabolism are an important cause of morbidity and mortality in newborn infants. These disorders are probably underdiagnosed because of their rarity, the nonspecific way many of them are expressed, and the difficulty clinicians have with their diagnosis. This chapter reduces this difficulty by providing a practical approach to the diagnosis of these disorders based on sets of common clinical and laboratory findings.

CHAPTER 51

The Kidney and Urinary Tract

Beth A. Vogt and Katherine MacRae Dell

In the past two decades, the field of clinical neonatal nephrology has broadened significantly, due to a variety of factors. For instance, the widespread use of invasive vascular catheters has resulted in a new set of complications, including acute kidney injury and renovascular hypertension related to thromboembolic disease. The improved survival of infants with extremely low birthweight and bronchopulmonary dysplasia has led to the relatively new complication of neonatal nephrocalcinosis. The advent of prenatal ultrasonography created new paradigms for the prenatal management of urinary tract anomalies (see Chapter 11).

The goals of this chapter are to review the anatomic and functional development of the kidney, outline the recommended approach to the evaluation of the neonate with suspected renal disease, and provide an overview of the common nephrologic and urologic problems seen in preterm and term neonates.

KIDNEY AND URINARY TRACT DEVELOPMENT

Kidney and urinary tract development is a complex process involving interactions between genes involved in the formation and maturation of the renal blood vessels, glomeruli, tubules, extracellular matrix, and uroepithelium. This carefully coordinated process involves the regulated activation and inactivation of hundreds of genes that encode transcription factors, growth factors and receptors, structural proteins, adhesion molecules, and other regulatory proteins.[39] Since the mid-1990s, the rapidly expanding fields of molecular genetics and proteomics have provided important new insights into the mechanisms involved in renal and urinary tract development. This section highlights some of the important pathways involved in these processes and provides examples of human diseases resulting from abnormalities in normal development.

Development of the Kidney

Three different kidney systems, the pronephros, mesonephros, and metanephros, form in succession during intrauterine development and are illustrated in Figure 51-1. The pronephros, a vestigial structure of 7 to 10 solid or tubular cell groups called *nephrotomes*, develops in the cervical region and disappears by the end of the fourth week of gestation. As the pronephros regresses, the mesonephros appears and is characterized by excretory tubules that form an S-shaped loop, with a glomerulus and Bowman capsule at the proximal end. At the distal portion, the tubule enters the collecting duct (also referred to as the *mesonephric,* or *wolffian,* duct), which does not drain into the coelomic cavity. During the second month of gestation, the urogenital ridge, which is the forerunner of the gonads, develops. By the end of the second month of gestation, most portions of the mesonephros disappear. However, a few caudal tubules remain in close proximity to the testes and ovaries, developing into the vas deferens in males and remaining as remnant tissue in females.

The formation of the metanephric, or definitive, kidney begins at 5 weeks of gestation, when the ureteric bud, an outgrowth of the dorsomedial wall of the mesonephric duct, invades a cord of mesenchymal cells called the *metanephric blastema*. The ureteric bud grows into the metanephric blastema and undergoes a series of divisions to form the major and minor caliceal system of the renal pelvis and collecting ducts of the kidney. At the tip of the branches, the mesenchymal cells of the metanephric blastema are induced by the advancing ureteric bud to differentiate into the epithelial cells that eventually become the glomeruli and renal tubules. Foci of the metanephric blastema become condensed adjacent to the branching ureteric bud to form “comma”-shaped bodies that then elongate to form S-shaped bodies (Fig. 51-2). The lower portion of the S-shaped body becomes associated with a tuft of capillaries to form the glomerulus, while the upper portion forms the tubular elements of the nephron.

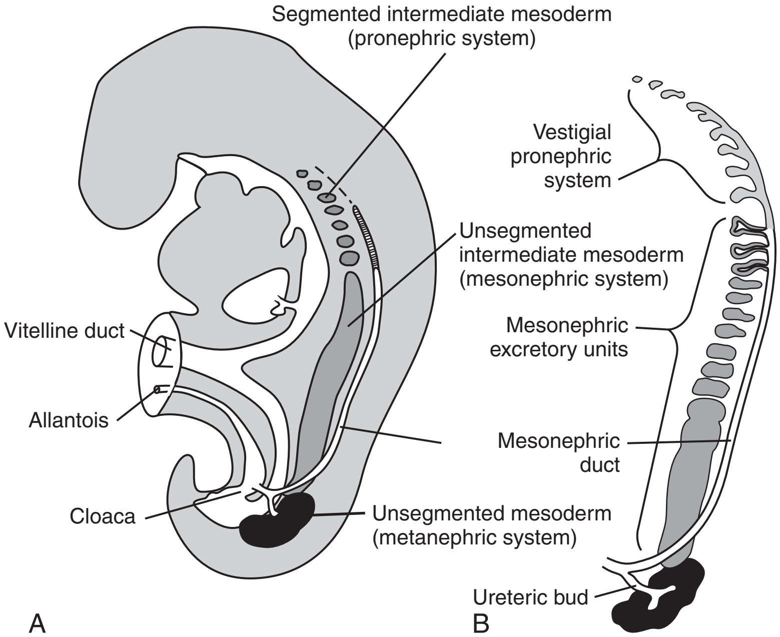

Figure 51–1. A, Schematic diagram showing the relation of the intermediate mesoderm of the pronephric, mesonephric, and metanephric systems. In the cervical and upper thoracic regions, the intermediate mesoderm is segmented; in the lower thoracic, lumbar, and sacral regions, it forms a solid, unsegmented mass of tissue known as the nephrogenic cord. Note the longitudinal collecting duct, initially formed by the pronephros but later taken over by the mesonephros. B, Schematic representation of the excretory tubules of the pronephric and mesonephric systems in a 5-week-old embryo. The ureteric bud penetrates the metanephric tissue. Note the remnant of the pronephric excretory tubules and longitudinal collecting duct. *(From Langman J, editor:* Medical embryology, *3rd ed, Baltimore, 1975, Williams & Wilkins, p 162.)*

The metanephric kidney ascends from the pelvic to the thoracolumbar region. This process is thought to occur as the result of a decrease in body curvature and body growth of the lumbar and sacral regions. In the pelvis, the metanephric kidney receives its blood supply from a pelvic branch of the aorta. During ascent, the metanephric kidney receives its blood supply from arterial branches at higher levels of the aorta. Although the pelvic vessels usually degenerate, the persistence of these early embryonic vessels leads to supernumerary renal arteries. The metanephric kidney becomes functional during the second half of pregnancy. Nephrogenesis, which is the formation of new nephron units, is complete at 34 weeks of gestation, when each kidney contains its definitive complement of approximately 800,000 to 1,200,000 nephrons.[2]

Studies of transgenic mice that carry mutations in certain developmentally expressed genes have provided important insights into the key proteins involved in renal development (Table 51-1). For example, mice lacking the transcription factor Wilms tumor (WT)-1 fail to develop kidneys or gonads due to the impaired development of the metanephric mesenchyme. Those lacking the glial derived neurotrophic growth factor (GDNF) develop renal agenesis due to the failure of ureteric bud formation. Those lacking α8-integrin, a cell-cell adhesion molecule, have impaired collecting tubule branching morphogenesis. Mice with mutations in the type 2 angiotensin II receptor gene develop a variety of structural abnormalities of the urinary tract, possibly due to abnormal vascular tone.

Specific mutations have now been identified in several congenital and inherited monogenic kidney diseases, which have provided important clues to the pathogenesis of disease (Table 51-2). For example, patients with congenital nephrotic syndrome of the Finnish type have mutations in the gene encoding nephrin, an important component of the glomerular basement membrane. Renal coloboma syndrome results from mutations in the transcription regulator PAX-2. Bartter syndrome, a disorder that may present in the newborn period with hypokalemia, metabolic alkalosis, and severe dehydration, is caused by mutations in the ion transport proteins responsible for sodium and potassium handling in the loop of Henle.

For some of these disorders, the pathogenesis may be evident from the nature of the abnormal protein product, such as impaired renal water handling in patients with nephrogenic diabetes insipidus who harbor mutations in genes encoding aquaporin 2 and the antidiuretic hormone receptor, the key proteins in regulating water handling in the collecting tubule.[45] However, there are several disorders, such as polycystic kidney disease, for which the causative genes have been identified but the precise mechanisms by which the mutated gene and its aberrant protein product actually cause disease have not been fully delineated.

Development of the Bladder and Urethra

The bladder and urethra are formed during the second and third months of gestation, which is summarized in Figure 51-3. During the fourth to seventh week of development, the cloaca, which is located at the proximal end of the allantois and is the precursor to the urinary bladder and urethra, is divided by the urorectal septum into the primitive urogenital sinus (anterior portion) and the anorectal canal (posterior portion). The primitive urogenital sinus develops into the bladder (upper portion), prostatic and membranous urethra (pelvic portion) in males, and the penile urethra (males) or urethra and vestibule (females). As the cloaca develops, the caudal portion of the mesonephric ducts is absorbed into the bladder wall. Similarly, the caudal portions of the ureters, which originate from the mesonephric ducts, enter the bladder. During these processes, the ureteral orifices move cranially and the

mesonephric ducts move closer together to enter the prostatic urethra, forming the trigone of the bladder. At the end of the third month of gestation, the epithelial proliferation of the prostatic urethra forms outbuddings that constitute the prostate gland in males. In females, the cranial portion of the urethra forms buds that develop into the urethral and paraurethral glands.

Physiology of the Developing Kidney

During intrauterine life, the kidneys play only a minor role in regulating fetal salt and water balance because this function is maintained primarily by the placenta. The most important functions of the prenatal kidneys are the formation and excretion of urine to maintain an adequate amount of amniotic fluid. After birth, there is a progressive maturation in renal

TABLE 51–1 Examples of Mouse Models of Developmental Kidney Diseases

Mutant Gene/Protein	Mutant Mouse Phenotype	Abnormal Kidney/Urinary Tract/Process
AGTR2/angiotensin type II receptor	Varied urinary tract abnormalities	Altered vascular tone/renal bloodflow
GDNF/glial-derived growth factor	Renal agenesis	Ureteric bud absent
HNF1B/hepatocyte nuclear factor 1β	Polycystic kidneys	Collecting tubule hyperplasia
Inv/inversin	Cystic kidneys	Altered left-right polarity
ITGA8/integrin, α8	Renal dysplasia	Abnormal ureteric bud induction and impaired collecting tubule branching
LMX1B/Lim homeobox transcription	Massive proteinuria/glomerular	Altered glomerular basement membrane architecture
PDGFB/platelet-derived growth factor-β	Hemorrhage and capillary leak	Abnormal glomeruli; impaired angiogenesis
PKHD1/fibrocystin	Polycystic kidneys	Collecting tubule hyperplasia
WT1/Wilms tumor suppressor gene protein	Renal agenesis; glomerulosclerosis	Absence/loss of metanephric mesenchyme

function, which appears to parallel the needs of the neonate for growth and development (Table 51-3).

RENAL BLOOD FLOW

Absolute renal blood flow (RBF) and the percentage of cardiac output directed to the kidneys increase steadily with advancing gestational age. The kidneys of a human fetus weighing more than 150 g receive approximately 4% of the cardiac output, compared with approximately 6% in the term infant. The relatively low RBF of the fetus is related to high renovascular resistance caused by the increased activity of the renin-angiotensin-aldosterone and sympathetic nervous systems. The renal blood flow dramatically increases postnatally, reaching 8% to 10% of the cardiac output at 1 week of life, and achieves adult values of 20% to 25% of the cardiac output at 2 years of age. This rise in renal blood flow is caused primarily by decreasing renovascular resistance and increasing cardiac output and perfusion pressure.

GLOMERULAR FILTRATION

The glomerular filtration rate (GFR) in the fetal kidney increases steadily with advancing gestational age (Fig. 51-4). By 32 to 34 weeks after conception, a GFR of 14 mL/min per 1.73 m^2 is achieved, which further increases to 21 mL/min per 1.73 m^2 at term (see Table 51-3). The GFR continues to increase postnatally, achieving adult values of 118 mL/min per 1.73 m^2 by the age of 2 years. The achievement of adult GFR may be delayed in preterm infants, especially those with very low birthweights and those with nephrocalcinosis.[52] The progressive increase in GFR during the initial weeks of postnatal life primarily results from an increase in glomerular perfusion pressure. Subsequent increases in GFR during the first 2 years of life are caused primarily by increases in renal blood flow and the maturation of superficial cortical nephrons, which lead to an increase in the glomerular capillary surface area.

CONCENTRATION AND DILUTION OF URINE

Newborn infants have a limited capacity to concentrate their urine, with maximal urinary osmolality of 800 mOsm/kg in a term infant; compared to that of a 2 year old, which approximates adult values of 1400 mOsm/kg (see Table 51-3). In contrast, the term newborn infant has full ability to maximally dilute urine in response to a water load, achieving adult values of 50 mOsm/kg. Preterm infants are unable to fully dilute their urine, but can achieve urine osmolalities of 70 mOsm/kg. However, the response of premature infants to an acute water load may be limited because of their low GFR and the decreased activity of sodium transporters in the diluting segment of the nephron. The excessive administration of water may place the newborn infant at a high risk for dilutional hyponatremia and hypervolemia. Urinary diluting and concentrating capacity in term and preterm infants is discussed in more detail in Chapter 36.

EVALUATION OF THE NEONATE WITH RENAL DISEASE

History

The results of prenatal ultrasonography should be carefully reviewed, with particular attention devoted to kidney size, echogenicity, structural malformations, amniotic fluid volume, and bladder size and shape (Box 51-1). Although the bladder may be identified and its volume discerned at 15 weeks of gestation, the kidneys are not visualized until after the 16th to 17th week of gestation in most fetuses. The presence of small or enlarged kidneys, renal cysts, hydronephrosis, bladder enlargement, or oligohydramnios suggests significant renal or urologic pathology.

The antenatal history should be reviewed thoroughly, with particular attention devoted to medications, toxins, and unusual environmental exposures during the pregnancy.

TABLE 51–2 Examples of Inherited Renal Disorders with a Known Genetic Basis That Present in Infancy

Disease	Mutated Gene/Protein	Kidney Disease Phenotype	Protein Function
Autosomal recessive polycystic kidney disease	*PKHD1*/fibrocystin	Polycystic kidneys	Receptor-like properties; function unknown
Bartter syndrome, neonatal/ infantile	*CCKb*/kidney chloride channel B *ROMK*/inwardly rectifying potassium channel	Hypokalemic metabolic alkalosis, recurrent dehydration	Sodium, potassium and/or chloride transport in the loop of Henle
Branchio-oto-renal syndrome	*EYA1*/eyes absent, *Drosophila*, homologue of, 1	Renal dysplasia	Regulator of gene transcription factors
Congenital nephrotic syndrome, Finnish type	*NPHS1*/nephrin	Nephrotic syndrome	Glomerular filtration barrier component
Denys-Drash/Beckwith-Wiedemann/aniridia/ hemihypertrophy	*WT1*/Wilms tumor suppressor gene	Progressive renal failure/ hypertension/Wilms tumor	Transcription factor
Distal renal tubular acidosis with sensorineural deafness	*ATP6N1B*/H^+-ATPase	Metabolic acidosis	Hydrogen ion transport
Fanconi-Bickel syndrome	*GLUT2*/solute carrier family 2 protein	Fanconi syndrome (global proximal tubular dysfunction)	Facilitative glucose transporter
Infantile nephronophthisis	*INV*/nephrocystin 2	Polyuria, small kidneys	Determination of left-right asymmetry
Infantile nephropathic cystinosis	*CTNS*/cystinosin	Cystinosis, renal failure	Cystine transporter
Nail-patella syndrome	*LMX1B*/Lim homeodomain protein	Glomerulonephritis, nephrotic syndrome	Regulator of type IV collagen production
Nephrogenic diabetes insipidus, X-linked	*AVPR2*/ADH receptor	Diabetes insipidus	ADH receptor
Renal coloboma syndrome	PAX2/PAX2 protein	Hypoplastic kidneys, renal failure	Induction/regulation of WT1
Simpson-Golabi-Behmal overgrowth syndrome	GPC3/glypican 3	Nephromegaly/renal dysplasia	Control of cell division and growth

Structural and functional alterations of the newborn kidney have been described in infants with antenatal exposure to angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), nonselective nonsteroidal anti-inflammatory drugs, and selective COX-2 inhibitors.[12] Classic ACE fetopathy (renal failure, limb deformities, hypotension, pulmonary hypoplasia, and hypocalvaria) is seen following second and third trimester exposure to ACE inhibitors, while first-trimester exposure to ACE inhibitors has been associated with increased risk of cardiovascular and central nervous system malformations.[19] Maternal exposure to immunosuppressive agents including tacrolimus and aminoglycosides including gentamicin have been associated with neonatal renal dysfunction.[12]

A review of the medical history of the family is important, including any prior fetal or neonatal deaths. Although there is no established genetic basis for many congenital renal anomalies, certain disorders such as renal hypoplasia/dysplasia, multicystic dysplastic kidney, and vesicoureteral reflux may have familial clustering. There is a clear genetic basis for certain diseases, including polycystic kidney disease and congenital nephrotic syndrome.

Physical Examination

The evaluation of blood pressure and volume status is critical in the newborn with suspected renal disease. Hypertension may be present in infants with polycystic kidney disease, acute kidney injury, renovascular or aortic thrombosis, or obstructive uropathy. Hypotension usually results from volume depletion, hemorrhage, or sepsis, any of which may lead to acute kidney injury. Edema may occur in infants with acute kidney injury, hydrops fetalis, or congenital nephrotic syndrome. Ascites may be present in infants with urinary tract obstruction congenital nephrotic syndrome, or volume overload. Special attention should be paid to the abdominal examination. In the neonate, the lower pole of each kidney is easily palpable because of the neonate's reduced abdominal muscle tone. The presence of an abdominal mass in a newborn should be assumed to involve the urinary tract until proven otherwise because two thirds of neonatal abdominal masses are genitourinary in origin.[16] The most common renal cause of an abdominal mass is hydronephrosis, followed by a multicystic dysplastic kidney. Less common causes of an abdominal mass include polycystic kidney disease, renal vein thrombosis, ectopic or fused kidneys, and renal tumors. The abdomen should be examined for the absence of or laxity in the abdominal muscles, which may suggest Eagle-Barrett ("prune-belly") syndrome. Distention of the newborn bladder may suggest lower urinary tract obstruction or an occult spinal cord lesion.

A number of anomalies should alert the physician to the possibility of underlying renal defects, including abnormal external ears, aniridia, microcephaly, meningomyelocele, pectus excavatum, hemihypertrophy, a persistent urachus, bladder or cloacal exstrophy, an abnormality of the external genitalia, cryptorchidism, imperforate anus, and limb

BOX 51–1 Prenatal Ultrasonography as a Diagnostic Tool for Abnormalities of the Urinary Tract

KIDNEYS

- Dilated renal pelvis
  - Physiologic
  - Hydronephrosis: vesicoureteral reflux, urinary tract obstruction
- Multicystic dysplastic kidney (prenatal differentiation from hydronephrosis may be difficult)
- Hyperechoic kidney (renal dysplasia, autosomal recessive polycystic kidney disease)
- Renal duplication, malposition
- Lack of visualization: renal agenesis, hypoplasia, malposition
- Renal tumors

URETER

- Hydroureter
- Ureterocele

BLADDER

- Dilation
  - With thickened wall: urethral valves
  - Without thickened wall: megacystis-megaureter syndrome, neurogenic bladder
- Bladder exstrophy, cloacal exstrophy
- Lack of visualization despite prolonged observation and maternal furosemide administration

COMPROMISED FETUS:

- severe intrauterine growth restriction, fetal stress, bilateral renal agenesis, cystic disease, ureteral obstruction

ASCITES

- Urinary ascites probable if bladder wall thickened or kidneys abnormal

HYDROPS FETALIS

- Most often due to nonrenal causes; occasionally caused by bilateral renal cystic disease, urinary tract obstruction, nephrotic syndrome

OLIGOHYDRAMNIOS

- Bilateral renal malformations, urinary tract obstruction
- Rupture of membranes, postmaturity, subacute fetal distress

POLYHYDRAMNIOS

- Renal tubular disorder with urinary concentrating defect
- Multiple pregnancy, upper gastrointestinal tract obstruction, neurologic disorders, maternal diabetes, fetal hydrops
- Pearlman syndrome

PLACENTAL EDEMA

- Congenital nephrotic syndrome of the Finnish type

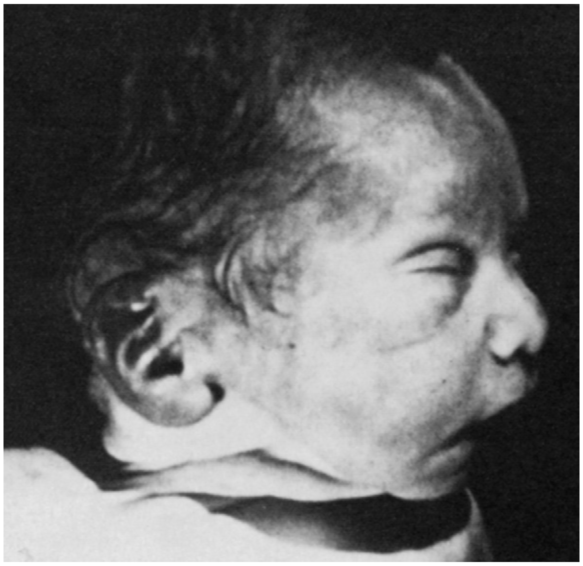

Figure 51–5. Potter facies. Characteristic findings include epicanthal folds, hypertelorism, low-set ears, a crease below lower lip, and a receding chin.

deformities. A single umbilical artery raises the suspicion of renal disease. In one study, 7% of otherwise normal infants with a single umbilical artery were found to have significant renal anomalies.[13] The utility of screening all infants with a single umbilical artery, however, remains controversial.

A constellation of physical findings, designated the *oligohydramnios (Potter) sequence*, may be seen in infants with bilateral renal agenesis (Fig. 51-5). The complete absence of fetal kidney function results in anhydramnios, which causes fetal deformation from compression by the uterine wall. The characteristic facial features include wide-set eyes, depressed nasal bridge, beaked nose, receding chin, and posteriorly rotated, low-set ears. Other associated anomalies include a small, compressed chest wall, with resulting pulmonary hypoplasia, and arthrogryposis (see Chapter 44). The condition is uniformly fatal. “Potter-like” features may be seen in infants with significant renal impairment and oligohydramnios related to severe antenatal urinary tract obstruction or disorders such as autosomal recessive polycystic kidney disease. Such patients often have pulmonary hypoplasia and spontaneous pneumothorax or pneumomediastinum resulting from their requirement for high ventilator pressures.

Laboratory Evaluation

URINALYSIS

The examination of a freshly voided specimen of urine provides immediate, valuable information about the condition of the kidneys. The collection of an adequate, uncontaminated specimen from the neonate can be very difficult. A specimen collected by cleaning the perineum and applying a sterile adhesive plastic bag may be useful in screening, but it may result in a false-positive urine culture because of fecal contamination. Bladder catheterization is more reliable but may be technically difficult in preterm infants. Suprapubic bladder aspiration is an alternative urinary collection method in preterm infants without intra-abdominal pathology or bleeding disorders.

Analysis of the urine should include inspection, measurement of specific gravity, urinary dipstick assessment, and microscopic analysis. The newborn urine is usually clear and nearly colorless. Cloudiness may represent a urinary tract infection or the presence of crystals. A yellow-brown to deep olive-green color may represent large amounts of conjugated bilirubin. Porphyrins, certain drugs such as phenytoin, bacteria, and urate crystals may stain the diaper pink and be confused with bleeding. Brown urine suggests bleeding from the upper urinary tract, hemoglobinuria, or myoglobinuria.

Urinary specific gravity may be measured by using a clinical refractometer or a urinary dipstick method. The specific gravity of neonatal urine is usually very low (less than 1.004) but may be factitiously elevated by high-molecular-weight solutes such as contrast agents, glucose or other reducing substances, or large amounts of protein. Urinary osmolality may be a more reliable measurement of the concentrating and diluting capacity of the kidney.

Urinary dipstick evaluation can also detect the presence of heme-containing compounds (i.e., red blood cells, myoglobin, and hemoglobin), protein, and glucose. White blood cell products such as leukocyte esterase and nitrite may also be detected on urinary dipstick evaluation and should raise the suspicion of urinary tract infection, mandating collection of a urine culture. The microscopic examination of urinary sediment may detect the presence of red blood cells, casts, white blood cells, bacteria, or crystals.

ASSESSMENT OF RENAL FUNCTION

Although 98% of term infants void during the first 30 hours of life,[17] a delay in urination for up to 48 hours should not be a cause for immediate concern in the absence of a palpable bladder, abdominal mass, or other signs or symptoms of renal disease. A failure to void for longer than 48 hours may suggest impairment of renal function and should prompt further investigation.

The serum creatinine level is the simplest and most commonly used indicator of neonatal kidney function. The serum creatinine concentration immediately after birth reflects the maternal creatinine concentration, neonatal muscle mass, and GFR at the time of delivery. In term infants, the serum creatinine level gradually decreases from 1.1 mg/dL to a mean value of 0.4 mg/dL within the first 2 weeks of life. However, in preterm infants, the plasma creatinine level does not fall steadily from birth but instead rises in the first 48 hours before beginning to fall to equilibrium levels.[38]

Failure of the serum creatinine level to fall or a persistent increase in serum creatinine suggests impairment of renal function. In general, each doubling of the serum creatinine level represents an approximately 50% reduction in GFR; for example, a rise in serum creatinine from 0.4 to 0. 8 mg/dL represents a 50% reduction in GFR. A reasonably accurate estimate of GFR can be made from the serum creatinine concentration by using an empirically derived formula that has been applied to normal preterm and term infants.[11]

Estimated GFR (mL/min per 1.73 m^2):

Preterm infants:

$$0.33 \times \text{length (cm)/serum creatinine (mg/dL)}$$

Term infants:

$$0.45 \times \text{length (cm)/serum creatinine (mg/dL)}$$

Radiologic Evaluation

Ultrasonography has become the most common method of imaging the neonatal urinary tract. It offers a noninvasive evaluation without exposure to contrast agents or radiation. Ultrasonography is indicated in infants with a history of any renal abnormality noted on antenatal ultrasound, as well as abdominal mass, acute kidney injury, hypertension, hematuria, oliguria, congenital malformations, or specific findings on physical examination that suggest anomalies of the urinary tract. Ultrasonography can identify hydronephrosis, cystic kidney disease, and abnormalities of kidney size and position. It also may be used as a screening tool for nephrocalcinosis and nephrolithiasis in preterm infants who have been receiving long-term loop diuretic therapy. A Doppler flow study of the renal arteries and aorta may be helpful in the evaluation of thrombosis in infants with suspected renovascular hypertension or acute kidney injury.

A diagnostic voiding cystourethrogram (VCUG) should be considered an important part of the radiologic examination in infants with significant hydronephrosis, renal dysplasia or anomaly, or documented urinary tract infection. This study is the procedure of choice to evaluate the urethra and bladder and to ascertain the presence or absence of vesicoureteral reflux. Voiding cystourethrography involves the instillation of a radiopaque contrast agent into the bladder by urinary catheterization. Films of the urethra during voiding and of the bladder and ureters toward the end of voiding are essential.

Other radiologic tests may occasionally be used for diagnostic purposes in the neonate (see Chapter 37). Radioisotopic renal scanning is of value in locating anomalous kidneys, determining kidney size, and identifying obstruction or renal scarring. Radioisotopic scans may also provide information about the relative blood flow to each kidney and the contribution of each kidney to overall renal function. Abdominal computed tomography is useful in the diagnosis of renal tumors, renal abscesses, and nephrolithiasis.

CLINICAL PROBLEMS

Hematuria

Hematuria is defined as five or more red blood cells per high-powered field on microscopic evaluation of a centrifuged urine sample. Blood can enter the urine from any location in the urinary tract, from the kidney to the urethra. The most frequent cause of hematuria in the neonate is acute tubular necrosis (ATN), which is caused by perinatal asphyxia, the administration of nephrotoxic drugs, or sepsis. Another important cause of hematuria is renal venous thrombosis, which must be considered in the infants of diabetic mothers, those with cyanotic congenital heart disease, those who are dehydrated, and those with indwelling umbilical venous catheters. Other causes of neonatal hematuria include urinary tract infection, trauma from catheterization or suprapubic aspiration, neoplasia, obstructive uropathy, coagulopathy, and thrombocytopenia. Extraurinary (e.g., vaginal, rectal, perineal, preputial) sources may also lead to apparent hematuria.

Several conditions can simulate hematuria, including myoglobinuria, hemoglobinuria, and pigmenturia. In infants with myoglobinuria and hemoglobinuria, the urine may look red or brown and test dipstick-positive for blood, but red blood cells are not present on microscopic examination of the urine. Myoglobinuria may be seen in infants with inherited metabolic myopathy, infectious myositis, or rhabdomyolysis. Hemoglobinuria may be present in infants with erythroblastosis fetalis or other forms of hemolytic disease. Urine discolored by bile pigments, porphyrins, or urate crystals may also raise the suspicion of hematuria, but in these conditions the urinary dipstick tests negative for blood and the microscopic examination reveals no red blood cells.

Proteinuria

Proteinuria is defined as a urinary dipstick value of at least 1+ (30 mg/dL), with a specific gravity of 1.015 or less, or a urinary dipstick value of at least 2+ (100 mg/dL), with a specific gravity of more than 1.015. Nearly any form of injury, whether glomerular or tubular, can result in an increase in urinary protein excretion. Common causes of neonatal proteinuria include ATN, fever, dehydration, cardiac failure, high doses of penicillin, and the administration of a contrast agent. Persistent massive proteinuria and edema in a neonate should prompt the consideration of congenital nephrotic syndrome, an autosomal recessive disorder characterized by proteinuria, failure to thrive, a large placenta, and chronic renal dysfunction. False-positive dipstick values for protein may be the result of highly concentrated urine, alkaline urine, infection, and detergents.

Glycosuria

The diagnosis of glycosuria is established by the presence of glucose on a urinary dipstick. Glycosuria frequently occurs when the serum glucose concentration exceeds the renal threshold, such as that in neonates with hyperglycemia related to sepsis or to the administration of total parenteral nutrition. It is important to measure the serum glucose concentration in neonates in whom glucose has been detected by urinary dipstick evaluation. The correction of hyperglycemia normalizes the urinary dipstick findings.

Isolated glycosuria with a normal serum glucose concentration is defined as renal glycosuria, a benign condition caused by an abnormality in the transport of proximal tubular glucose. Two forms of inherited renal glycosuria have been described. In type A, the defect involves a depression in the threshold and the maximum capacity of the renal tubule to reabsorb glucose (TmG). Type B renal glycosuria is characterized by a low threshold and a normal TmG. The inheritance pattern of renal glycosuria is autosomal recessive in most patients, although an autosomal dominant mode of transmission has been described. No therapy is necessary other than the recognition of the condition, avoidance of confusion with diabetes mellitus, and provision of a normal intake of carbohydrates.

If glycosuria is accompanied by other evidence of renal tubular dysfunction, such as an excessive urinary loss of potassium, phosphorus, and amino acids, a generalized proximal tubulopathy (i.e., Fanconi syndrome) should be considered. Glycosuria may also be seen in infants with congenital renal diseases such as renal dysplasia, in which there is significant tubular dysfunction. Glycosuria in an infant with severe, watery diarrhea should raise the suspicion of congenital intestinal glucose-galactose malabsorption syndrome.

Acute Kidney Injury

Acute kidney injury is an increasingly common condition in the neonatal intensive care unit, ranging from mild dysfunction to complete anuric kidney failure. Acute kidney injury is characterized by a deterioration in kidney function over hours to days, leading to an inability of the kidneys to excrete nitrogenous waste products and maintain fluid and electrolyte homeostasis. Although the criteria for neonatal acute kidney injury have varied among studies, a frequently used definition is a serum creatinine level of more than 1.5 mg/dL.[7] Oliguric acute kidney injury is characterized by a urine flow rate of less than 1 mL/kg per hour, whereas in nonoliguric acute kidney injury the urine flow rate is maintained above this level. Data on the incidence of acute kidney injury in the hospitalized neonatal population are variable, mainly because of the different criteria used to define the condition, ranging from 8% to 24%.[6,29] Risk factors for development of neonatal acute kidney injury include very low birthweight (less than 1500 g), low 5-minute APGAR score, maternal drug administration [(nonsteroidal anti-inflammatory drugs and antibiotics)], intubation at birth, respiratory distress syndrome, patent ductus arteriosus, phototherapy, and neonatal medication administration (nonsteroidal anti-inflammatory drugs, antibiotics, diuretics).[14]

The signs of acute kidney injury may include oliguria, systemic hypertension, cardiac arrhythmia, evidence of fluid overload or dehydration, decreased activity, seizure, vomiting, and anorexia. Laboratory evidence may include elevated serum creatinine and blood urea nitrogen, hyperkalemia, metabolic acidosis, hypocalcemia, hyperphosphatemia, and a prolonged half-life for medications excreted by the kidney (e.g., aminoglycosides, vancomycin). The causes of neonatal acute kidney injury are multiple and can be divided into prerenal, renal, and postrenal categories (Box 51-2).

PRERENAL AZOTEMIA

Prerenal azotemia is the most common type of acute kidney injury in the neonate and may account for up to 85% of all cases. Prerenal azotemia is characterized by inadequate renal perfusion, which, if promptly treated, is followed by improvements in renal function and urine output. The most common causes of prerenal azotemia are dehydration, hemorrhage, septic shock, necrotizing enterocolitis, patent ductus arteriosus, and congestive heart failure. The postnatal administration of medications that reduce renal blood flow, such as indomethacin or ibuprofen, angiotensin-converting enzyme inhibitors, and phenylephrine eyedrops can result in prerenal azotemia. In utero exposure to nonselective nonsteroidal anti-inflammatory drugs, COX2 inhibitors, angiotensin-converting enzyme inhibitors, and angiotensin receptor antagonists can also induce neonatal acute kidney injury.[12]

INTRINSIC (RENAL) ACUTE KIDNEY INJURY

ATN is the most common cause of intrinsic acute kidney injury in neonates. The causes of ATN include perinatal asphyxia, sepsis, cardiac surgery, a prolonged prerenal state, and nephrotoxic drug administration. The pathophysiology of ATN is complex and appears to involve renal tubular cellular injury, alterations in adhesion molecules, and changes in renal

BOX 51–2 Causes of Acute Kidney Injury in the Neonate

PRERENAL
Dehydration
Hemorrhage
Sepsis
Necrotizing enterocolitis
Congestive heart failure
Drugs: angiotensin-converting enzyme inhibitors, indomethacin, ibuprofen, amphotericin, tolazoline

RENAL
Acute tubular necrosis
Renal dysplasia
Polycystic kidney disease
Renal venous thrombosis
Uric acid nephropathy
Transient acute renal insufficiency of the newborn

POSTRENAL
Posterior urethral valves
Bilateral ureteropelvic junction obstruction
Bilateral ureterovesical junction obstruction
Neurogenic bladder
Obstructive nephrolithiasis

hemodynamics. Other causes of intrinsic acute kidney injury in the newborn include renal dysplasia, autosomal recessive polycystic kidney disease, and renal arterial or venous thrombosis. Transient acute kidney injury of the newborn is a poorly understood, rapidly reversible syndrome characterized by oliguric acute kidney injury and hyperechogenic renal medullary pyramids on ultrasound.[37] This syndrome has been reported in otherwise healthy term infants with sluggish feeding and is thought to be related to the deposition of Tamm-Horsfall protein or uric acid in the renal tubular collecting system.

OBSTRUCTIVE (POSTRENAL) ACUTE KIDNEY INJURY

Obstructive acute kidney injury is caused by bilateral urinary tract obstruction and can usually be reversed by relief of the obstruction. Obstructive acute kidney injury in the neonate may be related to a variety of congenital urinary tract conditions, including posterior urethral valves, bilateral ureteropelvic or ureterovesical junction obstruction, obstructive urolithiasis, and a neurogenic bladder. Extrinsic compression of the ureters or bladder by a congenital tumor such as a sacrococcygeal teratoma or intrinsic obstruction by renal calculi or fungus balls is a rare cause of obstructive acute kidney injury.

EVALUATION

A careful history should focus on prenatal ultrasound abnormalities, perinatal asphyxia, the prenatal or postnatal administration of potentially nephrotoxic drugs, and a family history of renal disease. The physical examination should focus on signs of volume depletion or volume overload, the abdomen, genitalia, and a search for other congenital anomalies or signs of the oligohydramnios (Potter) sequence. Levels of electrolytes, blood urea nitrogen, creatinine (Cr), calcium, phosphorus, albumin, and uric acid should be monitored frequently if significant metabolic abnormalities are present. Urine should be sent for urinalysis, urine culture, and urine sodium and creatinine determination. The fractional excretion of sodium (FE_{Na}), as well as other diagnostic indexes, may be useful in differentiating prerenal from intrinsic acute kidney injury (Table 51-4):

$$FE_{Na}\ (\%) = (UNa \times PCr)/(PNa \times UCr) \times 100\%$$

Neonates with an FE_{Na} value of more than 3.0% generally have intrinsic acute kidney injury, whereas those with an FE_{Na} value of less than 2.5% have prerenal acute kidney injury. Renal ultrasound is helpful in the identification of congenital renal disease and urinary tract obstruction.

MEDICAL MANAGEMENT

The prevention of acute kidney injury in newborn infants requires maintenance of an adequate circulatory volume, careful fluid and electrolyte management, prompt diagnosis and treatment of hemodynamic or respiratory abnormalities, and close monitoring of potentially nephrotoxic medications. In the case of established oliguric acute kidney injury, a urinary catheter should be placed to exclude lower urinary tract obstruction. If there is no improvement in urine output after bladder drainage is established, a fluid challenge of 10 to 20 mL/kg should be administered over 1 to 2 hours to exclude prerenal acute kidney injury.

A lack of improvement in urine output and serum creatinine suggests intrinsic acute kidney injury. The goal of medical management of intrinsic acute kidney injury is to provide supportive care until there is spontaneous improvement in renal function. Fluids should be restricted to insensible losses (500 mL/m^2 per day, or 30 mL/kg per day) plus urine output and other measured losses (see Chapter 36). Daily weights and careful intake and output measurements are essential to follow volume status. Nephrotoxic drugs

TABLE 51–4 Diagnostic Indexes in Acute Kidney Injury

Test	Prerenal AKI	Intrinsic AKI
BUN/Cr ratio (mg/mg)	>30	<20
FE_{Na} (%)	≤2.5	≥3.0
Urinary Na (mEq/L)	≤20	≥50
Urinary Osm (mOsm/kg)	≥350	≤300
Urinary specific gravity	>1.012	<1.014
Ultrasonography	Normal	May be abnormal
Response to volume challenge	UO >2 mL/kg/h	No increase in UO

AKI, acute kidney injury; BUN, blood urea nitrogen; Cr, creatinine; FE_{Na}, fractional excretion of sodium (Na); Osm, osmolality; UO, urinary output.

should be discontinued to reduce the risk of additional renal injury. Medications should be adjusted by dose, interval, or both according to the degree of renal dysfunction. Potassium and phosphorus should be restricted in those neonates with hyperkalemia or hyperphosphatemia. Metabolic acidosis may require treatment with intravenous or oral sodium bicarbonate. Loop and thiazide diuretics may prove helpful in augmenting the urinary flow rate. The role of low-dose dopamine in therapy for neonatal acute kidney injury has not been determined.

RENAL REPLACEMENT THERAPY

Renal replacement therapy should be considered if maximum medical management fails to maintain acceptable fluid and electrolyte levels. The two purposes of renal replacement therapy are ultrafiltration (removal of water) and dialysis (removal of solutes). The indications for the initiation of renal replacement therapy include hyperkalemia, hyponatremia with symptomatic volume overload, acidosis, hypocalcemia, hyperphosphatemia, uremic symptoms, and an inability to provide adequate nutrition due to the need for fluid restriction in the face of oliguria (Box 51-3).

Peritoneal dialysis is the most commonly used renal replacement modality in the neonatal population because it is technically less difficult and does not require vascular access or anticoagulation. For this procedure, hyperosmolar dialysate is repeatedly infused into and drained out of the peritoneal cavity through a surgically placed catheter, accomplishing ultrafiltration and dialysis. Cycle length, dwell volume, and the osmolar concentration of the dialysate can be varied to accomplish the goals of therapy. The relative contraindications to peritoneal dialysis include recent abdominal surgery, necrotizing enterocolitis, pleuroperitoneal leakage, and ventriculoperitoneal shunting.

Continuous renal replacement therapy (CRRT) is becoming a more frequently used therapeutic modality in the neonate whose condition is unstable.[51] For this procedure, the patient's blood is continuously circulated through a pump-driven extracorporeal circuit containing a highly permeable hemofilter. In continuous venovenous hemofiltration (CVVH), an ultrafiltrate of plasma is removed, a portion of which is returned to the patient in the form of a physiologic replacement fluid. In continuous venovenous hemodialysis (CVVH-D), countercurrent dialysate is used rather than replacement fluid to achieve solute removal. CRRT can be employed in conjunction with extracorporeal membrane oxygenation (ECMO) by putting the CRRT circuit in line with the ECMO circuit. The chief advantage of CRRT is the ability to carefully control fluid removal, which makes this modality especially useful in the neonate with hemodynamic instability. The main disadvantages are the need to achieve and maintain central vascular access and the need for continuous anticoagulation.

BOX 51–3 Indications for Dialysis

- Hyperkalemia
- Hyponatremia
- Acidosis
- Hypocalcemia
- Hyperphosphatemia
- Volume overload
- Uremic symptoms
- Inability to provide adequate nutrition

Intermittent hemodialysis is a less commonly used but technically feasible mode of renal replacement therapy in the neonatal population. Hemodialysis involves intermittent 3- to 4-hour treatment periods in which fluids and solutes are rapidly removed from the infant by using an extracorporeal dialyzer, with clearance achieved by the use of countercurrent dialysate. The chief advantage of hemodialysis is the ability to rapidly remove solutes and fluids, a characteristic that makes this modality the therapy of choice in neonatal hyperammonemia.[41] The main disadvantages are the requirement for central vascular access and the hemodynamic instability and osmolar shifts that may occur with rapid solute and fluid shifts.

The ability to provide renal replacement therapy may be limited by ability to place and maintain intravascular or peritoneal dialysis access in the very small premature neonate. If dialysis access cannot be established, care of the infant with acute kidney injury is limited to maximal supportive medical management with meticulous attention to fluid and electrolyte balance.

PROGNOSIS

The prognosis for neonates with acute kidney injury is variable, and largely related to the infant's underlying medical condition, with mortality rates ranging from 14% to 73%.[6] In general, those infants with prerenal acute kidney injury who receive prompt treatment for renal hypoperfusion have an excellent prognosis. Infants with postrenal acute kidney injury related to congenital urinary tract obstruction have a variable outcome, which depends on the degree of associated renal dysplasia.

Infants with intrinsic acute kidney injury have significant risks of morbidity and mortality. A study of 23 infants who received peritoneal dialysis during the first month of life showed that at 1 year 30% were on dialysis, 9% had chronic renal failure, 26% had made a full renal recovery, and 35% had died in the neonatal period.[9] There was a substantial difference in outcome according to the underlying cause of acute kidney injury; neonates with renal structural anomalies had a 17% mortality rate, and those with ATN had a 55% mortality rate.[9] A long-term study of infants with extremely low birthweight with neonatal acute kidney injury showed that 45% developed progressive renal disease, highlighting the need for long-term nephrology follow-up care.[1] Prominent risk factors for progressive kidney disease included proteinuria (urine protein/Cr ratio greater than 0.6 at 1 year of age), serum Cr greater than 0.6 mg/dL at 1 year of age, and body mass index greater than the 85th percentile. Other long-term sequelae seen in survivors of neonatal acute kidney injury include hypertension, an impaired capacity for urinary concentration, renal tubular acidosis, and impaired renal growth.

Hypertension

DEFINITION AND INCIDENCE

The incidence of hypertension in term or preterm neonates is estimated to be approximately 2%.[25] However, the determination of the true incidence of neonatal hypertension is problematic because of inconsistencies in the definition of hypertension, variations in blood pressure measurement techniques, and normal changes in blood pressure with gestational age and weight. Many other factors affect blood pressure readings, including the level of wakefulness, abdominal palpation, crying, and pain (see Chapter 43).

Useful data on normal infant blood pressures were published by Zubrow and colleagues, who prospectively measured blood pressure in nearly 700 infants.[54] From these data, the investigators were able to define mean blood pressure and 95% confidence limits for infants according to birthweight, gestational age, and postconceptional age (Figs. 51-6 to 51-8). Infants with blood pressure readings that consistently exceed the 95th percentile are defined as having significant hypertension (see Appendix B).

CAUSES

The causes of neonatal hypertension are varied and are outlined in Box 51-4. A number of risk factors for neonatal hypertension have been identified, including antenatal steroid administration, maternal hypertension, umbilical artery catheterization, acute kidney injury, patent ductus arteriosus, indomethacin treatment, and chronic lung disease.[47]

Renovascular hypertension is the most frequent cause of neonatal hypertension and accounts for up to 80% to 90% of all cases. The most common cause of renovascular hypertension is renal arterial thromboembolism related to umbilical artery catheterization. Risk factors for complications from umbilical artery catheters include maternal diabetes, sepsis, dehydration, birth trauma, perinatal asphyxia, patent ductus arteriosus, and cocaine exposure. Hypertension occurs in approximately 25% of patients with renal arterial thrombosis and may be associated with hematuria, oliguria, renal failure, congestive heart failure, and ischemia of the lower extremities.

Other causes of neonatal hypertension include hypervolemia related to oliguric acute kidney injury, structural renal disease, including autosomal recessive polycystic kidney disease, aortic coarctation, and obstructive uropathy. Medications such as corticosteroids, endocrine disorders, abdominal wall closure, and treatment with ECMO have been associated with elevation of blood pressure in the neonate. Neurologic causes of hypertension include intracranial hypertension and drug withdrawal. Twelve percent of infants with bronchopulmonary dysplasia develop hypertension, which is probably multifactorial in origin but may involve effects of umbilical

artery catheterization and the administration of corticosteroids and bronchodilators.[5]

CLINICAL PRESENTATION

The clinical presentation of hypertension in the neonate is variable. Although some babies may be asymptomatic, nonspecific symptoms such as poor feeding, irritability, and lethargy are common. Significant cardiopulmonary symptoms may include tachypnea, cyanosis, impaired perfusion, vasomotor instability, congestive heart failure, and hepatosplenomegaly. Neurologic symptoms such as tremors, hypertonicity, hypotonicity, opisthotonos, asymmetric reflexes, hemiparesis, seizures, apnea, or coma may also occur. The renal effects of hypertension may include acute kidney injury and sodium wasting related to pressure natriuresis.

EVALUATION

The first step is to determine whether the hypertension persists when the infant is quiet and relaxed. A complete physical examination is imperative, including four blood pressure measurements of the extremities to diagnose or rule out aortic coarctation. The infant should be examined carefully for signs of volume overload, including peripheral edema, cardiac gallop, or rales. Ambiguous genitalia in a hypertensive infant should raise the suspicion of congenital adrenal hyperplasia. Initial laboratory studies should include a urinalysis and determinations of serum electrolytes, blood urea nitrogen, serum creatinine, and serum calcium. Although the measurement of plasma renin activity is advocated by some investigators, the findings are often variable and difficult to interpret in neonates.

Ultrasonography of the kidneys with a Doppler flow study of the aorta and renal arteries should be performed to exclude a renal arterial or aortic thrombus or structural anomalies of the urinary tract. Magnetic resonance angiography may be considered, although its use may be limited in the very small infant. Angiography may be necessary for a sick infant with vascular insufficiency of the lower extremities, congestive heart failure, or acute kidney injury. Echocardiography should be performed to exclude aortic coarctation and evaluate the left ventricular mass. Thyroid function studies and urinary studies for catecholamines, 17-hydroxysteroids, and 17-ketosteroids should be reserved for those rare instances when the results of the previously mentioned studies are normal.

TREATMENT

The clinician has a wide variety of intravenous and oral antihypertensives that may be used in the management of neonatal hypertension (Tables 51-5 and 51-6). In general, treatment should be individualized according to the suspected underlying cause of the hypertension. Neonates with signs

and symptoms of a hypertensive emergency such as cardiopulmonary failure, acute neurologic dysfunction, and renal insufficiency are best treated with a continuous intravenous infusion of an antihypertensive agent such as nitroprusside, nicardipine, esmolol, or labetalol. The chief advantage of a continuous infusion is the ability to quickly increase or decrease the rate of infusion to achieve the desired blood pressure. The goal of therapy is a gradual decrease in blood pressure to minimize injury to the brain, heart, and kidneys. Blood pressure should not be lowered below the 95th percentile for at least 24 to 48 hours to avoid the possibility of cerebral and optic disc ischemia.

Oral antihypertensive agents are best used in infants with less severe hypertension or in those whose acute hypertension has been controlled with intravenous infusions and who are ready to switch to chronic oral therapy. Captopril is widely used in the treatment of hypertensive infants and is quite effective, given the high incidence of renovascular hypertension. Careful attention to urine output and the levels of serum creatinine and potassium is recommended when initiating treatment with angiotensin-converting enzyme inhibitors because neonates may be extremely sensitive to the reduction in renal blood flow associated with the administration of these agents. Other useful oral agents include diuretics, beta blockers, calcium channel blockers, and vasodilators (see Table 51-6).

TABLE 51–5 Intravenous Antihypertensive Medications

Drug	Dose	Interval	Action
Diazoxide	2 to 5 mg/kg/dose	q 5 min prn; then q 4 to 24 h	Vasodilator
Esmolol	100 to 300 μg/kg/min	IV infusion	Beta blocker
Hydralazine	0.1 to 0.4 mg/kg/dose	q4 to 6 h	Vasodilator
Labetalol	0.25 to 3.0 mg/kg/hr	IV infusion or bolus	Alpha and beta blocker
Nicardipine	1 to 3 μg/kg/min	IV in fusion	Calcium channel blocker
Sodium nitroprusside	0.5 to 8.0 μg/kg/min	IV infusion	Vasodilator

IV, intravenous; prn, as required.

TABLE 51–6 Oral Antihypertensive Medications

Drug	Dose	Interval	Class
Amlodipine	0.1 to 0.3 mg/kg/dose	q 12	Calcium channel blocker
Captopril	0.01 to 0.5 mg/kg/dose	q 6 to 12 h	Angiotensin-converting enzyme inhibitor
Chlorothiazide	5 to 15 mg/kg/dose	q 12 h	Distal tubule diuretic
Furosemide	1 to 6 mg/kg/dose	q 8 to 24 hr	Loop diuretic
Labetalol	1 to 3 mg/kg/dose	q 8 to 12 hr	Alpha and beta blocker
Propranolol	0.25 to 1.0 mg/kg/dose	q 6 to 8 hr	Beta blocker

In infants with suspected renovascular hypertension, the umbilical artery catheter should be removed as soon as possible. Systemic heparinization may be considered to prevent the extension of the clot. If the hypertension cannot be controlled medically or massive aortic thrombosis results in major complications, thrombolysis with urokinase, streptokinase, or tissue plasminogen activator may be considered. If severe hypertension persists, surgical thrombectomy or nephrectomy may be contemplated.

PROGNOSIS

Hypertension related to umbilical artery catheters usually resolves with time and infants do not typically require antihypertensive medications beyond 12 months of age. Infants may require increases in their antihypertensive medications following discharge from the hospital due to rapid growth, but over time antihypertensive agents may be weaned by maintaining a stable medication dose as the infant grows in size. Despite blood pressure normalization, long-term consequences of neonatal renovascular hypertension have been described. In a report of 12 children studied at a mean follow-up of almost 6 years, Adelman found that 5 of 11 patients displayed unilateral renal atrophy on ultrasound or intravenous pyelography despite having normal rates of creatinine clearance.[3] Follow-up radionuclide scans remained abnormal for all patients studied, even for those without renal atrophy identified on ultrasound. Although the long-term significance of these findings is unknown, long-term nephrology follow-up is indicated to survey for chronic hypertension and kidney disease.

Nephrocalcinosis

Renal medullary calcifications were first described in the premature infant in 1982 by Hufnagle and coworkers.[31] Since then, nephrocalcinosis has become a well-known complication in the neonatal population, occurring in 27% to 65% of hospitalized premature infants weighing less than 1500g.[32,49] Infants with nephrocalcinosis may present with microscopic or gross hematuria, granular material in the diaper, acute kidney injury related to ureteral obstruction, or urinary tract infection. Nephrocalcinosis may also be discovered incidentally on abdominal imaging studies.

Nephrocalcinosis, defined as calcium deposition in the renal interstitium, develops as the consequence of an imbalance between stone-promoting and stone-inhibiting factors. The primary risk factor in neonates is hypercalciuria (excessive urinary calcium excretion), which is commonly caused by chronic treatment with loop diuretics. Other risk factors include low gestational age, low birthweight, severe respiratory disease, low urine volume, the hypercalciuric effect of corticosteroids or xanthine derivatives, hypocitraturia, hyperuricosuria, long duration of parenteral hyperalimentation, metabolic acidosis, and a familial history of nephrolithiasis.[28]

Routine ultrasonographic screening should be considered for all infants who receive diuretics for chronic lung or heart disease. In those with documented nephrocalcinosis or nephrolithiasis, the use of agents that increase urinary calcium excretion, such as loop diuretics and corticosteroids, should be minimized or discontinued if possible. A high urinary flow rate should be maintained to reduce the probability of urinary crystallization. Oral calcium supplements should be discontinued, and metabolic acidosis, if present, should be treated with potassium citrate because chronic acidosis enhances urinary calcium excretion. Thiazide diuretics such as chlorothiazide may be effective in reducing urinary calcium excretion, although serum calcium should be monitored closely to avoid hypercalcemia. The goal of therapy should be the maintenance of the spot urinary calcium to creatinine ratio less than 0.86 for infants younger than 7 months of age.[44]

The usual outcome for infants with neonatal nephrocalcinosis is spontaneous resolution over time. In one study, nephrocalcinosis persisted in 34% of preterm infants at 15 months of age, and in only 15% at 30 months of age.[46] However, there is evidence that neonatal nephrocalcinosis is associated with impairment in kidney function (GFR less than 85 mL/min/1.73 m^2) and tubular function (phosphaturia and renal tubular acidosis),[34] highlighting the importance of long-term nephrology follow-up care.

Renal Venous Thrombosis

Renal venous thrombosis, once a common occurrence, is now infrequent, possibly because of the better obstetric management of mothers with diabetes, prevention of polycythemia, and prevention and treatment of dehydration. Risk factors for renal venous thrombosis include poorly controlled maternal diabetes mellitus, dehydration, perinatal asphyxia, inherited prothrombotic states, and the presence of an umbilical venous catheter. Thrombosis begins in the small renal veins and propagates toward the main renal vein, ultimately reaching the inferior vena cava. Thrombosis is usually unilateral but may be bilateral and is associated with adrenal infarction in a minority of patients.

The classic clinical triad of symptoms in renal venous thrombosis includes a flank mass, gross hematuria, and thrombocytopenia, although all elements of the triad may not be present in each patient. Additional signs may include oliguric acute kidney injury, hypertension, vomiting, lethargy, anorexia, fever, and shock. Ultrasonography reveals a typical image, characterized by nephromegaly, the loss of corticomedullary differentiation, and increased renal echogenicity. A Doppler study may reveal renal venous or vena caval thrombosis. Uptake may be absent or severely diminished on a radionuclide scan.

There are no evidence-based guidelines for management of neonatal renal venous thrombosis. Supportive medical treatment consists of the correction of fluid and electrolyte imbalances as well as the treatment of acute kidney injury, possibly including dialysis support. Anticoagulation (unfractionated heparin, low molecular weight heparin) and fibrinolytic therapies (streptokinase, urokinase, and recombinant tissue plasminogen activator) have been used with anecdotal success.[35] Surgical thrombectomy is considered in patients with thrombosis of the inferior vena cava, and nephrectomy may be necessary in infants with severe refractory hypertension. The perinatal mortality rate in infants with renal venous thrombosis has decreased progressively during the past few decades. However, the prognosis for the affected kidney is poor, with progressive atrophy in up to 70% of kidneys.[35] The long-term consequences in infants with renal venous thrombosis include chronic kidney disease, renal tubular dysfunction, and systemic hypertension.

CONGENITAL AND INHERITED DISORDERS OF THE KIDNEY AND URINARY TRACT

Many of the disorders of the kidney and urinary tract that present in infancy are the result of congenital malformations or inherited disorders (Box 51-5). Most of the congenital disorders occur sporadically, and the pathogenesis of many of these disorders is not well defined. Alternatively, some patients may have clinical findings consistent with well-defined genetic diseases that display classic mendelian inheritance patterns, such as autosomal dominant, autosomal recessive, or X-linked inheritance. In many cases, the mutated genes in these diseases have been identified. The following commentaries review some of the more common of these disorders.

BOX 51–5 Overview of Congenital and Inherited Disorders of the Kidney and Urinary Tract That Present in Infancy

UROLOGIC ANOMALIES

- Ureteropelvic junction or ureterovesical junction obstruction
- Posterior urethral valves
- Eagle-Barrett syndrome
- Vesicoureteral reflux

CYSTIC AND DYSPLASTIC DISORDERS

- Dysplasia/hypoplasia
  - Hypoplasia
  - Dysplasia
  - Multicystic dysplastic kidney
  - Unilateral or bilateral renal agenesis
- Polycystic kidney disease
  - Autosomal recessive polycystic kidney disease
  - Autosomal dominant polycystic kidney disease
  - Glomerulocystic kidney disease
- Other cystic disorders
  - Infantile nephronophthisis
  - Cystic dysplasia associated with congenital abnormalities

TUBULAR TRANSPORT DISORDERS

- Renal tubular acidosis
- Fanconi syndrome
- Bartter syndrome
- Nephrogenic diabetes insipidus
- Tubular disorders associated with syndromes such as oculocerebrorenal syndrome of Lowe, cystinosis, and galactosemia
- Pseudohypoaldosteronism

MISCELLANEOUS DISORDERS

- Congenital nephrotic syndrome
- Teratogen fetopathies (e.g., angiotensin-converting enzyme inhibitors)
- Tumors (e.g., Wilms tumor, neuroblastoma, congenital mesoblastic nephroma)

Congenital Urinary Tract Malformations

RENAL AGENESIS

Unilateral renal agenesis, or the congenital absence of the kidney, occurs in 1 in 500 to 3200 live births and bilateral renal agenesis occurs in 1 in 4000 to 10,000.[42] Renal agenesis occurs when the ureteric bud fails to induce proper differentiation of the metanephric blastema, an event that may be related to both genetic and environmental factors. Renal agenesis may be seen in infants with the VACTERL association (i.e., *v*ertebral abnormalities, *a*nal atresia, *c*ardiac abnormalities, *t*racheoesophageal fistula or *e*sophageal atresia, *r*enal agenesis and dysplasia, and *l*imb defects), caudal regression syndrome, branchio-oto-renal syndrome, and multiple chromosomal defects, but it may also occur in otherwise healthy infants.[42] Because contralateral urinary tract abnormalities, including vesicoureteral reflux, ureteropelvic junction obstruction, renal dysplasia, and ureterocele, occur in up to 90% of individuals with unilateral renal agenesis,[8] a thorough evaluation of the urinary tract, including a voiding cystourethrogram, should be considered in all patients.

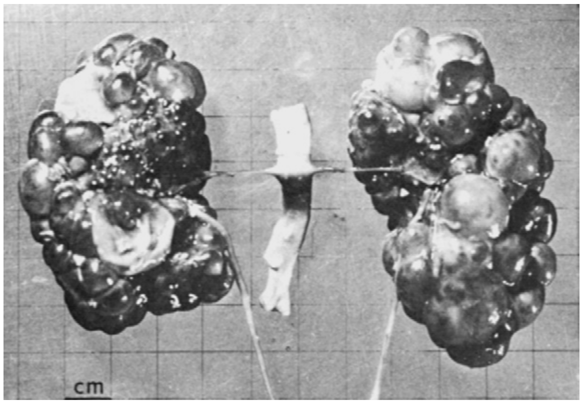

Figure 51–9. Bilateral multicystic dysplastic kidneys in a newborn infant. Kidneys are enlarged and irregularly cystic; the usual reniform configuration is barely apparent. Both ureters are atretic, and the renal arteries are extremely small. This condition is one cause of the total absence of renal function.

RENAL DYSPLASIA

Renal dysplasia is characterized by abnormal renal development in the fetus, leading to replacement of the renal parenchyma by cartilage and disorganized epithelial structures. The pathogenesis of renal dysplasia may involve mutations in developmental genes, altered interaction of the ureteric bud with the extracellular matrix, abnormalities of renal growth factors, and urinary tract obstruction. Renal dysplasia frequently occurs in infants with obstructive uropathy and a variety of congenital disorders, including Eagle-Barrett syndrome; the VACTERL association; branchio-oto-renal syndrome; CHARGE syndrome (i.e., *c*oloboma, *h*eart disease, choanal *a*tresia, *r*estricted growth and developmental delay with or without anomalies of the central nervous system, *g*enital hypoplasia, and *e*ar anomalies or deafness); Jeune syndrome; and trisomies 13, 18, and 21. The function of dysplastic kidneys is variable, and infants with bilateral dysplasia may exhibit signs of renal insufficiency as early as the first few days of life. Concentration and acidification defects may also be present, but hematuria, proteinuria, and hypertension are unusual findings. Children with bilateral renal dysplasia generally develop progressive renal insufficiency during childhood and adolescence.

MULTICYSTIC DYSPLASTIC KIDNEY

The multicystic dysplastic kidney (MCDK) is a nonfunctional kidney, devoid of normal renal architecture, composed of multiple large cysts that resemble a cluster of grapes (Fig. 51-9).[43] Its incidence is estimated at 1 in every 4300 live births and occurs twice as often on the left side as the right side. The pathogenesis is poorly understood but may involve failure of the ureteric bud to integrate and branch appropriately into the metanephros. Although, in the past, infants with MCDK were primarily identified after detection of an abdominal mass in the neonatal period, the widespread use of prenatal ultrasonography has led to identification of many cases of MCDK in utero. Historically, a full evaluation of the urinary tract, including a VCUG, was advised for all infants with MCDK to rule out abnormalities of the contralateral urinary tract including vesicoureteral reflux. However, many clinicians now reserve this study for infants with "complex MCDK," defined as MCDK with contralateral renal dysplasia, hydronephrosis, bladder abnormality, ureterocele, or cryptorchidism.[24]

The majority of MCDKs undergo partial or complete spontaneous involution over time. The contralateral kidney, if unaffected by other urologic malformations, generally grows larger than expected because of compensatory hypertrophy, allowing the child to maintain normal renal function. It is common practice to use serial ultrasonography to follow up patients with MCDKs to ensure involution over time and appropriate compensatory growth of the contralateral kidney. Infants with complex MCDK have a higher incidence of urinary tract infection and progression to kidney failure and should be followed up closely after discharge from the hospital. Although an MCDK poses a theoretical risk of hypertension and malignancy, surgical removal is reserved for children in whom the MCDK fails to involute or grows larger over time.

HYDRONEPHROSIS

Hydronephrosis, defined as significant dilation of the upper urinary tract (Fig. 51-10), is the most common congenital condition detected by prenatal ultrasonography, and with the advent of improved ultrasonography technology, it is being detected at a higher rate.[4] Mild dilation of the renal pelvis is frequently reported in late gestation (see Chapter 9). The most common causes of hydronephrosis are physiologic hydronephrosis, ureteropelvic or ureterovesical junction obstruction, posterior urethral valves, Eagle-Barrett syndrome, and vesicoureteral reflux.

Prenatal Management

A finding of prenatal hydronephrosis raises many questions, including those about the underlying cause of the abnormality and potential treatment options. The ability of prenatal ultrasonography to predict the specific urinary tract anatomy and the long-term renal prognosis remains limited. Certain

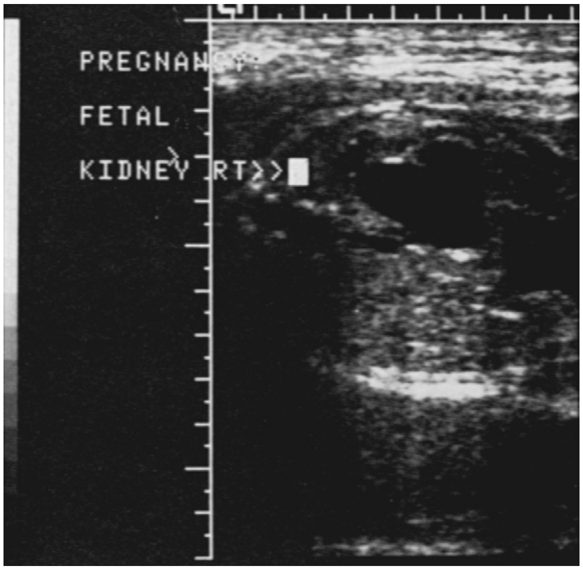

Figure 51–10. Sonogram of the right kidney in a 32-week-old fetus. Notice the large dilation of the collecting system.

findings on prenatal ultrasonography, such as increased renal echogenicity, bilateral disease, and oligohydramnios raise concern for long-term renal dysfunction. Early identification of a urinary tract abnormality allows consideration of prenatal consultation with nephrology or urology, enables coordination of prompt postnatal care, and affords the parents an opportunity to adjust to the possibility of a congenital anomaly. Prenatal intervention including percutaneous vesicoamniotic shunt placement, bladder aspiration, and drainage of a severely distended kidney remains an unproved therapy that involves significant risks, including preterm labor and chorioamnionitis.

Postnatal Management

After delivery, many clinicians advise the administration of prophylactic antibiotics to newborns with hydronephrosis to prevent urinary tract infection. Common choices of antibiotics are ampicillin and amoxicillin (20 mg/kg per day in two divided doses) administered until a VCUG is performed to determine the presence or absence of vesicoureteral reflux.[4,23] Ultrasonography of the kidneys and urinary tract should be performed within the first few days of life for all infants with moderate to severe hydronephrosis on prenatal ultrasound. Because the degree of hydronephrosis may be significantly underestimated because of the low GFR during the first 3 days of life, repeat ultrasonography is mandatory within several weeks. Infants with only mild hydronephrosis on prenatal ultrasonography should have their initial postnatal ultrasound scans performed at 2 weeks of age. A pediatric nephrologist or urologist should coordinate further evaluation, possibly to include a VCUG and/or radionuclide renal scan to determine the precise cause of the hydronephrosis.

Physiologic Hydronephrosis

Up to 15% of all prenatally detected hydronephrosis ultimately resolves spontaneously and is not associated with an anatomic abnormality of the urinary tract. Physiologic hydronephrosis may be caused by a delay in the maturation of the ureter, which leads to transient urinary flow obstruction. The hydronephrosis in these patients generally resolves within the first 2 years of life.

Ureteropelvic Junction Obstruction

Ureteropelvic junction obstruction is the most common cause of moderate to severe congenital hydronephrosis and may be the result of incomplete recanalization of the proximal ureter, abnormal development of the ureteral musculature, abnormal peristalsis, or polyps. Ureteropelvic junction obstruction is more common in boys and may be associated with other congenital anomalies, syndromes, or other genitourinary malformations. The diagnosis is confirmed by an obstructive pattern observed on a diuretic-enhanced radionuclide scan. Many clinicians advocate antibiotic prophylaxis to prevent urinary tract infection, although this practice remains somewhat controversial in cases of ureteropelvic junction obstruction without reflux. Definitive treatment involves surgical repair.

Ureterovesical Junction Obstruction

Ureterovesical junction obstruction is the second most common cause of congenital hydronephrosis and is characterized by hydronephrosis with associated ureteral dilation. This disorder may be related to the deficient development of the distal ureter or the presence of a ureterocele. The diagnosis is confirmed by a radionuclide scan and voiding cystourethrogram. Ureterovesical junction obstruction is usually not associated with other congenital malformations. Antibiotic prophylaxis to prevent urinary tract infection remains somewhat controversial in cases of ureterovesical junction obstruction without associated reflux. Definitive treatment involves surgical repair.

Posterior Urethral Valves

Posterior urethral valves represent the most common cause of lower urinary tract obstruction, with an incidence of 1 in 5000 to 8000 live male births. A posterior urethral valve is composed of a congenital membrane that obstructs or partially obstructs the posterior urethra. The prenatal ultrasound scan may show hydronephrosis; dilated ureters; a thickened, trabeculated bladder; a dilated proximal urethra; and oligohydramnios. The antenatal presentation may include a palpable, distended bladder; a palpable prostate on rectal examination; a poor urinary stream; and signs and symptoms of renal and pulmonary insufficiency. The voiding cystourethrogram is diagnostic for posterior urethral valves and reveals associated vesicoureteral reflux in 30% of patients.

Treatment is centered on securing adequate drainage of the urinary tract, initially by placement of a urinary catheter and later by primary ablation of the valves; vesicostomy; or upper urinary tract diversion. The long-term outcome for infants with posterior urethral valves depends on the degree of associated renal dysplasia and correction of the obstruction postnatally does not necessarily result in subsequent normal kidney growth. As many as 30% of the boys with posterior urethral valves who present in infancy are at risk for progressive renal insufficiency in childhood or adolescence.

Eagle-Barrett Syndrome

Eagle-Barrett syndrome is characterized by a dilated, unobstructed urinary tract; deficiency of abdominal wall musculature; and bilateral cryptorchidism (Fig. 51-11). The estimated incidence is 1 in 35,000 to 50,000 live births, with more than 95% of the cases occurring in boys. Two theories of pathogenesis are in utero urinary tract obstruction and a specific mesodermal injury between the 4th and 10th weeks of gestation.[50] The most common urinary tract abnormalities in infants with Eagle-Barrett syndrome are renal dysplasia or agenesis, vesicoureteral reflux, and a large-capacity, poorly contractile bladder. Cardiac, pulmonary, gastrointestinal, and orthopedic anomalies are present in a large percentage of patients with Eagle-Barrett syndrome. Treatment in the neonatal period involves the optimization of urinary tract drainage, the management of renal insufficiency, and antibiotic prophylaxis. Management later in childhood may include the surgical repair of reflux, orchiopexy, reconstruction of the abdominal wall, and renal transplantation.

Vesicoureteral Reflux

Vesicoureteral reflux is defined as the retrograde propulsion of urine into the upper urinary tract during bladder contraction. The underlying cause of vesicoureteral reflux is believed to be ectopic insertion of the ureter into the bladder wall, resulting in a shorter intravesicular ureter, which acts as an incompetent valve during urination. Vesicoureteral reflux is graded from I to V, with grade I indicating the lowest and grade V the highest. In infants and children evaluated for their first urinary tract infection, at least one third have vesicoureteral reflux identified on a voiding cystourethrogram. Although the exact genetic basis of this condition has not been determined, there appears to be a genetic component because the incidence of vesicoureteral reflux is at least 30% in first-degree relatives.[40]

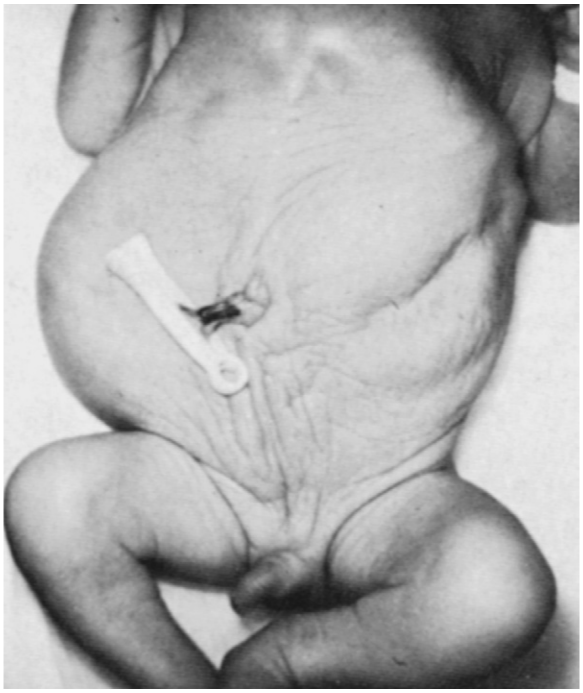

Figure 51–11. Eagle-Barrett syndrome (i.e., "prune-belly" syndrome). Notice the distinct, flabby abdomen that is indicative of absent or deficient abdominal musculature.

Primary vesicoureteral reflux tends to resolve over time as the intravesical segment of the ureter elongates with growth. The rate of spontaneous resolution is dependent on the grade of vesicoureteral reflux, the child's age at presentation, and whether the reflux is unilateral or bilateral. Daily oral antibiotic prophylaxis is thought to be important for the prevention of urinary tract infection, although this is somewhat controversial in patients with low-grade vesicoureteral reflux. Surgical repair is considered in children with high-grade vesicoureteral reflux or breakthrough urinary tract infections despite antibiotic prophylaxis. Long-term complications of vesicoureteral reflux include hypertension, renal scarring, and chronic kidney disease ("reflux nephropathy").

EXSTROPHY-EPISPADIAS COMPLEX

The exstrophy-epispadias complex (EEC) includes a spectrum of malformations that ranges from the mildest form, epispadias, through classic bladder exstrophy, to the most severe form, exstrophy of the cloaca, which may encompass omphalocele, bladder exstrophy, imperforate anus, and spinal defects.[22]

The incidence of EEC is estimated at 1 in 10,000 births with a male predisposition of 1.5:1.[10,15,36] Epispadias occurs at a rate of 2.4 per 100,000; classic bladder exstrophy varies from 2.1 to 4.0 per 100,000 live births (the highest rate of 8.1 per 100,000 is found in Native American Indians);[15] exstrophy of the cloaca ranges from 0.5 to 1 per 200,000 live births.[22]

Enlargement or mechanical disruption of the cloacal membrane (bladder portion of the cloaca and the overlying ectoderm) prevents the invasion of mesodermal cells along the infraumbilical midline, resulting in exstrophy. Deformities of the cloacal membrane may result in hypospadias, epispadias, vesical and cloacal exstrophy, double urethra, and cloacal membrane agenesis. If rupture of the membranes occurs before the fourth week of gestation, exstrophy of the cloaca ensues. If the rupture occurs after 6 weeks of gestation, epispadias or classic bladder exstrophy occurs. This is a multifactorial disorder with a strong genetic predisposition that is still under investigation.[10,36,53] This disorder has a small risk of recurrence within families, and maternal smoking appears to enforce the severity.[26]

The clinical presentation of classic bladder exstrophy is characterized by an evaginated bladder plate with urine dripping from the ureteric orifices on the bladder surface. Bilateral inguinal hernias are usually present as well. Pubic bones can be felt on both sides of the bladder. The penis appears shorter and the epispadic urethra covers the dorsum of the penis. Testes are usually descended. In females, the clitoris is completely split next to the open urethra.[22]

Epispadias is categorized by three degrees of severity, with severe forms involving the entire urethra and bladder.[22] Cloacal exstrophy is the more severe form and can easily involve different organs that require immediate surgical attention.[22]

A renal sonogram is mandatory for every infant with exstrophy-epispadias complex to obtain a baseline examination of both kidneys before repair. Spine ultrasound and radiographs are required to define individual abnormalities. Hip radiographs and possibly magnetic resonance imaging of the pelvis help estimate the symphysis gap and hip localization.[22]

Treatment is surgical and patients require long-term follow-up and a multidisciplinary team that includes a pediatric urologist, pediatric orthopedic surgeon, and appropriate support team.[22]

Inherited Renal Disorders

Inherited renal disorders include a spectrum of abnormalities involving the glomeruli or renal tubules. Monogenic diseases (those with single gene defects) that may present in the newborn period include congenital nephrotic syndrome, polycystic kidney diseases, and tubular transport abnormalities.

CONGENITAL NEPHROTIC SYNDROME

Congenital nephrotic syndrome is a rare condition that is defined as the development of nephrotic syndrome within the first 3 months of life.[33] As in other forms of nephrotic syndrome, the clinical characteristics include massive proteinuria, hypoalbuminemia, hyperlipidemia, and edema. Most of the reported cases of primary congenital nephrotic syndrome occur in infants with Finnish ancestry (CNS-F); in Finland, the estimated incidence of CNS-F is 1 in 8200 live births. CNS-F is a well characterized autosomal recessive disorder and is the primary focus of this section. However, congenital nephrotic syndrome has also been described in infants of non-Finnish ancestry, in infants with other forms of kidney disease including diffuse mesangial sclerosis, and in infants with congenital infections.

A prenatal diagnosis of congenital nephrotic syndrome should be suspected in mothers with a high serum or amniotic fluid α-fetoprotein concentration because the amniotic fluid contains large amounts of protein resulting from urinary protein losses. The ultrasonographic detection of placental edema, ascites, or fetal hydrops should also raise the suspicion of this disorder (see Chapters 8 and 9).

Infants with CNS-F, in whom the disease process begins during intrauterine life, typically have full-blown nephrotic syndrome at birth, with massive proteinuria, profound hypoalbuminemia, hyperlipidemia, and edema. Forty-two percent of the infants with CNS-F are delivered prematurely; the mean gestational age is 36.6 weeks. Many infants, particularly those born after 37 weeks, are small for their gestational age. The placenta is always large, weighing greater than 25% of the infant's birthweight.

CNS-F is caused by mutations in *NPHS1*, the gene encoding nephrin, which is located on the long arm of chromosome 19. Nephrin is a key component of the slit diaphragm, an epithelial cell structure that plays a major role in the glomerular filtration barrier. Alterations in nephrin cause disruption of the filtration barrier, leading to massive urinary protein loss and the clinical characteristics of nephrotic syndrome. The renal histopathology of CNS-F includes mesangial hypercellularity, tubular microcysts, and variably sized glomeruli, many of them very small and having a characteristic fetal appearance, with prominent, cuboidal epithelial cells (Fig. 51-12). Although CNS-F with *NPHS1* mutations accounts for the majority of patients with CNS, other genetic forms of CNS have been identified, including disorders associated with mutations in *NPHS2* (podocin), *WT-1* (Wilms tumor suppressor gene), and *LAMB2* (laminin beta-2 gene).

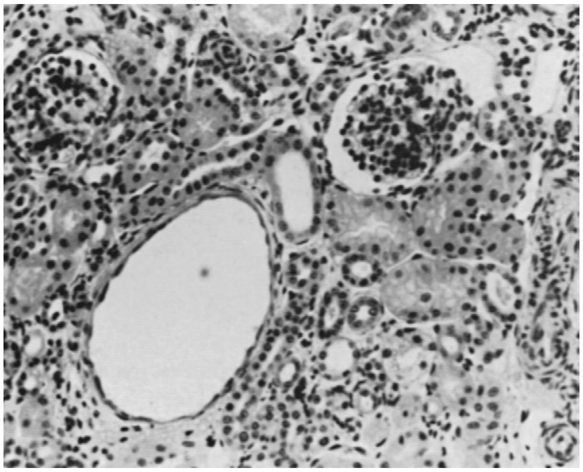

Figure 51–12. Congenital nephrotic syndrome of the Finnish type. Notice the glomerular mesangial hypercellularity and tubular microcysts.

The treatment of congenital nephrotic syndrome is complex. The clinician should first exclude congenital infections such as syphilis, human immunodeficiency virus, cytomegalic inclusion disease, hepatitis, rubella, and toxoplasmosis, all of which have been associated with treatable forms of nephrotic syndrome in neonates. Unlike other forms of nephrotic syndrome occurring later in life, CNS-F is resistant to therapy with corticosteroids and immunosuppressive agents. Current treatment includes intravenous albumin supplementation, aggressive nutritional support, correction of associated hypothyroidism, prompt treatment of infectious and thromboembolic complications, bilateral nephrectomy for the management of protein loss, peritoneal dialysis support, and early renal transplantation.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

Autosomal recessive polycystic kidney disease (ARPKD) is an inherited disorder characterized by polycystic kidneys and congenital hepatic fibrosis; it occurs in approximately 1 in 40,000 live births.[20] ARPKD is distinct from renal dysplasia (including cystic dysplasia), a disorder usually seen in patients with chromosomal or syndromic conditions. The majority of patients with ARPKD present in the newborn period, although rare presentations in later childhood are described. Prenatal ultrasonography shows enlarged, echogenic kidneys. Although the amniotic fluid volume is initially normal, oligohydramnios is often noted in the late middle trimester. The newborn infant with ARPKD may present with palpable abdominal masses, severe hypertension, and renal insufficiency. Respiratory failure related to pulmonary hypoplasia and marked abdominal distention from the massively enlarged kidneys are common in neonates with ARPKD.

ARPKD is caused by mutations in *PKHD1*, located on chromosome 6p21. *PKHD1* encodes encodes fibrocystin, a very large, novel protein with receptor-like properties for which the exact function is unknown. Renal histopathology reveals that after a transient phase of proximal tubular cyst formation, the principal site of subsequent cyst formation is the collecting duct (Fig. 51-13). Progressive interstitial fibrosis is an additional histopathologic feature of ARPKD. In addition, virtually all infants with ARPKD have some degree of congenital hepatic fibrosis with biliary dysgenesis, although clinical evidence of hepatic involvement is present in only 40% of patients.

The management of the neonate with ARPKD is largely supportive. Ventilatory support is critical in neonates with pulmonary hypoplasia or respiratory embarrassment (see Chapter 44). Hypertension is often a primary concern and may require the administration of continuous intravenous infusions of several antihypertensive agents. Patients may require correction of electrolyte imbalances, notably hyponatremia. Most patients with ARPKD ultimately require dialysis or kidney transplantation. The long-term consequences of hepatic fibrosis may include portal hypertension, bleeding varices and ascending cholangitis. Hepatic synthetic function typically remains intact even in patients with significant liver disease.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Autosomal dominant polycystic kidney disease (ADPKD) is the most common inherited renal disorder, occurring at an incidence of 1 in 1000 live births; however, neonatal presentation is relatively rare.[18] ADPKD is characterized by progressive bilateral renal cyst formation, although the dyssynchronous development of cysts may account for unilateral or asymmetric involvement in the neonate. The clinical spectrum of neonatal ADPKD ranges from severe neonatal manifestations that are indistinguishable from those of ARPKD to variable degrees of renal insufficiency and hypertension to asymptomatic cysts seen on renal ultrasonography. Because the clinical presentation of neonatal ARPKD and ADPKD can be very similar, an examination of the patient's parents for the presence of renal cysts is important in establishing the correct diagnosis. However, approximately 10% of patients with ADPKD will have a new mutation. Therefore, the absence of cysts in either parent does not completely exclude the diagnosis of ADPKD.

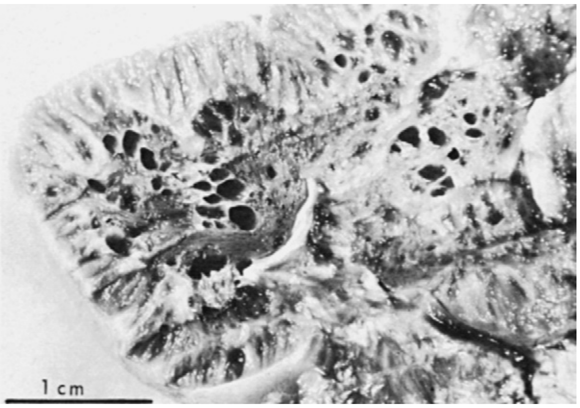

Figure 51–13. Autosomal recessive polycystic kidney disease in a newborn infant showing preservation of lobar structure and corticomedullary differentiation. The cortex is thick and spongy, and the medullary pyramids contain grossly apparent cysts; the latter are sometimes visible radiographically. *(From Elkin M, et al: Cystic diseases of the kidney—radiological and pathological considerations,* Clin Radiol *20:65, 1969, with permission.)*

ADPKD results from mutations in two genes, *PKD1* and *PKD2*.[27] Mutations in the *PKD1* gene, located on chromosome 16, account for approximately 85% of the cases of ADPKD. The *PKD1* gene encodes polycystin 1, a large protein of unknown function that may play a role in cell-cell or cell-matrix interactions. Mutations in the *PKD2* gene, located on the long arm of chromosome 4, account for only 15% of the cases of ADPKD. The *PKD2* gene product polycystin 2 is a voltage-gated ion channel.

The prognosis for an infant with ADPKD presenting in the neonatal period or antenatally was initially thought to be poor. However, a recent study suggests that over 90% of these patients maintain intact renal function during childhood.[48] Although ADPKD is a systemic disease that can affect the liver, gastrointestinal tract, aorta and cerebral vessels, extrarenal manifestations in children are rare. Approximately 50% of all patients with ADPKD ultimately develop end-stage renal disease requiring dialysis or kidney transplantation.

NEONATAL BARTTER SYNDROME

Neonatal Bartter syndrome (previously known as *hyperprostaglandin E syndrome*) is one of the inherited hypokalemic tubulopathies that also includes classic Bartter syndrome and Gitelman syndrome.[21] Bartter syndrome is inherited as an autosomal recessive trait; the incidence of neonatal Bartter syndrome is 1 in 50,000 to 100,000 live births. Newborn infants with neonatal Bartter syndrome typically present with profound salt wasting, polyuria, hypokalemia, and hypercalciuria. Bartter syndrome is discussed in detail in Chapter 36.

RENAL TUBULAR ACIDOSIS

Renal tubular acidosis is caused by a defect in the reabsorption of bicarbonate or in the secretion of hydrogen ions that is not related to a decrease in GFR. Renal tubular acidosis should be suspected in infants with persistent hyperchloremic (i.e., nonanion gap) metabolic acidosis. There are three forms of renal tubular acidosis: proximal (type II), distal (type I), and hyperkalemic (type IV). Type II renal tubular acidosis is caused by impaired proximal tubular bicarbonate reabsorption, with a relatively normal distal tubular ability to acidify the urine. Type I renal tubular acidosis is characterized by an inability to acidify the urine (excrete H^+ ions) despite the presence of metabolic acidosis. Type IV renal tubular acidosis manifests a defect in ammoniagenesis, which is due to hyperkalemia from mineralocorticoid deficiency or tubular resistance to aldosterone. There are primary and secondary forms of renal tubular acidosis; they may be sporadic or inherited as classic mendelian traits. Renal tubular acidosis is discussed in detail in Chapter 36.

TUMORS OF THE KIDNEY

Renal tumors in the newborn infant are uncommon and include congenital mesoblastic nephroma, multilocular cystic nephroma, and Wilms tumor (i.e., nephroblastoma). Other renal neoplasms, including renal cell carcinoma, rhabdoid tumor, lymphoma, and teratoma, are rare in the newborn infant. The clinical presentation of a renal tumor in the neonatal period is usually that of abdominal swelling or a palpable mass. There may be hypertension, hematuria, fever, and feeding intolerance.

Congenital mesoblastic nephroma is the most common renal neoplasm in the first year of life. Approximately 60% of all congenital mesoblastic nephromas are diagnosed before 6 months of age; the clinical presentation is an abdominal mass. Congestive heart failure and hypertension are less common manifestations. Nephrectomy is curative, with the exception of infrequent local recurrences and rare pulmonary metastases.

Multilocular cystic nephroma is a benign renal tumor that consists of large cysts separated by fibrous septa. This tumor arises from metanephric blastema and has features of immature blastema, tubules, and skeletal muscle on histopathologic examination. The prognosis is excellent with surgical removal alone for these patients.

Wilms tumor is a malignancy that accounts for 90% of all renal tumors diagnosed in the pediatric population. However, 80% of all Wilms tumors are diagnosed in patients between the ages of 1 and 5 years, making its appearance uncommon in the first year of life and rare in the first month of life.[30] Most of these tumors occur sporadically, but 15% are associated with congenital anomalies or syndromes, including congenital aniridia, hemihypertrophy, WAGR syndrome (i.e., *W*ilms tumor, *a*niridia, *g*enitourinary anomalies, and mental *r*etardation), Denys-Drash syndrome (i.e., Wilms tumor, male pseudohermaphroditism, and nephrotic syndrome caused by diffuse mesangial sclerosis), and Beckwith-Wiedemann syndrome (i.e., omphalocele, macroglossia, and visceromegaly). Two candidate genes for Wilms tumor have been localized: WT-1, which is located on chromosome 11p13, and another gene on chromosome 11p15.

Definitive therapy for a localized renal mass begins with surgical exploration, and in most cases the primary treatment is nephrectomy. Infants with multilocular cystic nephromas or congenital mesoblastic nephromas require no postoperative therapy. Infants with malignant tumors such as Wilms tumor are treated according to well established oncologic protocols. The prognosis for most infants with neonatal renal tumors is good, although an infant with an aggressive Wilms tumor, an atypical congenital mesoblastic nephroma, or a renal sarcoma may have a poor prognosis.

CHAPTER 52

The Skin

Steven B. Hoath and Vivek Narendran

The skin, as the perceived surface of the body, comes into being at the moment of birth. The intersection between genetics and environment is amply demonstrated by the phenotype of newborn skin. The initial evaluation of a newly born infant includes drying the baby to prevent heat loss and an informed assessment of skin color, perfusion, and integrity. Pathologic processes visible on the skin surface range from general signs of internal organ dysfunction (cyanosis, pallor, jaundice) to clinical evidence of specific diseases (vesicles, petechiae) to cutaneous determinants of gestational age (breast buds, plantar creases, desquamation). Maternal-infant bonding is, in large part, a complex dynamic interaction between skin surfaces.[42]

At birth, the skin of the term infant must perform multiple physiologic functions critical for survival in an extrauterine environment (Box 52-1).[22] Many of these functions depend on structural development of the skin during the last trimester of pregnancy. The development of a competent epidermal barrier, for example, is essential for temperature regulation, maintenance of fluid homeostasis, infection control, and prevention of penetration of environmental toxins and drugs.

The epidermal permeability barrier primarily resides in the outermost layer of the epidermis, the stratum corneum. This layer, approximately one fourth the thickness of this sheet of paper, develops in utero during the third trimester of pregnancy in conjunction with a protective mantle of vernix caseosa. Preterm infants with extremely low birthweight (less than 1000 grams birthweight) lack a well-developed stratum corneum and pose special problems for newborn caregivers. The stratum corneum is necessary for the adherence of thermistors, cardiorespiratory monitors, and endotracheal tubes and forms the primary environmental interface with caregivers and parents. Box 52-2 gives a summary of general principles of skin care drawn from the literature.[8,38]

In addition to prematurity, a host of diseases and disorders of the fetus and newborn present with cutaneous manifestations. The advantage of the accessibility of the skin to physical examination is counterbalanced by the extreme structural and functional diversity of this organ. The caregiver must distinguish benign and transient lesions of newborn skin, such as erythema toxicum, from potential life-threatening diseases such as herpes simplex neonatorum. A basic understanding of the structural development of the skin, as well as the multiple functions subserved by the skin during transition to extrauterine life, is of basic importance to all newborn caregivers.[20,22]

This chapter provides an overview of the principles of newborn skin care followed by a summary of the many diseases of the newborn presenting with primary or secondary cutaneous manifestations. It is important to recognize that many common cutaneous findings in the newborn, such as sebaceous gland hyperplasia and neonatal pustular melanosis, point clearly to an intrauterine etiology. Thus far, however, an understanding of the biology of the fetus and its amniotic fluid environment is not sufficiently advanced to offer definitive explanatory mechanisms.

THE STRUCTURAL BIOLOGY OF FETAL AND NEONATAL SKIN

Development of the Epidermis

Human skin has two distinct but interdependent components—the epidermis and the dermis (Fig. 52-1). The epidermis has marked regional variations in thickness, color, permeability, and surface chemical components. It consists of a highly ordered, compact layering of keratinocytes and melanocytes. Traditionally, the epidermis is segmented into distinct structural and functional compartments called the stratum germinativum (basale), stratum spinosum, stratum granulosum, and stratum corneum (see Fig. 52-1). Intermixed is a third distinct cell type, the Langerhans cell, which is derived from bone marrow precursors and migrates into the primitive epidermis.

The process of cutaneous morphogenesis can be divided into embryonic and fetal periods (Fig. 52-2).[23,37] This transition, which occurs at approximately 2 months or 60 days, is an important time in skin development because many critical morphogenetic events occur during this transitional period. Between 30 and 40 days of development, the embryonic skin consists of a two-layered epidermis: the basal layer associated with the basal lamina and the periderm, which serves as a cover and a presumptive nutritional interface

BOX 52–1 Multiple Physiologic Roles of the Skin at Birth

Barrier to water loss
Thermoregulation
Infection control
Immunosurveillance
Acid mantle formation
Antioxidant function
Ultraviolet light photoprotection
Barrier to chemicals
Tactile discrimination
Attraction to caregiver

BOX 52–2 Principles of Newborn Skin Care

DELIVERY ROOM
Provide immediate drying and tactile stimulation.
Remove blood and meconium.
Leave vernix intact and spread to allow absorption.

BATHING
Limit frequency.
Use neutral pH cleansers.
Use only water for infants weighing less than 1000 g.
Avoid antibacterial soaps.

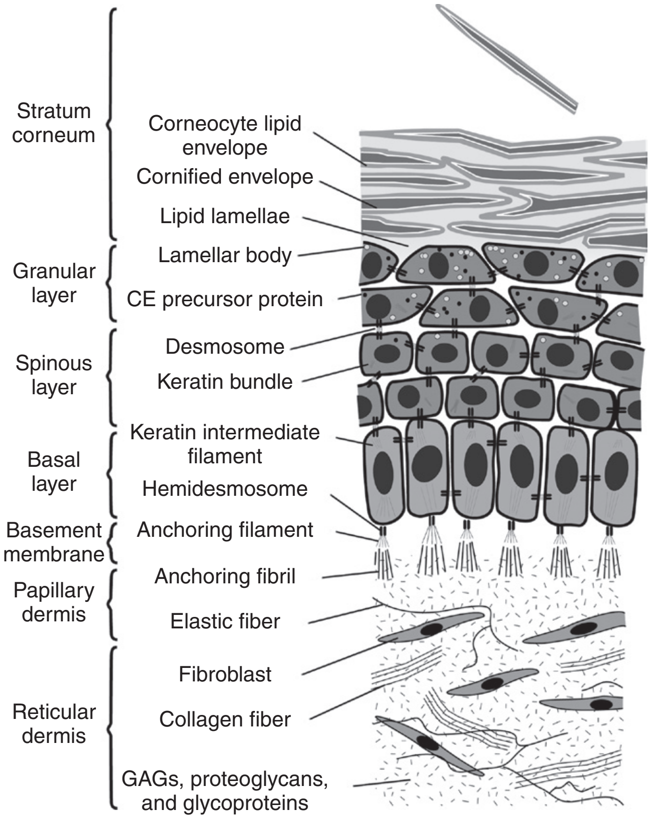
EMOLLIENTS
Avoid petrolatum-based ointments in infants with very low birthweight during the first week of life.
Use emollients as needed for dryness in older infants.

DISINFECTANTS
Use chlorhexidine, and remove excess after procedure.
Use of isopropyl alcohol and alcohol-based disinfectants is discouraged in infants with very low birthweight until the stratum corneum has formed.

ADHESIVES
Minimize use of adhesives.
Use hydrogel electrodes.
Avoid solvents and bonding agents.
Counsel patience during tape removal.

TRANSEPIDERMAL WATER LOSS
For infants younger than 30 weeks' gestation, select high incubator humidity (>60%) and transparent, semipermeable dressings to reduce evaporative water and heat loss.
Use incubators and supplemental conductive heat to avoid drying effects of radiant warmers.
Measure humidity routinely.

CORD CARE
Allow natural drying.
Avoid the routine use of isopropyl alcohol.



Stratum corneum
Granular layer
Spinous layer
Basal layer
Basement membrane
Papillary dermis
Reticular dermis
Corneocyte lipid envelope
Cornified envelope
Lipid lamellae
Lamellar body
CE precursor protein
Desmosome
Keratin bundle
Keratin intermediate filament
Hemidesmosome

Figure 52–1. Structure of the skin. The normal term infant's skin is composed of three separate layers: dermis, basement membrane, and epidermis. The epidermis can be subdivided into four further strata (basal, spinous, granular, corneum), each representing a specific stage in terminal differentiation. CE, cornified envelope; GAG, glycosaminoglycan (GAG). *(From Hardman MJ, Byrne C: Skin structural development. In Hoath SB et al, editors:* Neonatal skin: structure and function, *2nd ed, New York, 2003, Marcel Dekker.)*

with the amniotic fluid. The basal layer includes cells that give rise to the future definitive epidermis, whereas the periderm is a transient layer that covers the embryo and fetus until the epidermis keratinizes at the end of the second trimester. Basal cells join with each other and peridermal cells by a relatively few desmosomes but do not yet form hemidesmosomes with the basement membrane. Small numbers of keratin intermediate filaments are associated with these junctions. Matrix adhesion of the embryonic epidermis is likely mediated by actin-associated α6β4 integrin.[37]

Langerhans cells and melanocytes migrate into the embryonic epidermis and are identifiable at 40 and 50 days of gestation, respectively. At this stage, the Langerhans cells do not express CD1 antigen on their cell surfaces, nor are Langerhans cell granules identifiable. Likewise, at this time, the melanocyte lacks the characteristic cytoplasmic organelle, the melanosome. A third immigrant cell, the Merkel cell, does not appear to be present in embryonic epidermis and may differentiate at a later stage from keratinocytes in situ.

At the time of embryonic-fetal transition (60 days' gestation), the epidermis begins to stratify, forming an intermediate layer of cells. These young keratinocytes still contain a high volume of glycogen in their cytoplasm and produce large amounts of intermediate filaments in association with the desmosomes. At this time, new keratins are identifiable as markers of differentiation as well as the pemphigus antigen, which is detectable on the cell surface. These cells, unlike

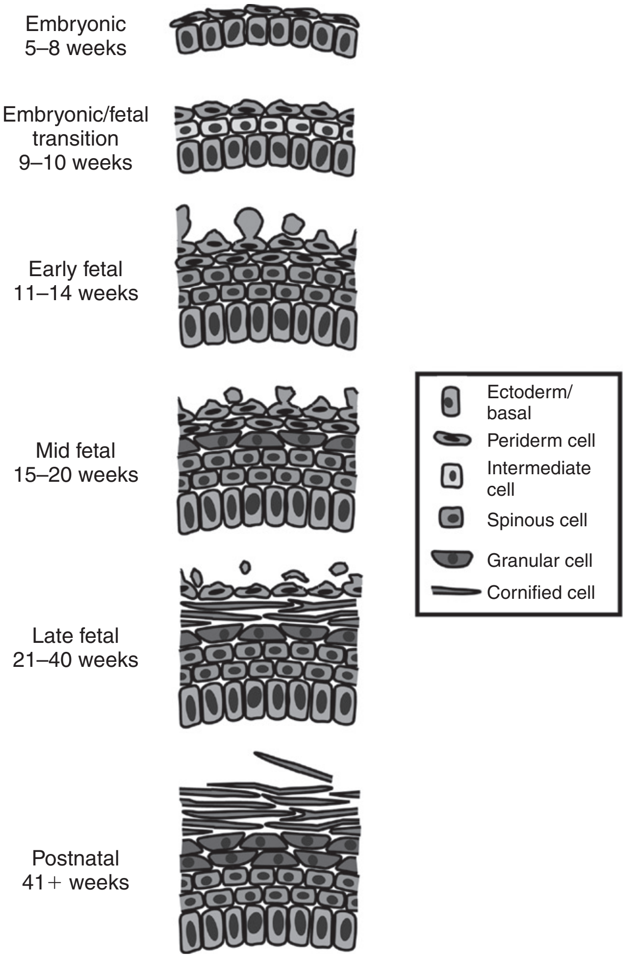

Figure 52–2. Schematic diagram of the six key stages of epidermal differentiation and development. The epidermis develops from a single layer of undifferentiated ectoderm (5-8 weeks) to a multilayered stratified differentiated epithelium with a competent epidermal barrier (40 weeks). The periderm undergoes intense proliferation (11-14 weeks) and forms characteristic blebs and microvilli thought to be functionally important. Regression and disaggregation of the periderm occurs concomitant with formation of the vernix caseosa (not shown). *(From Hardman MJ, Byrne C: Skin structural development. In Hoath SB et al, editors:* Neonatal skin: structure and function, *2nd ed, New York, 2003, Marcel Dekker pp 1-19.)*

adult spinous cells, remain proliferative and continue to express epidermal growth factor receptors on their surfaces. Two to three additional layers of intermediate cells are added during the second trimester. These cells show a progressive increase in the number of keratin filaments but do not further differentiate until the onset of keratinization in the interappendageal epidermis around 22 to 24 weeks' gestation.

The Langerhans cells in the embryonic epidermis begin to express CD1 antigen and contain Langerhans granules after the embryonic-fetal transition. The numbers of Langerhans cells increase significantly during the third trimester; however, the function of these cells in fetal skin remains unknown. Between 80 and 90 days' gestation, melanocytes also increase in density at a time when keratinocytes in the epidermis are forming appendages, and melanin synthesis begins at the end of the first trimester. Transfer of melanosomes to keratinocytes occurs in the fifth month of gestation.

Melanin production is low in the newborn, who is not as pigmented as the older child and is more sensitive to sunlight, but there is no significant difference in the number of melanocytes in light, medium, or deeply pigmented skin or in infant or adult skin. Difference in color is the result of the shape, size, chemical structure, and distribution of melanosomes and the activity of individual melanocytes. Color variations in human skin have a presumptive sun protective function and may serve as camouflage.

DEVELOPMENT OF THE APPENDAGES

The appendages derive from embryonic invaginations of epidermal germinative buds into the dermis.[24] They include hair, sebaceous glands, apocrine glands, eccrine glands, and nails. The arrector pili muscle is attached to the hair follicle. Lanugo (i.e., fine, soft, immature hair) frequently covers the scalp and brow of the premature infant. The scalp line may be poorly demarcated, and lanugo also may cover the face. Scalp hair is usually somewhat coarser and matures earlier in dark-haired infants.

The growth phases of the hair follicle are usually synchronous at birth. Eighty percent of the follicles are in the resting state. During the first few months of life, the synchrony between hair loss and regrowth is altered so that 20% of scalp hairs are growing in the same phase at the same time. Hair may become coarse and thick, acquiring an adult distribution, or there may be temporary alopecia.

There are sex differences in hair growth; boys' hair grows faster than girls' hair. In both sexes, scalp hair growth is slower at the crown. The normal pattern of hair growth is disturbed in many chromosomal disorders. Evidence supports a genetic link between the formation of clockwise posterior parietal hair whorls and specific (right) handedness of the individual.[30] This finding supports an unexpected association between gene-based hair patterning and human brain development. Evidence has shown the human hair follicle can synthesize cortisol de novo and is a functional equivalent of the hypothalamic-pituitary-adrenal axis.[27] The significance of this skin-brain connection remains to be elucidated.

The eccrine sweat glands are coiled structures that form during the first trimester as a downgrowth from epidermal cellular clones.[50] No new glands are formed after birth. They are distributed over the entire body surface and are innervated by sympathetic cholinergic nerves. During the first 24 hours of life, term infants usually do not sweat; on approximately the third day, sweating begins on the face. Palmar sweating begins later. Thermal sweating as a function of body or environmental temperature should be distinguished from emotional sweating associated with crying or pain. The latter is best assessed on the palms and soles.[50]

The sebaceous glands differentiate primarily from the epithelial portion of the hair follicle at approximately 13 to 15 weeks of life and almost immediately produce sebum in all hairy areas.[58] The glands develop as solid outpouchings from the upper third of the hair follicle. These solid buds become filled with liquid centrally where the cells disintegrate; acini and ducts develop, opening most frequently into the canals between the hair follicle wall and hair shaft. Ectopic glands occur occasionally on the lips, buccal mucosa, esophagus, and vagina.

Surprisingly little is know about the regulation of the rapid growth and activity of sebaceous glands up to and immediately after birth. Hypothetically, secretion by the fetal adrenal gland of weak androgens such as dehydroepiandrosterone (DHEA) is followed by intrasebocyte conversion to testosterone and production of products of the pilosebaceous unit such as vernix caseosa.[58] This hypothesis remains to be fully tested, but it has the singular advantage of functionally integrating two disparate and unexplained facts: the mutual hyperplasia of the sebaceous gland and the adrenal cortex during the latter half of gestation in the human fetus. Androgens are the only hormones that unequivocally have a stimulating effect on the sebaceous glands; estrogens depress their growth. Between 2 months and 2 years, the sebaceous glands of the normal infant begin a period of quiescence that lasts until puberty.

The apocrine glands are relatively large organs that originate from and empty into a hair follicle. Embryologically, they develop somewhat later than the eccrine glands. Apocrine development is advanced by 7 or 8 fetal months, when the glands begin to produce a milky-white fluid containing water, lipids, protein, reducing sugars, ferric iron, and ammonia. In the newborn, the acini are well formed. The biologic function of the gland is unknown in infants, but it is related to pheromone production in other animal species.

VERNIX BIOLOGY

Vernix caseosa, a unique material that coats the fetal skin surface during the last trimester of pregnancy, contains lipids of sebaceous origin as well as numerous water-laden fetal corneocytes. A growing body of evidence supports the hypothesis that vernix caseosa participates in regionally "waterproofing" the skin surface, thereby allowing cornification to occur, initially around the hair follicles and then over the interfollicular skin.[21] A better understanding of vernix caseosa and fetal sebaceous gland physiology is biologically relevant and may be applicable to care of the infant with very low birthweight and to clinical situations in which the epidermal surface is inadequately developed, burned, or traumatized.

Physiologically, vernix is a hydrophobic material containing wax esters, cholesterol, ceramides, and squalene in addition to other minor lipid components. Vernix has high water content (~ 80%), with the water primarily distributed within flat, polygonal, cornified squames. As term approaches, vernix detaches from the fetal skin surface under the influence of pulmonary surfactant and is swallowed by the fetus. In close analogy to breast milk, vernix contains multiple molecules associated with the innate immune system, including lysozyme, lactoferrin, and defensins, as well as antioxidants such as alpha-tocopherol.[21,57] Vernix possesses both emollient (moisturizing) as well as cleansing functions. Thus, at birth the human infant is covered with a complex material possessing endogenous anti-infective, antioxidative, moisturizing, and cleansing capabilities. Extreme prematurity, as well as postmaturity, are associated with diminished vernix on the skin surface at birth.

Development of the Dermis

The fetal dermis acquires some of the characteristics of adult dermis around 20 weeks' gestation. However, it is only in the more mature fetus that the true structural and biochemical qualities of the newborn dermis are detectable. The dermis contains three identifiable zones: the region adjacent to the basement membrane, the papillary, and the reticular dermis (see Fig. 52-1). The superficial dermis has finer collagen fibers and is biochemically more active than the deeper zone. The papillary dermis also is more susceptible to light injury and elastic tissue degeneration than the reticular dermis. The dermis has a symbiotic relationship with and may exert a controlling influence on the epidermis. It is a metabolically active tissue that contains fibrous elements, amorphous ground substance, free cells, nerves, blood vessels, and lymphatics.

The fibrous elements are collagen and elastic tissue. Collagen types I, III, V, and VI comprise the dermal collagens, whereas type IV is present in the basement membrane of the dermal-epidermal junction and dermal vessels, and type VII occurs in anchoring fibrils and basal keratinocytes. With increasing age, collagen becomes progressively less soluble, and thicker bundles predominate. The morphologic characteristics and chemical properties of cutaneous elastic fibers differ from those of collagen. Elastic fibers are first detectable in the skin by histochemical means and electron microscopy at around 20 weeks' gestation.

The fibroblasts are the most numerous cells in the dermis. They produce collagen and the glycosaminoglycans of the ground substance. Mast cells (which produce heparin and histamine), histiocytes, macrophages, lymphocytes, neutrophils, and an occasional plasma cell and eosinophil are also present in the dermis. The major glycosaminoglycans in the ground substance of skin are hyaluronic acid and dermatan sulfate (i.e., chondroitin sulfate B). An increase in age brings a shift from hyaluronic acid toward dermatan sulfate and a decrease in water content of the dermis.

BLOOD AND LYMPHATIC VESSEL DEVELOPMENT

The vascular network supplying the skin develops in early embryonic life from the mesoderm.[51] In 60- to 70-day-old fetuses, there are two vascular networks: a superficial one that appears to correspond to the subpapillary plexus of adult skin and a deeper network that represents the deep reticular vascular network of adult skin. New capillary beds organize to supply the developing epidermal appendages from the fifth month of gestation. These two networks persist into the newborn period; however, the arrangement of vessels remains unstable for the first year of life, and further organization of the vascular network occurs postnatally.

Vasomotor tone is controlled by a delicate and complex series of neural and pharmacologic mechanisms that involve the sympathetic nervous system, norepinephrine, acetylcholine, and histamine and may involve serotonin, vasoactive polypeptides, corticosteroids, and prostaglandins. The physiologic requirements of skin vary considerably; skin blood flow ranges from 0.1 to 150 mL/mm^3 of tissue per minute.[51]

DEVELOPMENT OF CUTANEOUS INVERVATION

The nerve networks in the dermis develop at a very early embryologic age and appear to be distributed in a random fashion. The most superficial nerves have the smallest diameter and are the least myelinated. In addition to the dermal nerve network, which may show considerable regional variation, nerve fibers may serve particular regions or structures such as hair follicles, eccrine glands, arrector pili muscles, and the subepidermal zone. Superficial nerves conduct mechanosensory stimuli from the specialized Merkel cells within the epidermis. The sebaceous glands are not innervated.

Special neurologic structures include a dense perifollicular nerve network with exquisite tactile sensory properties and mucocutaneous end organs highly concentrated in erogenous zones. Meissner tactile organs are found in newborn skin as undeveloped structures that mature after birth. Merkel corpuscles probably govern two-point tactile discrimination on palms and fingertips; they are disk-shaped terminals that are seen during the 28th week of fetal life. After birth, these receptors undergo little alteration. Vater-Pacini corpuscles are found around the digits, palms, and genitals; they are fully formed and numerous at birth.[22]

The arrector pili muscles are innervated by sympathetic nerves, and norepinephrine acts as the neurotransmitter. The eccrine glands are innervated by sympathetic fibers, but acetylcholine acts as the neurotransmitter. Parasympathetic fibers may accompany the sensory nerves in the vessel walls and cause vasodilation. The axon reflex is poorly developed in the newborn; in the neonate of low birthweight, axon-reflex sweating may be difficult to elicit.[50]

DISORDERS AND DISEASES OF FETAL AND NEONATAL SKIN

This section provides a cursory synopsis of normal and abnormal aspects of newborn skin. An accurate description of primary and secondary skin lesions underlies the proper identification of skin condition and whether appropriate treatment is needed. Tables 52-1 and 52-2 describe the basic lesional morphology of infant skin with specific examples. More definitive treatises on normal skin structure, function, development, and specific disease states are available.[12,20] The remainder of this chapter delineates specific conditions of newborn skin ranging from transient lesions to definitive cutaneous diseases and diagnostic categories.

Transient Cutaneous Lesion

A number of benign and transient lesions of the skin are commonly observed in a normal nursery population. It is important for the infant caregiver to distinguish such ephemeral lesions from significant life-threatening diseases with cutaneous manifestations.

TABLE 52–1 Primary Cutaneous Lesions*

Type	Description	Clinical Examples
Macule	A circumscribed, flat lesion with color change, up to 1 cm in size; by definition, they are not palpable	Ash leaf macules, café-au-lait spots, capillary ectasias
Patch	Same as macule but greater than 1 cm in size	Nevus depigmentosus, nevus simplex, mongolian spots
Papule	A circumscribed, elevated, solid lesion, up to 1 cm in size; elevation may be accentuated with oblique lighting	Verrucae, milia, juvenile xanthogranuloma
Plaque	A circumscribed, elevated, plateau-like, solid lesion, greater than 1 cm in size	Mastocytoma, nevus sebaceous
Nodule	A circumscribed, elevated, solid lesion with depth, up to 2 cm in size	Dermoid cysts, neuroblastoma
Tumor	Same as a nodule but greater than 2 cm in size	Hemangioma, lipoma, rhabdomyosarcoma
Vesicle	A circumscribed, elevated, fluid-filled lesion up to 1 cm in size	Herpes simplex, varicella, miliaria crystallina
Bulla	Same as a vesicle but greater than 1 cm in size	Sucking blisters, epidermolysis bullosa, bullous impetigo
Wheal	A circumscribed, elevated, edematous, often evanescent lesion, due to accumulation of fluid within the dermis	Urticaria, bite reactions, drug eruptions
Pustule	A circumscribed, elevated lesion filled within purulent fluid, less than 1 cm in size	Neonatal pustular melanosis, erythema toxicum neonatorum, infantile acropustulosis
Abscess	Same as a pustule but greater than 1 cm in size	Pyodermas

*These lesions arise de novo and are therefore most characteristic of the disease process.

Modified from Yan AC et al, editors Lesional morphology and assessment. In Eichenfeld LF et al, editors: *Textbook of neonatal dermatology*. Philadelphia, 2008, Saunders, p 33.

TABLE 52–2 Secondary Cutaneous Lesions*

Type	Description	Clinical Examples
Crust	Results from dried exudates overlying an impaired epidermis. Can be composed of serum, blood, or pus.	Epidermolysis bullosa, impetigo
Scale	Results from increased shedding or accumulation of stratum corneum as a result of abnormal keratinization and exfoliation. Can be subdivided further in pityriasiform (branny, delicate), psoriasiform (thick, white, and adherent), and ichthyosiform (fish scale–like).	Ichthyoses, postmaturity desquamation, seborrheic dermatitis
Erosion	Intraepithelial loss of epidermis. Heals without scarring.	Herpes simplex, certain types of epidermolysis bullosa
Ulcer	Full thickness loss of the epidermis with damage into the dermis. Will heal with scarring.	Ulcerated hemangiomas, aplasia cutis congenita
Fissure	Linear, often painful break within the skin surface, as a result of excessive xerosis.	Inherited keratodermas, hand and foot eczema
Lichenification	Thickening of the epidermis with exaggeration of normal skin markings caused by chronic scratching or rubbing.	Sucking callus, atopic dermatitis
Atrophy	Localized diminution of skin. *Epidermal atrophy* results in a translucent epidermis with increased wrinkling, whereas *dermal atrophy* results in depression of the skin with retained skin markings. Use of topical steroids can result in epidermal atrophy, whereas intralesional steroids may result in dermal atrophy.	Aplasia cutis congenita intrauterine scarring, and focal dermal hypoplasia
Scar	Permanent fibrotic skin changes that develop as a consequence of tissue injury. In utero scarring can occur as a result of certain infections or amniocentesis or postnatally from a variety of external factors.	Congenital varicella, aplasia cutis congenita

*These lesions arise as characteristic modifications of primary lesions through environmental interaction (e.g., drying) or subject interaction (e.g., scratching).
Modified from Yan AC et al: Lesional morphology and assessment. In Eichenfeld LF et al, editors: *Textbook of neonatal dermatology*, Philadelphia, 2008, Saunders, 2008, p 33.

SEBACEOUS GLAND HYPERPLASIA AND MILIA

Approximately 40% of infants have multiple, white, 1-mm cysts (i.e., milia) scattered over the cheeks, forehead, nose, and nasolabial folds. These milia may be few or numerous, but they frequently occur in clusters. Milia are often confused with the smaller, flatter, more yellow dots of sebaceous gland hyperplasia seen on the midface as well (Fig. 52-3). Histologically, milia are keratogenous cysts similar to Epstein pearls, which are distributed along the midpalatal raphe. Bohn nodules are cysts that occur on the palate and the buccal and lingual aspects of the dental ridges and represent remnants of mucous gland tissue. Intraoral lesions are found in 75% to 80% of newborns. Because all these cysts exfoliate or involute spontaneously within the first few weeks of life, no treatment is required.

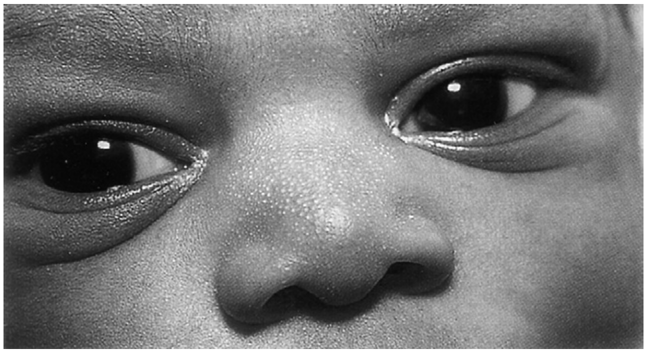

Figure 52–3. Sebaceous gland hyperplasia is manifested by tiny yellow-white follicular papules without inflammation over the nose and surrounding area. *(From Lucky AW: Transient benign cutaneous lesions in the newborn. In Eichenfield LF et al, editors:* Neonatal dermatology, *Philadelphia, 2008, Saunders.)*

PIGMENTARY LESIONS[53]

The most frequently encountered pigmented lesion is the mongolian spot (cutaneous melanosis), which occurs frequently in African-American, Asian, and Native American infants and, infrequently, in white infants. Although most of these lesions are found in the lumbosacral area, occurrence at other sites is not uncommon. The pigmentation is macular and gray-blue, lacks a sharp border, and may cover an area 10 cm or larger in diameter. Pigmentary lesions result from delayed disappearance of dermal melanocytes.

Most of these lesions gradually disappear during the first few years of life, but aberrant lesions in unusual sites are more likely to persist. Because of their distinctive color and morphology, mongolian spots are not easily confused with congenital pigmented melanocytic nevi or café-au-lait spots, which have their onset later in infancy or in early childhood, although occasionally they may be present at birth.

Abnormal hyperpigmentation of the areolas and genitals may be evidence of the existence of an in utero glucocorticoid insufficiency associated with defects in the biosynthesis of hydrocortisone.

TRANSIENT MACULAR STAINS OR SALMON PATCHES[41]

Salmon patches or transient macular stains are present in up to 70% of normal newborns (Fig. 52-4A-B). They are usually found on the nape, the eyelids, and the glabella. In a prospective study of affected infants, most of the facial lesions had faded by 1 year of age, but those on the neck were more persistent. Surveys of adult populations confirm the persistence of the nuchal lesions in approximately one fourth of the population.

HARLEQUIN COLOR CHANGE

Harlequin color change is a phenomenon observed in the immediate neonatal period and is more common in the infant with low birthweight. The dependent side of the body becomes intensely red, and the upper side pales, with a sharp midline demarcation. The peak frequency of attacks in one series occurred on the second, third, and fourth days, but episodes were observed during the first 3 weeks of life. These episodes are of no pathologic significance. They have been attributed to a temporary imbalance in the autonomic regulatory mechanism of the cutaneous vessels; there are no accompanying changes in the respiratory rate, muscle tone, or response to external stimuli.

ERYTHEMA TOXICUM

Erythema toxicum is a benign and self-limited eruption that usually develops between 24 and 72 hours of age, but new lesions may appear until 2 to 3 weeks of age.[45] The disorder is more common in term infants than in premature infants, which suggests that it may represent an inflammatory reaction requiring mature skin. These lesions may vary considerably in character and number; they may be firm, 1- to 3-mm, pale yellow-to-white papules or pustules on an erythematous base resembling flea bites or erythematous macules as large as 3 cm in diameter. Individual lesions are evanescent, often lasting only a matter of hours. They may be found on any area of the body but occur only rarely on the palms and soles. They are asymptomatic with no related systemic involvement, and their cause is unknown, although a variety of specific cytokines have been implicated in the pathogenesis.[39] A microscopic examination of a Wright-stained or Giemsa-stained smear of the pustule contents demonstrates numerous eosinophils; Gram stains are negative for bacteria, and cultures are sterile. No treatment is necessary, because spontaneous resolution occurs in 6 days to 2 weeks.

TRANSIENT NEONATAL PUSTULAR MELANOSIS

Transient neonatal pustular melanosis is a distinctive eruption that consists of three types of lesions. First-stage lesions are small, superficial vesiculopustules with little or no surrounding erythema.[45] These rapidly progress to the second stage, which consists of collarettes of scale or scale crust surrounding a hyperpigmented macule (third stage) (Fig. 52-5A-C). All three types of lesions may be present at birth, but the macules are observed more frequently. The lesions may be profuse or sparse and occur on any body surface, including the palms, soles, and scalp. Sites of predilection are the forehead, submental area and anterior neck, and lower back. When intact pustules rupture, a pigmented macule often is discernible central to the collarette of scale, which represents the margin of the unroofed pustule. Presumably, the macules result from postinflammatory hyperpigmentation, and those present at birth may be the sequelae of in utero pustular lesions.

Pustular melanosis may be confused with erythema toxicum, congenital cutaneous candidiasis, or staphylococcal pyoderma.[45,53] Cultures and Gram stains of smears prepared from intact pustules are devoid of organisms; Wright stains of intralesional contents demonstrate cellular debris, polymorphonuclear leukocytes, and a few or no eosinophils, in contrast to those of erythema toxicum. Although the pustules disappear in 48 hours, the hyperpigmented macules may

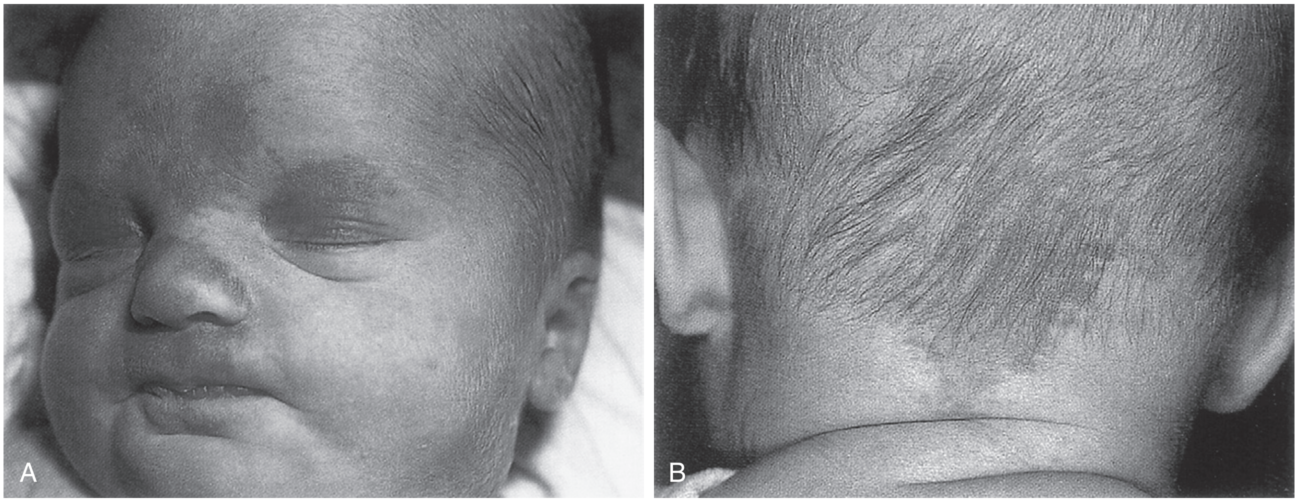

Figure 52–4. Capillary ectasias or transient macular stains (salmon patches). Also called a nevus simplex, these lesions appear on the glabella, eyelids, nose, and upper lip (**A**). The most common location for a nevus simplex is the nape of the neck (**B**). *(From Lucky AW: Transient benign cutaneous lesions in the newborn. In Eichenfield LF et al, editors:* Neonatal dermatology, *Philadelphia, 2008, Saunders.)*

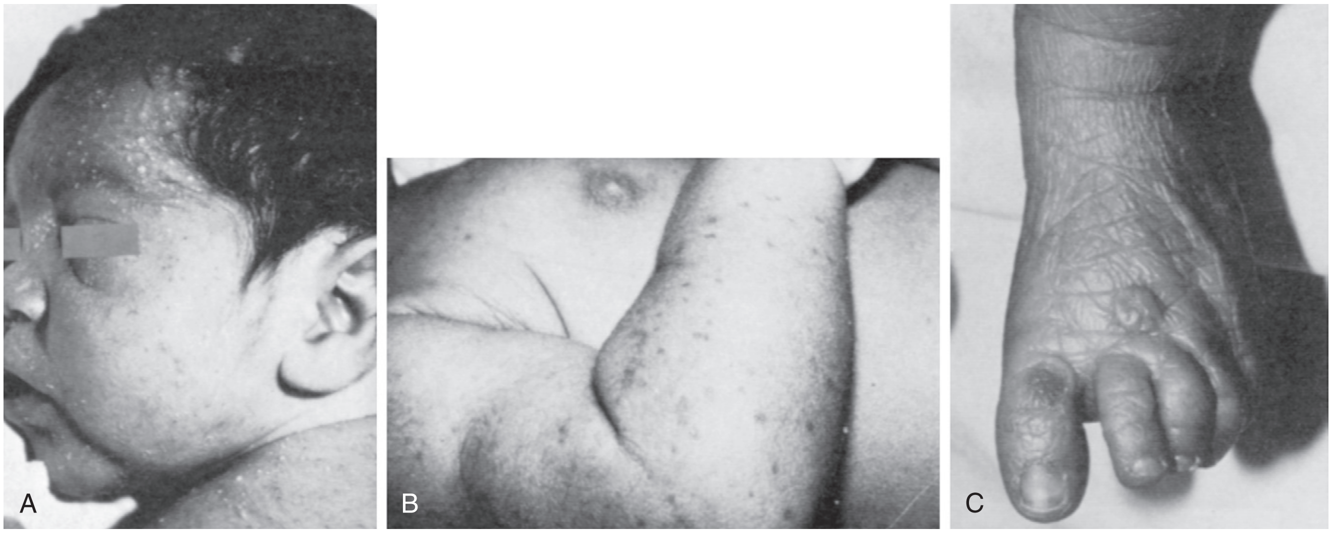

Figure 52–5. Transient neonatal pustular melanosis. **A**, Superficial pustules on the face and shoulders of a 1-day-old infant. Some have ruptured, leaving a collarette of scale. **B**, Pigmented macules on the arm and chest of a newborn. **C**, Large pustule on the dorsum of the foot and hyperpigmented macule on the toe of a neonate.

persist for as long as 3 months. Neither type of lesion requires therapy, and although the cause is unknown, parents may be reassured that the disorder is benign and transient.

MILIARIA

Miliaria is an eruption resulting from eccrine sweat duct obstruction leading to sweat retention.[45] The three types of lesions are superficial thin-walled vesicles without inflammation (i.e., miliaria crystallina); small, erythematous grouped papules (i.e., miliaria rubra); and nonerythematous pustules (i.e., miliaria pustulosis or profunda).

The eruption most frequently develops in the intertriginous areas and over the face and scalp. It is exacerbated by exposure to a warm and humid environment. Miliaria sometimes can be confused with erythema toxicum; rapid resolution of the lesions when the infant is placed in a cooler environment differentiates them from pyoderma. A Wright-stained smear of vesicular lesions demonstrates only sparse squamous cells or lymphocytes, permitting exclusion of infectious vesicular eruptions. No topical therapy is indicated.

NEONATAL ACNE AND INFANTILE ACNE

Neonatal acne (i.e., neonatal cephalic pustulosis) is a relatively common condition that affects both sexes. It consists of small red papules and pustules on the face during the first weeks of life (Fig. 52-6). Comedones and cysts are usually absent. The lesions are asymptomatic and resolve spontaneously over several weeks. It has been suggested that occurrence of these lesions is coincident with colonization by the yeast *Pityrosporon ovale*.

In contrast, infantile acne is an uncommon but distressing facial eruption (usually in male infants) that has its onset somewhat later, during the first few months of life.[19,45] This condition resembles acne in the adolescent patient and is characterized by comedones, papules, pustules, and, rarely, nodules. The duration may vary, but the disorder usually clears spontaneously during the latter portion of the first year of life. This condition probably represents a heightened response of the sebaceous glands to neonatal androgens.[19] No treatment or treatment with mild topical acne preparations to produce drying and peeling should suffice. Occasionally, the infant may be left with pitted scarring, and some may experience severe acne as adolescents.

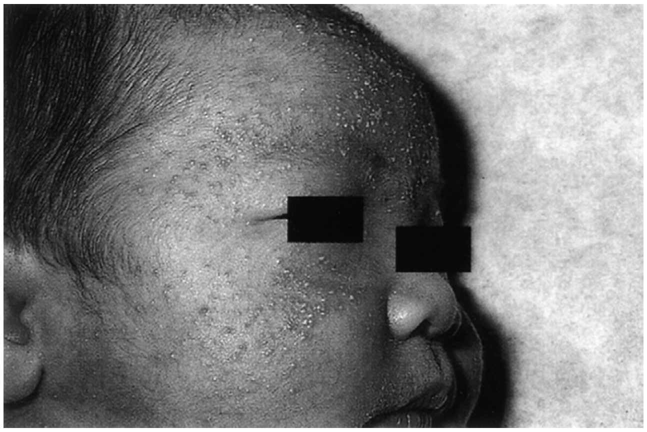

Figure 52–6. Neonatal acne (cephalic pustulosis). Commonly seen on the cheeks and scalp during the first 2 to 4 weeks after birth; usually manifested by small red papules and pustules without comedones. *(From Lucky AW: Transient benign cutaneous lesions in the newborn. In Eichenfield LF et al, editors:* Neonatal dermatology, *Philadelphia, 2008, Saunders.)*

INFANTILE ACROPUSTULOSIS

Infantile acropustulosis consists of pruritic papules and vesiculopustules with onset from birth to 10 months of age. The lesions appear in crops every 2 to 3 weeks and last 7 to 10 days. They involve the hands and feet primarily but occasionally may affect the limbs as well. Because of the distribution, it is often confused with scabies. It is more common in African-American and in male infants. The condition resolves spontaneously. A subcorneal pustule filled with neutrophils is seen on skin biopsy. Therapy consists of topical steroids and antihistamines.

Disorders of Cornification: The Scaly Baby

The most common causes of excessive scaling in the neonate are physiologic desquamation and dysmaturity, neither of which is of long-term significance. Less common causes include the congenital ichthyoses and the ectodermal dysplasias (particularly hypohidrotic ectodermal dysplasia), all of which are chronic, heritable disorders.[32] Disorders of cornification that may manifest during the first weeks of life are given in Table 52-3.

PHYSIOLOGIC DESQUAMATION AND DYSMATURITY

The gestational age of a newborn with accentuated physiologic desquamation usually is 40 to 42 weeks (see Chapter 27); peak shedding occurs near the eighth day of life. These infants are otherwise normal in physical appearance and behavior. In contrast, the dysmature infant (see Chapter 14) has distinctive characteristics. The body is lean, with thin extremities and decreased subcutaneous fat. The ponderal index is low and indicates diminished body weight in relation to length. The skin is often scaly with parchment-like desquamation, especially of the distal extremities. There is often meconium staining of the skin as well as the nails and umbilical cord. The hair is abundant, and the nails are abnormally long. In the normal infant with accentuated physiologic scaling and the dysmature infant, desquamation is a transient phenomenon, and the integument continues to serve its intended protective function. In contrast, the infant with congenital ichthyosis may have serious difficulties early in life because of impaired barrier function and subsequent risks of secondary infection.

ICHTHYOSES

The term *ichthyosis* derives from the similarity of the skin condition to the scales of a fish. It refers to a complex and often confusing plethora of conditions characterized by disorders of cornification with or without systemic symptoms. Ichthyosis in the newborn period may manifest as scaling only, scaling and erythroderma, a collodion membrane, or the thickened plates of harlequin ichthyosis. Two descriptive terms have been used for ichthyotic conditions that occur only in the newborn: *harlequin ichthyosis* and *collodion baby*. Attempts to classify this complex set of disorders based on phenotypic and genotypic criteria recognize three main groups: (1) bullous ichthyosis and related disorders due to keratin mutations, (2) nonbullous ichthyosiform erythroderma and lamellar ichthyosis mainly due to transglutaminase 1 mutations, and (3) syndromic ichthyosis, namely, systemic (multiorgan) diseases with many different causes.[55] Selected conditions with particular relevance to the newborn are highlighted below, followed by a general overview of treatment strategies.

Harlequin Ichthyosis

Harlequin ichthyosis (i.e., harlequin fetus) is a rare, very severe disorder of keratinization inherited as an autosomal recessive trait in most families, although a dominant form may exist, and sporadic cases occur frequently. This clinical phenotype represents a heterogeneous group of disorders characterized by perturbations of epidermal intercellular lipid, altered lamellar granules, and variation in expression or processing of structural proteins involved in normal epidermal keratinization. Although the histologic, ultrastructural, and biochemical findings of the various subtypes differ, their clinical features are indistinguishable. The skin of affected infants is markedly thickened, hard (armor-like), and hyperkeratotic, with deep crevices running transversely and vertically. The fissures are most prominent over areas of flexion. Rigidity of the skin around the eyes results in marked ectropion, although the globe is usually normal. The ears and nose are underdeveloped, flattened, and distorted, and the lips are everted and gaping, producing a “fish-mouth” deformity. The nails and hair may be hypoplastic or absent. Extreme inelasticity of the skin is associated with flexion deformity of all joints. The hands and feet are ischemic, hard, and waxy in appearance, with poorly developed distal digits.

Most harlequin fetuses are born prematurely, usually between 32 and 36 weeks’ gestation, adding to their morbidity and mortality. Complications include sepsis, distal gangrene, and difficulties with feeding and respiration. Most infants die in the neonatal period; however, therapeutic trials of oral retinoids combined with intensive nursing care have resulted in survival of several of these infants. All surviving infants have had chronic, severe ichthyosis.

Collodion Baby

The collodion baby is less severely affected than the infant with harlequin ichthyosis and may represent a phenotypic expression of several genotypes. This condition eventuates in lamellar ichthyosis or congenital ichthyosiform erythroderma in approximately 60% of patients. Sjögren-Larsson syndrome, Conradi-Hünermann syndrome, trichothiodystrophy, dominant lamellar ichthyosis, and neonatal Gaucher disease account for the remainder of the infants born with a collodion membrane. Rarely, shedding of the collodion membrane results in a normal underlying integument (i.e., lamellar exfoliation of the newborn). Collodion babies often are born prematurely. The infant is covered with a cellophane-like membrane, which by its tautness may distort the facial features and the digits (Fig. 52-7). Less commonly, only part of the integument is involved. The membrane is shiny and brownish-yellow, resembling an envelope of collodion or oiled parchment, and may be perforated by hair. The presence of ectropion, eclabium, and crumpled ears causes these infants to resemble one another for the first few days of life. Fissuring and peeling begin shortly after birth, and large sheets may desquamate, revealing erythema of variable intensity. After the membrane has fissured, no respiratory difficulties are encountered. Complete shedding of the collodion membrane may take several weeks. Pedigree information and histopathologic examination of a skin biopsy are additional aids in the delineation of the specific type of ichthyosis.

Despite the apparent thickened skin, these infants have an abnormal epidermal barrier, which may lead to complications such as dehydration, electrolyte imbalance, temperature instability, and cutaneous and systemic infection. Pneumonia from aspiration of squamous cells found in the amniotic fluid is another potential complication.

TABLE 52–3 Disorders of Cornification That Usually Manifest during the First Weeks

Disorder (Inheritance)	Clinical Features	Mutation	Protein/function
CHILD syndrome (XD)	Unilateral ichthyosiform erythroderma, chondrodysplasia punctata, cataracts, limb reduction defects, aymmetric organ hypoplasia	3β-Hydroxysteroid delta isomerase	Enzyme involved in cholesterol synthesis
CHIME syndrome (Zunich-Kaye syndrome) (AR)	Ichthyotic erythematous plaques, cardiac defects; typical facies, retinal colobomas, mental retardation, hearing loss, anomalous dentition	Unknown	Unknown
Congenital ichthyosiform erythroderma (AR)	Fine white scales, background erythema	Ichthynin, member of DUF803 protein family	Uncertain, likely membrane receptor
Conradi-Hünermann: X-linked chondrodysplasia punctata (XD)	Striated ichthyosiform hyperkeratosis, alopecia, cataracts, frontal bossing, short proximal limbs, stippled calcifications of the epiphyseal regions	Emopamil binding protein	Enzyme involved in cholesterol synthesis
Epidermolytic hyperkeratosis (AD)	Scaling and blistering	Keratins 1, 10	Cytoskeleton structural protein
Familial peeling skin (AR)	Superficial acral skin peeling	Keratinocye transglutaminase 5	Stratum corneum cross-linking enzyme
Gaucher disease (AR)	Collodion membrane with later mild scaling, hepatoslenomegaly, neurologic abnormalities	β-Glucocerebrosidase	Enzyme
Harlequin ichthyosis (AR)	Thick armored scale with fissuring, ectropion, eclabion	ATP-binding cassette	ABC transporter
Ichthyosis follicularis (usually X-linked recessive)	Follicular hyperkeratosis, nail dystrophy, alopecia, photophobia, short stature, psychomotor delay	Unknown	Unknown
Ichthyosis hystrix (AD)	Plaques of hyperkeratosis Superficial peeling	Keratin 1	Cytoskeleton structural protein
KID syndrome (may be AD, AR)	Verrucous plaques, stippled pattern of keratoderma, vascularizing keratitis, deafness	Connexin 26	Gap junction protein
Lamellar ichthyosis (usually AR)	Collodion membrane with large adherent plates	Transglutaminase 1 or ATP-binding cassette	Stratum corneum cross-linking enzyme or ABC transporter
Netherton syndrome (AR)	Erythroderma in infancy, scant hair (bamboo hair), often failure to thrive, atopic diathesis, food allergies	SPINK5	Serine protease inhibitor
Neutral lipid storage disease (AR)	Collodion membrane or ichthyosiform erythroderma, liver abnormalities, mental retardation, muscle atrophy	CGI-58	Enzyme in esterase/lipase family
Recessive X-linked ichthyosis	Collodion membrane, large dark scales, corneal opacities, cryptorchidism	Steroid sulfatase	Metabolic enzyme
Sjögren-Larsson (AR)	Fine lamellar scale, spastic diplegia, seizures, retinal "glistening white dots"	Fatty aldehyde dehydrogenase gene	Metabolic enzyme
Trichothiodystrophy (AR)	Collodion membrane, broken hair, photosensitivity, short stature, decreased fertility, susceptibility to infection	Xeropigmentosum protein	DNA repair enzymes, regulation of transcription

ABC, ATP-binding cassette; AD, autosomal dominant; AR, autosomal recessive; CHILD, congenital hemidysplasia, ichthyosiform erythroderma, limb defects; KID, keratitis, ichyosis, deafness; XD, X-linked dominant.

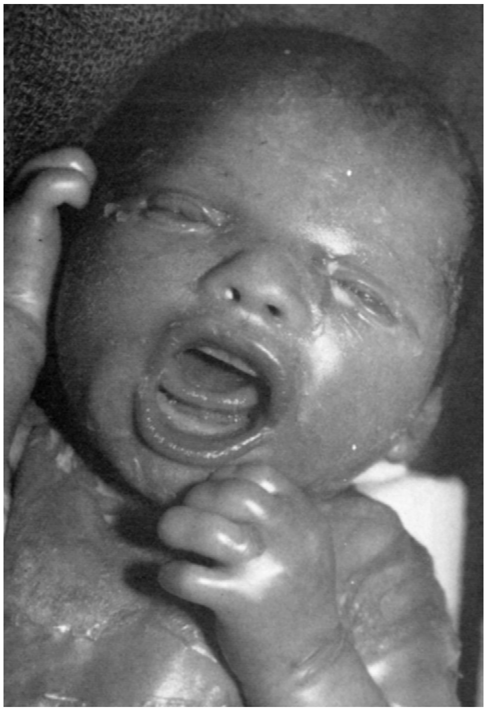

Figure 52–7. Collodion baby with ectropion, eclabium, and deformed digits.

X-Linked Ichthyosis

X-linked ichthyosis is the most common form of ichthyosis in the newborn period affecting approximately 1/2500 males.[55] In contrast, ichthyosis vulgaris occurs with a frequency of 1/300 but appears first in early childhood and will not be discussed. Steroid sulfatase (arylsulfatase) deficiency is the cause of the clinical manifestations of X-linked ichthyosis, which may include alterations in the skin, eye, and testes of affected infants. Most patients have cutaneous findings at birth, and 80% to 90% show scaling by 3 months of age. Rarely, a collodion membrane may be present. The hyperkeratosis is variable, but the scales typically are large, thick, and dark and are prominent over the scalp, neck, anterior trunk, and extensor extremities. Sparing of palms and soles and partial sparing of the flexures are helpful diagnostic features. Systemic manifestations are generally absent, and complications are rare. Skin biopsy is helpful (although the histologic pattern resembles that of lamellar ichthyosis), showing hyperkeratosis, a well-developed granular layer, hypertrophic epidermis, and a perivascular lymphocytic infiltrate. This form of ichthyosis is clinically apparent in affected homozygous males and not in heterozygous females. Because of the steroid sulfatase enzyme deficiency in the somatic tissues of affected males, increased levels of cholesterol sulfate can be documented by serum lipoprotein electrophoresis, and assays of steroid sulfatase activity show depressed levels of enzyme in cultured leukocytes, fibroblasts, amniocytes, and scales, confirming the diagnosis. Cryptorchidism is seen in approximately 25% of affected males; these patients may be at increased risk for testicular cancer. Deep stromal corneal opacities have also been found in about 50% of male infants with the disorder and in a smaller percentage of female carriers, but they do not affect vision. Female carriers of the gene for X-linked ichthyosis, when pregnant with an affected male fetus, have a deficiency of placental steroid sulfatase reflected by low maternal urinary estriol excretion and a difficult or prolonged labor that often requires intervention.

Babies affected with the rare condition of multiple sulfatase deficiency may have similar cutaneous findings but also have systemic features of a storage disease (i.e., metachromatic leukodystrophy), because they have a deficiency of several other sulfatases. Approximately 10% of patients have a contiguous gene deletion syndrome; this condition results from a larger deletion of the terminal short arm of the X chromosome. Deletion of the genes that are contiguous with the steroid sulfatase gene may result in mental retardation, Kallmann syndrome, and a bone dysplasia (i.e., X-linked recessive chondrodysplasia punctata).

Management of Ichthyosis

Management of ichthyotic patients in the newborn period runs the gamut from amelioration of mild cosmetic problems with excessive dryness and scaling to treatment of potentially life-threatening illness due to deficits in the epidermal barrier and subsequent infection. Table 52-4 lists the primary signs, symptoms, and pathogenetic mechanisms that form the primary targets of therapy for ichthyosis. Severely affected infants require aggressive topical care, liberal use of bland emollients, and careful monitoring of electrolyte needs. The infant should be placed in an environment with increased humidity, and prompt attention should be paid to signs of infection. Often the long-term goal of ichthyotic therapy is to eliminate scaling due to excessive cornification and to reduce dryness (xerosis) of the skin without inducing irritation. Keratolytic agents should be used with caution in the neonatal period and during the first 6 months of life, however. Although the stratum corneum is often thick and scaly, the barrier is compromised, and the risks of systemic absorption of potentially toxic substances, such as lactic acid and salicylic acid, are significant (see Table 52-8). Liberal use of

TABLE 52–4 Primary Targets for Ichthyosis Therapy

Signs and Symptoms	Pathogenetic Mechanisms
Dryness	Abnormal quality or quantity of scales
Scaling	Abnormal thickness of stratum corneum
Fissures and erosions	Skin inflammation
Keratoderma	Barrier failure
Erythema	Secondary infections
Pruritus	Obstruction of adnexal ducts
Anhidrosis	Stiffness of the skin
Ectropion	

Adapted from Vahlquist A et al: Congenital ichthyosis: an overview of current and emerging therapies. *Acta Derm Venereol* 88:4, 2008.

bland emollients generally suffice for lubrication during the neonatal period.

Future Prospects

At present there is no definitive cure for ichthyosis, and current therapies are generally palliative. Over the past decade, however, the molecular bases of many of these predominately monogenetic disorders have been elucidated (see Table 52-3). Identification of the affected genes opens the door for prenatal diagnosis and genetic counseling for these potentially lethal conditions. Unusual associations between skin and brain have been described, including a link between steroid sulfatase deficiency in X-linked ichthyosis and attention-deficit/hyperactivity disorder. Rapid progress in this field is anticipated, including the possibility of cutaneous gene therapy.[55] Parents are referred to an extensive online support group for families of infants with cornification disorders, the Foundation for Ichthyosis and Related Skin Types, FIRST (www.scalyskin.org).

Vesicobullous Eruptions

Blistering eruptions in the neonatal period may be caused by infections, congenital diseases, or infiltrative processes or may be of unknown origin.[25] The proper management of infants with such eruptions depends on knowledge of the cause of the disease or, when this is not possible, on an understanding of the pathogenesis of the type of blister encountered. Establishing the pathogenesis often depends on determining at which level within the skin the blister has occurred.

Blister sites may be intraepidermal or subepidermal. In the epidermis, the blister can be very high (subcorneal), midepidermal, or basal. The midepidermal blister may be formed by primary separation of intercellular contacts (e.g., acantholysis), by secondary edematous disruption of intercellular contacts (e.g., spongiosis), or by intracellular injury as seen in patients with viral infections. The diagnosis of a blistering disease usually requires a family history, an immediate past history of the infant and mother, laboratory studies to exclude infectious agents, evaluation of the infant's general state of health, consideration of the morphologic characteristics of the eruption, and often a biopsy of the affected skin. The biopsy should be obtained from a fresh, typical, small lesion and should include some surrounding skin.

BACTERIAL AND YEAST INFECTIONS

Colonization of the newborn's skin begins at birth. The organisms acquired at birth are similar to those found on adult skin.[8] *Staphylococcus epidermidis* (coagulase negative) predominates, but diphtheroids, streptococci, and coliform bacteria also are found. The newborn skin affords an excellent culture medium for *Staphylococcus aureus;* the groin and other skin sites may become colonized before the umbilicus. *Candida albicans* usually is not found on normal skin but may be present in the oral mucosa or in the diaper area as a result of fecal contamination (see Chapter 39).

SEPSIS

Bacterial sepsis in the neonate can manifest with vesicles, pustules, or bullae. The most common cause of sepsis manifesting with pustules is *S. aureus.* Group B *Streptococcus agalactiae* is a leading cause of neonatal sepsis, pneumonia, and meningitis, but it rarely manifests in the neonate at birth with vesicles, pustules, or bullae.[31] In an attempt to decrease the frequency of Group B *Streptococcus agalactiae* infection, maternal prophylaxis is recommended before delivery under certain conditions. Other occasional causes of pustules and sepsis in neonates include *Listeria monocytogenes, Haemophilus influenzae, Pseudomonas aeruginosa,* and *Klebsiella pneumoniae.*

STAPHYLOCOCCAL INFECTION AND IMPETIGO

Superficial skin infections due to *S. aureus* range from localized bullous impetigo to generalized cutaneous involvement with systemic illness. In contrast to congenital blistering diseases, which are often present at birth, skin infections with *S. aureus* usually develop after the first few days of life.[26,52] They may be bullous, crusted, or pustular. Typical lesions are small vesicles or pustules or large, fragile bullae filled with clear, turbid, or purulent fluid. They rupture easily, leaving red, moist, denuded areas, often with a superficial varnish-like crust. Although they may develop anywhere on the body, the blisters and pustules commonly occur in the diaper area and on axillae and periumbilical skin. When the epidermis is shed in large sheets, staphylococcal scalded skin syndrome should be suspected. The diagnosis is made by Gram stain and culture of the blister fluid, which can distinguish this eruption from streptococcal impetigo and other bullous disorders of the neonatal period. Blood cultures should be obtained from affected infants before initiating systemic antibiotic therapy, even if the infants are usually otherwise well. Contacts and nursery personnel should be investigated for a source of the infectious organism. The infant should be placed in isolation and observed carefully for early signs of sepsis. A high index of suspicion during examination of other infants in the nursery is the most effective means of preventing epidemic spread of this infection (see Chapter 39).

Compresses of physiologic saline solution and systemic antibiotics to cover the principal etiologic possibilities are indicated until culture results are available. Fluid and electrolyte replacement therapy may be required if the disease is extensive. Recovery is usually complete in several days, and there is no residual scarring.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

The staphylococcal scalded skin syndrome is a severe bullous eruption heralded by a bright erythema that resembles a scald. The erythema begins on the face and gradually spreads downward to involve the remainder of the skin, with accentuation in the flexural areas. The level of cleavage is superficial, occurring in the granular layer of the epidermis; the bullae, therefore, are flaccid and easily ruptured and rapidly progress into areas of denudation. The infant is febrile, irritable, and has marked cutaneous tenderness. The face, neck, and flexural areas are the first to be eroded (Fig. 52-8A). The entire upper epidermis may be shed from the limb like a glove (see Fig. 52-8B). Crusting around the mouth and eyes results in a typical facies. Conjunctivitis is common, as is hyperemia of the mucous membranes, but oral ulcerations do not occur. Infants with a milder form of the disease display a scarlatiniform eruption, with perioral and flexural desquamation but without bullae or denudation. Like staphylococcal

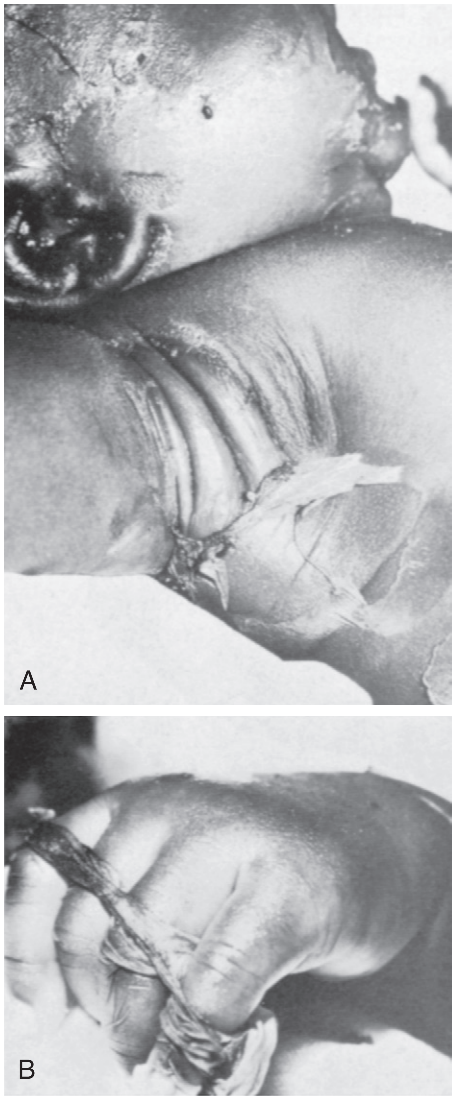

Figure 52–8. Staphylococcal scalded skin syndrome. **A**, Extensive denudation in the axilla. **B**, Glovelike shedding of the superficial portion of the epidermis.

pyoderma, staphylococcal scalded skin syndrome is rarely seen at birth, with most neonatal cases presenting between 3 and 7 days of life.

The infecting organism in scalded skin syndrome is *S. aureus*, usually a group 2 phage type, although other phage types occasionally have been incriminated. These organisms produce an exotoxin (i.e., exfoliatin) that has proteolytic activity on desmoglein-1, a molecule found within the desmosomes of keratinocytes, that is responsible for the cutaneous manifestations.[34,52] Two major serotypes of the toxin, A and B, cause bullous impetigo and scalded skin syndrome. In cases of the former, the toxin produces exfoliation and blisters locally, whereas in the latter, the toxin circulates systemically with widespread epidermal necrolysis. Histologic examination of the skin demonstrates separation at the level of the granular layer with cell death and acantholysis; there is a striking absence of inflammatory infiltrate. Because intact bullae are sterile, cultures should be obtained from the nasopharynx, conjunctival sac, umbilicus, abnormal skin, blood, urine, and any other suspected focus of infection that might have provided a portal of entry for the organism.

Treatment consists of prompt systemic administration of penicillinase-resistant semisynthetic penicillin and fluid and electrolyte replacement if necessary. Flaky desquamation occurs during the healing phase. Scarring never occurs because the blister cleavage plane is intraepidermal.

STREPTOCOCCAL INFECTION

Infection with group B β-hemolytic streptococci rarely produces skin lesions, but vesicles, bullae, and erosions have been reported. Epidemics of group A streptococcal infection may occur primarily as omphalitis or, rarely, as isolated pustules. Infants with these infections should be treated aggressively with parenteral antibiotics because sepsis, cellulitis, meningitis, and pneumonia have been documented.

MISCELLANEOUS BACTERIAL INFECTIONS

Listeria, *Haemophilus*, and congenital syphilis may also be the cause of cutaneous vesicles or pustules in the newborn. *P. aeruginosa* may cause large hemorrhagic bullae in the neonatal period. This is usually a nosocomial infection seen primarily in infants with low birthweights. The skin lesions result from septicemia and hematogenous spread to the skin. In older children, the pustules and bullae are in the perineal region, but in the newborn, they may occur anywhere. The lesions rapidly ulcerate, leaving "punched-out" erosions. Diagnosis can be made by performing a Gram stain or culture of the bullae or the base of the ulcer. Parenteral antibiotics should be administered immediately; the prognosis is usually poor.

VIRAL LESIONS

One of the most important causes of blistering in the neonatal period is herpes simplex infection.[25] Frequently, an inconspicuous cutaneous lesion heralds severe systemic infection. The infection may be acquired in utero or perinatally. Intrauterine herpes simplex infection typically manifests with vesicles at birth or within 24 hours. The vesicular eruption may be widespread or even bullous, resembling epidermolysis bullosa. Rarely, congenital scars may be present. Additional findings include low birthweight, microcephaly, chorioretinitis, and neurologic changes. Neonatal herpes simplex may be limited to the skin, eyes, and mouth or may be disseminated with multiple organ involvement. The cutaneous lesions usually develop at 6 to 13 days of life, concurrent with or after nonspecific systemic signs and symptoms. Typically, the lesions are 1- to 3-mm vesicles usually occurring on the scalp or face. Vesicles may be present on the torso or buttocks, especially in a breech delivery. Rarely, pustules, erosions, or oral ulcerations may be the only cutaneous findings. In infants with cutaneous lesions suggestive of herpes simplex infection, antiviral therapy should be administered immediately, and the diagnosis can be confirmed by scraping the base of a fresh vesicle and staining with Giemsa or Wright stain (i.e., Tzanck test), immunofluorescence, or viral culture. Current recommendations for prevention of herpes simplex infections include caesarean section for women with active lesions or prodromal symptoms consistent with herpes. Vaccines against herpes simplex virus 2 have been of low efficacy. High-dose, prolonged acyclovir therapy remains the treatment of choice for neonatal herpes simplex infections.

Primary varicella may occur in the newborn if the mother has a primary varicella infection in the last 3 weeks of the pregnancy. The onset of this diffuse vesicular disease is 5 to 10 days of age, and the lesions may be numerous and monomorphic, given the infant's impaired ability to mount an immune response. Varicella zoster has also been reported in the neonatal period in infants of mothers who have had primary varicella during pregnancy. These vesicles are unilateral and occur in a dermatomal distribution. The vesicles of varicella, herpes zoster, and herpes simplex have a similar histologic pattern (see Chapter 39, Part 4), with cleavage in the midepidermis. Acantholysis and marked destruction of individual cells result in the ballooning type of degeneration characteristic of viral vesicles.

Table 52-5 lists common viral infections of the neonate that may appear with cutaneous manifestations. Diagnostic workup and characteristic histology and laboratory findings are given.

CANDIDIASIS

(See also Chapter 39, Part 3)

Candida species are commensal organisms commonly found in the gastrointestinal and female genital tracts. Roughly one third of health care workers in neonatal intensive care units test positive for *Candida* on routine surveillance cultures, and up to 40% of women are culture positive for *Candida* at the time of delivery. Candidiasis in the first 4 weeks of life is usually benign and is localized most often to the oral cavity (thrush) or the diaper area. If maternal vaginal organisms are acquired during the birth process, the infant may manifest symptomatic mouth lesions or become an intestinal carrier. Fecal contamination is the usual source of the organism in candidal dermatitis. Paronychial lesions also may occur, particularly in thumb-sucking infants. The lesions of thrush are detectable as creamy white patches of friable material on the buccal mucosa, gums, palate, and tongue. Early cutaneous lesions consist of erythematous papules and vesicopustules that become confluent, forming a moist, erosive, scaly dermatitis surrounded by satellite pustules. Candidiasis in the preterm infant may manifest as a different erythema.

Rarely, cutaneous candidiasis may be congenital as a result of ascending infection from a vaginal or cervical focus. Risk factors for this type of candidiasis include a foreign body in the uterus or cervix, premature birth, and a history of vaginal candidiasis. Affected infants usually have a widespread eruption with pustules on the palms and soles and, occasionally, nail dystrophy (Fig. 52-9). Distinctive yellow-white papules on the umbilical cord and placenta represent *Candida* granulomas. *C. albicans* may be demonstrable on histologic examination of these tissues and may be cultured from the amniotic fluid.

Although candidal infection is usually localized to skin, infants who weigh less than 1500 g are also at risk for systemic infections. In addition to birthweight less than 1500 g, risk factors for disseminated candidiasis include central line placement, respiratory therapy, antibiotic use, and parenteral nutrition. Marked differences in the rate of systemic candidiasis among centers has been described. Use of cefotaxime appears to increase the incidence.[2a]

In the chronic mucocutaneous or granulomatous forms of candidiasis (rare in the neonatal period), the scalp, lips, hands, and nails may be sites of chronically scaling, heaped-up lesions. These two forms of infection often are associated with a defect in the immune response, multiple endocrinopathies, or both.

The diagnosis is aided by identification of budding yeast spores on Gram stain or of spores and pseudohyphae on a potassium hydroxide preparation. Growth of the organism is rapid on Sabouraud dextrose or Mycosel agar.

Treatment depends on the extent of involvement. Topical antifungal agents from the imidazole group are the most effective for disease limited to the skin. Systemic administration of amphotericin B, 5-fluorocytosine, or an imidazole should be reserved for patients with evidence of disseminated disease. Fluconazole or itraconazole for disseminated candidiasis in the neonate with low birthweight may provide an alternative to systemic amphotericin B and 5-fluorocytosine.

HEREDITARY BLISTERING DISEASES

Epidermolysis Bullosa

Epidermolysis bullosa (EB) refers to a group of heterogeneous diseases that are characterized by simplex (intraepidermal), junctional (lucidolytic), or dystrophic (subepidermal) subtypes with blisters produced by minor degrees of trauma and heat.[5] These disorders are the result of a variety of inherited defects of the proteins that maintain skin integrity. The clinical phenotypes vary according to the region within the skin that the defective protein is expressed and at what depth the resultant blister occurs. Traditionally, EB has been classified by clinical phenotype, histologic and ultrastructural features (i.e., depth of blister), and inheritance pattern. Advances have made molecular analysis of the defect available as well.[15] At present, 10 distinct genes are linked etiologically to EB subtypes. First trimester prenatal diagnosis is available, and preimplantation genetic testing is possible in select centers.[15]

The clinical features may be quite variable in the newborn period, making it difficult to identify the specific subtype of EB and the expected prognosis. The subtypes of EB that may manifest in the neonatal period are listed in Table 52-6. Some subtypes of EB are severe, life-threatening diseases, and others are mild and do not manifest until adolescence. Friction-induced blistering of the skin is the classic feature of EB. If there is friction in utero, the baby may be born with large areas of denuded skin. In the past, this was referred to as Bart syndrome, but further delineation of the molecular defects has shown that several subtypes of EB can result in this clinical picture (see Table 52-6). More frequently, the birth process or minor perinatal trauma causes blistering of the skin. The more severe, dystrophic, recessive form of EB is associated with low birthweight.

Junctional EB of the Herlitz type deserves special mention because it is almost always present at birth and is a very severe form of EB. The epidermis loosens after minimal trauma, and bullae of various sizes are formed anywhere on

TABLE 52–5 Diagnosis of Selected Neonatal Viral Infection with Cutaneous Manifestations

Virus	Culture	Histology of Skin Lesion	PCR	Serology
CMV	Widely available; reliable, culture urine, saliva; shell vial technique yields results in 48-72 hours	Skin lesions are due to extramedullary hematopoiesis, not due to viral replication in skin	Highly sensitive; well studied in plasma as a marker of disseminated CMV infection in immune compromised hosts	Rising antibody titer to CMV IgG is a sensitive and specific test; CMV IgM is not a sensitive test in the newborn
Enterovirus	Available in reference laboratories; culture vesicular lesions, pharynx (during the acute phase of illness), and stool (up to 6 weeks following the illness)	Nonspecific	Highly sensitive; not widely available	Not usually helpful, as no class specific antibody response can be measured and type-specific serologies are not widely available
HIV	Available; not highly sensitive in newborn, repeat culture at 1 month of age	Nonspecific	Sensitive means of diagnosis, can be repeated at 1-2 months, 4-6 months, and at 18 months of age	Nonspecific passive maternal antibody present at birth persists
HSV	Widely available; reliable; culture skin lesions	Tzanck stain of epithelial cells from the bottom of a vesicle: specific for herpesviruses HSV and VZV; direct fluorescent antibody stains for HSV 1 or 2	Highly sensitive; best studied on CSF (sensitivity of skin lesions not well studied)	Rising antibody titer to HSV IgG is a sensitive and specific test; HSV IgM is not a sensitive test in the newborn
Rubella	Not usually available; culture pharynx	Skin lesions are due to extramedullary hematopoiesis, not due to viral replication in skin	Not well studied	Rising antibody titer to rubella IgG is a sensitive and specific test; rubella IgM is not a sensitive test in the newborn. Compare mother's prenatal serology test results with those at the time of birth
VZV	Available in many reference laboratories; culture skin lesions	Tzanck stain (see above): specific Stains available for VZV	Highly sensitive, but not well studied on skin lesions; not widely available	Rising antibody titer to VZV IgG is a sensitive and specific test; VZV IgM is not a sensitive test in the newborn

CMV, cytomegalovirus; CSF, cerebrospinal fluid; HIV, human immunodeficiency virus; HSV, herpes simplex virus; IgG, IgM, immunoglobulin G, M; PCR, polymerase chain reaction; prn, as required; VZV, varicella-zoster virus.
Adapted from SF Friedlander, JS Bradley: Viral Infections. In Eichenfield LF et al, editors: *Textbook of neonatal dermatology,* Philadelphia, 2008, Saunders, p 193.

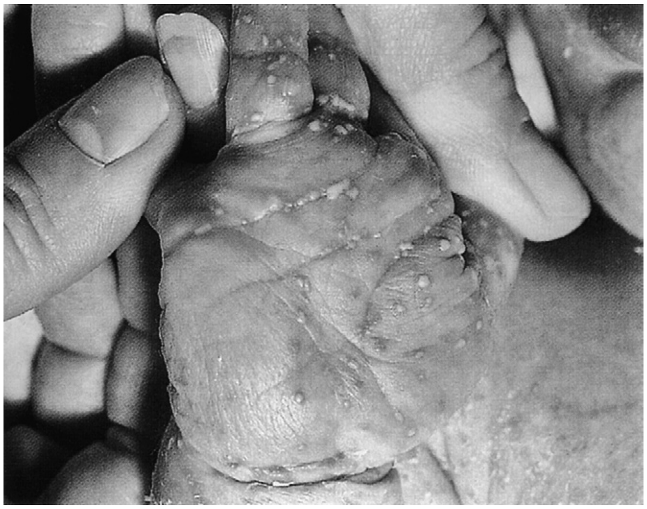

Figure 52–9. Congenital candidiasis with typical circumscribed lesions on the palm.

the body (Fig. 52-10). The nails are frequently involved. Oral and anal lesions also occur. Many lesions heal spontaneously, but large bullae may fail to heal and result in moist, chronic vegetative lesions consisting of exuberant granulation tissue. There may be significant loss of electrolytes and protein through these erosions.

Blisters and erosions may also be severe and widespread in the Dowling-Meara subtype of EB simplex. This subtype may be distinguished clinically by the characteristic grouping of the blisters and the formation of milia. In all forms of EB, blisters may be elicited readily by gentle rubbing (Nikolsky sign). Mild trauma can result in a blister within a few minutes to hours, and the resulting fresh lesions may be used for histopathologic examination. Treatment is aimed at protecting the skin from trauma and secondary infection.

Scarring or dystrophic EB has recessive and dominant forms. In contrast to the simplex and junctional groups (except the Dowling-Meara type), milia may mark the site of healed blisters. In the severe form of recessive dystrophic EB, hemorrhagic erosions and blisters may be present at birth, especially on the feet. The toe and finger lesions may heal with fusion of digits and loss of nails, resulting in a characteristic mitten-like envelope of the hands. As the fingers fuse (this usually takes several years), the hands and arms become fixed in a flexed position, and contractures develop. Repeated episodes of blistering, infection, and scar formation lead to severe deformities, loss of hair, mucosal scarring, dysphagia, anemia, and retarded physical and sexual development. Visceral amyloidosis, hyperglobulinemic purpura, clotting abnormalities, and squamous cell carcinoma are associated with this severe, life-limiting disease.

The dominant forms of scarring EB usually are less severe than the major recessive type. Lesions may be generalized or localized at birth, or they may appear later and may be limited to the elbows, knees, hands, feet, and sacrum (see Fig. 52-10B). Oral involvement is common but is usually not severe. Nails may be lost, but deforming scars and contractures occur infrequently. Red plaques rather than blisters may result from injury. The lesions heal with soft, wrinkled scars. Pigmentary change and milia may be formed at old blister sites. The general health is usually unimpaired.

The initial diagnosis of EB is a clinical one, and other disorders that cause blistering, particularly infections, should be excluded. Clinical differentiation of EB subtypes is difficult or impossible; for this reason, all infants with the diagnosis should undergo skin biopsy to obtain a more precise diagnosis. Light microscopy may be helpful in determining the level of cleavage, but results can often be difficult to interpret. Immunofluorescence mapping of biopsied EB skin specimens is the currently recommended primary laboratory method of diagnosing EB subtypes.[15] If available, electron microscopy, immunofluorescence mapping, and DNA mutational analysis are used simultaneously to confirm the diagnosis.

Unfortunately, there is no effective cure for infants with EB. Treatment is aimed at protecting the skin from trauma and secondary infection. Management strategies for treating neonatal EB are given in Box 52-3. Recent progress using gene-based and cell-based molecular therapies holds hope for future approaches that may cure or ameliorate specific EB subtypes.[54]

Incontinentia Pigmenti

Incontinentia pigmenti (IP) is a rare, X-linked, dominant genodermatosis that affects the skin, skeletal system, eyes, and central nervous system (CNS).[11] IP results from mutations in the *NEMO* gene that inhibit expression of NF-kappa B essential modulator. Molecular analysis of the *NEMO* gene is now possible, as is analysis of skewed X-chromosome inactivation, although the diagnosis of IP is typically based on characteristic clinical findings.[11] Almost all patients are female, but affected male patients have been reported and are thought to represent genetic mosaicism or Klinefelter syndrome.

The cutaneous lesions usually are present at birth and have three morphologic stages. Initially, there are inflammatory, clear-to-yellow vesicles, which are arranged linearly and appear in crops during the first few weeks of life. The vesicular lesions occur on the trunk and limbs and vary in density from few to many. They sometimes appear distinctly pustular or crusted. Gray-to-brown, warty excrescences develop next, usually on the distal limbs. The third stage consists of patterned, macular hyperpigmentation in streaks and whorls on the trunk and extremities. Occasionally, pigmentation may accompany some of the early lesions. A fourth stage consisting of atrophic, hypopigmented streaks has been described in some individuals. Nail hypoplasia, areas of alopecia, and ocular and skeletal abnormalities also may be detected. There is often peripheral eosinophilia during the vesicular phase of the disease. The diagnosis should be considered when inflammatory vesicles arranged in lines are seen in a newborn female infant. Delayed dentition, partial anodontia, and abnormalities of the CNS can occur but may not be apparent during the neonatal period. Biopsy of a small blister demonstrates a subcorneal vesicle filled with eosinophils. The differential diagnosis includes herpes simplex infection and other blistering diseases. The clinical evolution of the cutaneous process, the demonstration of a large number of eosinophils in the skin lesions and peripheral blood, and the presence of pigment-laden macrophages in the upper dermis of end-stage lesions establish the diagnosis. No specific therapy is required for the skin lesions; if inflammation becomes excessive during the vesicular phase, treatment with compresses and topical

TABLE 52–6 Clinical Presentation and Diagnosis of Selected Epidermolysis Bullosa Subtypes in the Neonatal Period

EB Subtype (Usual Inheritance)	CLINICAL FEATURES		Protein System	Prognosis
	Cutaneous	Extracutaneous		
Dystrophic EB, dominant (AD)	Mild to moderate blistering (may be more severe in newborn period), milia, scarring, CLAS, nail dystrophy	Mild mucosal blistering	Type VII collagen	Good, improvement with age
Dystrophic EB, recessive (Hallopeau-Siemens) (AR)	Severe blistering, milia, scarring, CLAS	Severe mucosal blistering GI involvement common Urological involvement	Type VII collagen	Disability, reduced life expectancy
EB simplex, Dowling-Meara (AD)	Moderate to severe blistering, starts generalized, then grouped (herpetiform), milia, nail dystrophy, shedding, CLAS	Mild mucosal blistering	Keratin 5 or 14	Good, improvement with age
EB simplex, Koebner (AD)	Mild to moderate blistering, often generalized, rare scarring, milia, CLAS	Occasional mucosal blistering	Keratin 5 or 14	Good, some patients improve after puberty
EB simplex, Weber-Cockayne (AD)	Mild blistering, often localized, sometimes in first 24 mo, but often not until later infancy or childhood, rare scarring, milia	Rare mucosal involvement	Keratin 5 or 14	Good
Junctional, Herlitz type (AR)	Severe generalized blistering which heals poorly, granulation tissue, scarring, nail dystrophy, CLAS	Severe mucosal blistering GI involvement common Laryngeal involvement with airway obstruction Urologic involvement	Laminin 5 ($\alpha3/\beta3/\gamma2$ chain)	Death mostly within first 2 years of life
Junctional EB, non-Herlitz type (AR)	Moderate blistering, atrophic scars, nail dystrophy	Mild mucosal blistering Enamel hypoplasia	Laminin 5 or type XVII collagen	Good
Pyloric atresia-junctional EB (AR)	Severe blistering, CLAS	Pyloric atresia, urologic involvement: ureterovesicular obstruction, hydronephrosis	$\alpha6/\beta4$ Integrin	Often early death, in some patients good prognosis

AD, autosomal dominant; AR, autosomal recessive; CLAS, congenital localized absence of skin; EB, epidermolysis bullosa; GI, gastrointestinal.
Adapted from Bruckner AL: Epidermolysis bullosa. In Eichenfield LF et al, editors: *Textbook of neonatal dermatology*, Philadelphia, 2008, Saunders, p 159.

steroids may be helpful. An ophthalmologic examination is indicated for all infants with this disorder.

Zinc Deficiency

Zinc deficiency occurs in the genetic disorder acrodermatitis enteropathica and as an acquired condition attributable to inadequate zinc intake.[40] Acrodermatitis enteropathica, a rare disorder, is inherited as an autosomal recessive trait. The gene for this disorder has been localized to chromosomal region 8q24.3 and encodes for a member of the ZIP family of metal transporters.[40] It is characterized by acute vesicobullous, eczematous, and psoriasiform eruptions around the eyes, mouth, and genitals and on the peripheral extremities (Fig. 52-11). Secondary infection with *C. albicans* is a common complication. The onset may be as early as the third week of life, but more frequently it occurs later in infancy. Failure to thrive, hair loss, ocular changes, marked irritability, and paronychial lesions are additional features of the disease. Chronic, severe, and intractable diarrhea is the most serious manifestation and may be life threatening. The disease is caused by a defect in zinc absorption or transport, and extremely low plasma zinc levels have been documented in untreated patients. The exact nature of the defect is unknown. Oral zinc sulfate is the treatment of choice and has induced dramatic remissions of the disease.

A similar eruption has been observed in premature infants maintained on total parenteral nutrition inadequately supplemented with zinc. These infants suffer from relative zinc

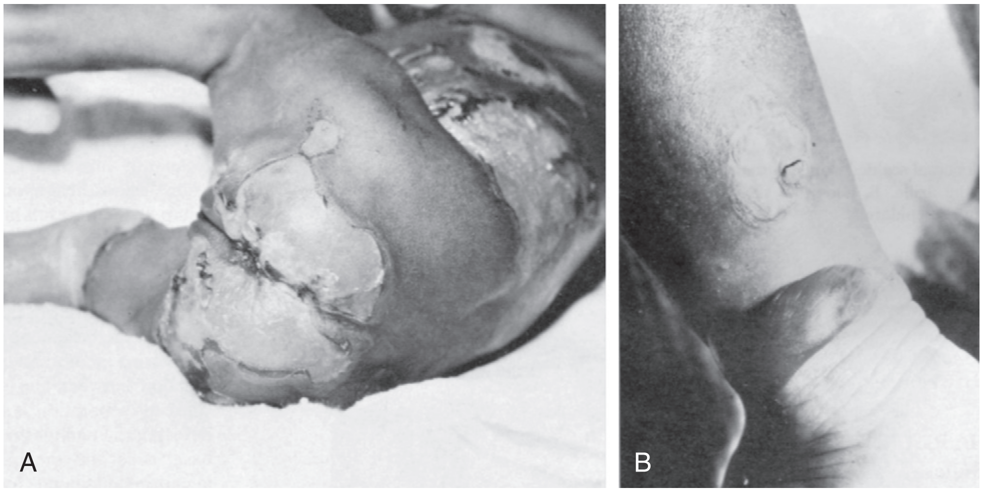

Figure 52–10. **A**, Denudation as a result of blistering in an infant with junctional epidermolysis bullosa. **B**, Large intact bulla and ruptured bulla on the leg of an infant with dominant dystrophic epidermolysis bullosa.

deficiency caused by high metabolic demands. Premature and term infants receiving breast milk with low levels of zinc and infants with malabsorption syndrome or cystic fibrosis also have developed symptomatic zinc deficiency. Maternal zinc deficiency in pregnancy may result in fetal malformation, growth restriction, prematurity, postmaturity, and perinatal death.

Pigmentary Abnormalities

The melanocyte system of the newborn skin usually is not at maximum functional maturity. As a result, all babies regardless of racial pigmentation may look pink or tan at birth. Within the first few weeks, pigmentation becomes more evident because melanin production has been stimulated by exposure to light.

DIFFUSE HYPERPIGMENTATION

The intensity of pigmentation must be considered in light of the infant's genetic and racial background. Diffuse hyperpigmentation in the newborn is unusual. It may be caused by a gene whose main effect is on the melanocyte, by a hereditary disease that has secondary pigmentary consequences, by endocrinopathy, by a nutritional disorder, or by hepatic disease.[53] Although in such cases hyperpigmentation may be described as diffuse, it may be accentuated in certain areas such as the face, over bony prominences, or in the flexural creases.

LOCALIZED HYPERPIGMENTATION

Café-au-Lait Macules

Café-au-lait spots are pigmented macules that may be present in the newborn infant, and they are light brown in whites and dark brown in African Americans. Whereas lesions are seen in 24% to 36% of older children, most commonly on the trunk, they are present in 0.3% to 18% of newborns, usually over the buttocks.[16] Lesions vary with ethnicity and race. Lesions that are larger than 0.5 cm in diameter and more than six in number, especially when accompanied by "freckling" in the flexures, strongly suggest neurofibromatosis. The axillary freckles really represent tiny café-au-lait macules. Café-au-lait spots are usually the first cutaneous lesions to appear in a patient with neurofibromatosis, but additional genetic and clinical investigations may be required to establish a diagnosis. For example, small, pigmented spots (i.e., Lisch nodules) may be detected on the iris by slit-lamp examination in most patients older than the age of 6 years with classic neurofibromatosis. Patients with tuberous sclerosis also may have café-au-lait spots that are identical in appearance to those of neurofibromatosis, but they are usually accompanied by white macules, which are discussed later.

McCune-Albright Syndrome

In a patient with McCune-Albright syndrome (i.e., polyostotic bone dysplasia, café-au-lait spots, and multiple endocrine disorders), the pigmented patches may be solitary or multiple, unilateral, elongated, and large (>10 cm) and often have a ragged, irregular border. It is caused by a mutation of the *GNAS1* gene leading to increased stimulation of the adenylate cyclase system.[16]

Congenital Melanocytic Nevi

Congenital nevi represent nested proliferations of melanocytes that are present at birth or appear in the first months of life. Small nevi (<1.5 cm) are seen in 1% to 2% of newborns, intermediate nevi (1.5 to 20 cm) in 0.6%, and large nevi (see below) in less than 0.02%.[16] Small lesions (as opposed to giant pigmented nevi) are flat and light to dark brown, often with variegated color or speckling and an accentuated epidermal surface ridge pattern. These lesions vary in site, size, and number but are most often solitary. Histologically, they are characterized by the presence of nevus cells in the dermis, and most have nevus cells extending into the deeper dermis, fat, and perivascular, periappendageal, and perineural sites. There is no clearcut evidence that the small congenital nevus is a premalignant lesion, and conservative management consisting of serial observation with photographic documentation may be appropriate.[16] Decisions about surgical excision are based on location, size of lesion and expected surgical result. Laser treatment may lighten small nevi but does not completely remove the melanocytes, and its use for this indication is controversial.

BOX 52–3 Management of Epidermolysis Bullosa in the Neonatal Period

MINIMIZE TRAUMA TO SKIN AND PROMOTE COMFORT

Use gentle handling and reduce friction.

When possible, use wrapping or suturing instead of taping when applying instruments or monitors; if taping is necessary, leave probes in place.

Use oral sucrose with dressing changes.

Administer acetaminophen or opiate agonist for extreme discomfort.

PROVIDE IDEAL (MOIST) WOUND-HEALING ENVIRONMENT

Open and drain tense vesicles with sterile needle.

Perform gentle daily débridement of crust in bathtub.

Apply emollients and nonstick primary dressing.

Protect wound and secure primary dressing with secondary dressing such as gauze wrap and stockinette or Coban tape.

Tape dressing to itself and not to skin.

PREVENT SEPSIS AND BACTERIAL SUPERINFECTION OF WOUNDS

Observe wounds for purulence and foul smell.

Monitor colonization with weekly surveillance cultures.

Apply topical antibiotics combined with emollient on open erosions to control colonization.

Cover gram-positive organisms with intravenous antibiotics if there are signs or symptoms of sepsis.

MAXIMIZE NUTRITION WITH MINIMAL TRAUMA FOR OPTIMAL WOUND HEALING AND GROWTH

Breast feed if there is mild oral involvement and the infant can feed through pain.

If not, have mother pump breast milk, and bottle feed with high-flow nipple or drip feeds.

Add breast milk fortifier to maximize caloric intake.

For formula-fed baby, use high-calorie formulas.

Obtain dietary consultation and follow up to ascertain energy needs and how to meet them.

MONITOR FOR EXTRACUTANEOUS COMPLICATIONS

Eye: Request ophthalmology consultation for redness or photophobia.

Gastrointestinal: If oral involvement, watch for feeding intolerance.

Genitourinary: Look for gross hematuria, meatal narrowing in boys; consider urinary source if infant is febrile.

Polyhydramnios: Look for pyloric atresia.

Respiratory: Monitor airway for hoarse cry or stridor as a sign of laryngeal involvement.

PROVIDE PSYCHOSOCIAL SUPPORT

Provide counseling regarding prognosis once diagnosis is known. Emphasize unpredictability of course even when subtype is known.

Discuss usual short-term complications in general terms.

Provide access to peer counseling through Internet sites and local chapters of national patient advocacy groups.

Expanded from AL Bruckner: Epidermolysis bullosa. In Eichenfield LF et al, editors: *Textbook of neonatal dermatology*, Philadelphia, 2008, Saunders, p 159.

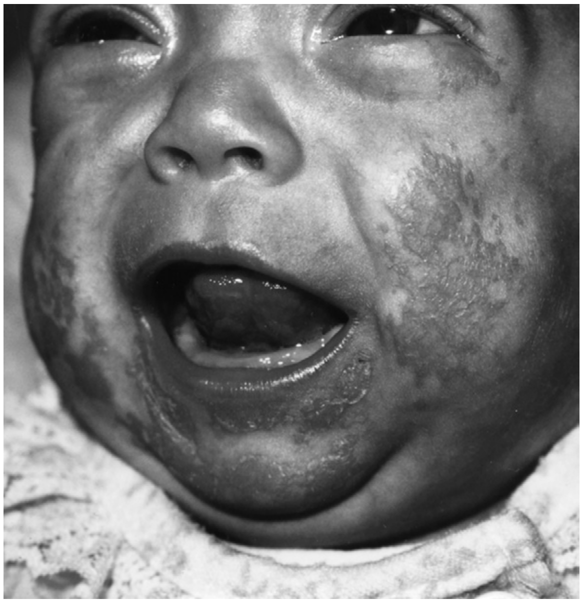

Figure 52–11. Recalcitrant perioral eruption in a premature, breast-fed infant with zinc deficiency. The eruption cleared rapidly with oral zinc replacement.

Congenital Giant Melanocytic Nevi

The giant (>20 cm) nevus (Fig. 52-12) is the most important of the congenital melanocytic (pigmented) nevi.[16] The lifetime risk of malignant transformation and melanoma is estimated to be 6% to 8%.[16] The onset of melanoma in utero has been reported. These nevi may occupy 15% to 35% of the body surface, most commonly involving the trunk. The pigmentation often is variegated from light brown to black. The

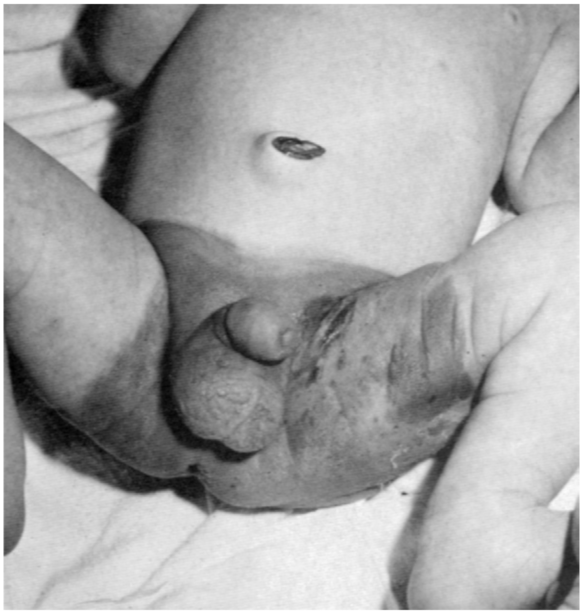

Figure 52–12. Giant pigmented nevus on the bathing trunk area.

affected skin may be smooth, nodular, or leathery in consistency. Prominent hypertrichosis is often present. Almost invariably, numerous satellite nevi coexist elsewhere on the body. Leptomeningeal melanocytosis has been documented in some of these patients, and this complication may manifest as seizures.

Because of the significant incidence of malignant degeneration, the hideous deformity, and the intense pruritus that may accompany them, it is desirable, when feasible, to excise these lesions surgically as soon as possible. Lasers, dermabrasion, and tissue expansion techniques have been used in conjunction with surgical excision for removal and cosmesis of large lesions.[17]

Peutz-Jeghers Syndrome

The cutaneous lesions of the Peutz-Jeghers syndrome may be present at birth or develop soon thereafter. They consist of brown to blue-black macules, somewhat darker than freckles, that develop around the nose and mouth. The lips and oral mucosa often are involved, as are the hands, fingertips, and toes. Macular hyperpigmentation is the only visible sign of this autosomal dominant disorder until adolescence, when the patient begins to suffer from attacks of intussusception, bleeding, and subsequent anemia secondary to coexisting small bowel polyposis.

Xeroderma Pigmentosum

Xeroderma pigmentosum is transmitted by an autosomal recessive gene and results in marked hypersensitivity to ultraviolet light. The skin is normal at birth, but changes develop soon thereafter depending upon the degree of exposure to ultraviolet light. The infant develops erythema, speckled hyperpigmentation, atrophy, actinic keratoses, and all known types of cutaneous premalignant and malignant lesions. The outcome is often fatal by the second decade of life as a result of metastatic disease. The underlying abnormality in most cases is a deficiency in an endonuclease that is responsible for the repair of DNA damaged by ultraviolet light. Approximately 20% of patients have neurologic problems. Protection from ultraviolet light exposure is mandatory to prevent skin damage and tumor development. Prenatal diagnosis of xeroderma pigmentosum is possible using autoradiography to measure DNA repair of amniotic fluid cells or chorionic villi fibroblasts.

Postinflammatory Hyperpigmentation

Hyperpigmentation may result secondarily from any inflammatory process in the skin and may have many causes, including primary irritant dermatitis, infectious processes, panniculitis, and hereditary diseases such as EB. The hyperpigmentation may result from enhanced melanosome production, larger melanin deposits in basal cells, greater numbers of keratinocytes, an increase in the thickness of the stratum corneum, or deposits of melanin in dermal melanophages. Hyperpigmentation usually fades gradually over weeks to months without treatment although a low-potency topical steroid may decrease residual inflammation.

Blue Nevus

Occasionally, a blue nevus (so called because of its Prussian blue color), or dermal melanocytoma, may be present at birth. It usually is a 1- to 3-cm, oval, dome-shaped, black-blue tumor found on the upper half of the body. It grows very slowly and has little tendency to become malignant but may be difficult to differentiate clinically from vascular tumors. Excisional biopsy is diagnostic and curative.

HYPOPIGMENTATION

Diffuse or localized reduction or absence of cutaneous pigment in the neonate may be caused by a heritable or developmental disorder or may result from a nutritional disease or postinflammatory change.[6] Decrease in cutaneous melanin may be caused by an absence or destruction of melanocytes or by a defect in one of four biologic processes: formation of melanosomes, formation of melanin, transfer of melanosomes to keratinocytes, and transport of melanosomes by keratinocytes.

Albinism

Albinism (e.g., complete albinism, oculocutaneous albinism), which occurs in all races, has an incidence of 1 case per 17,000 persons in the United States. The phenotypic picture is caused by an autosomal recessive gene. Several forms of this disorder have been delineated.[46] The affected infant usually has markedly reduced skin pigment, yellow or white hair, pink pupils, gray irides, photophobia, and cutaneous photosensitivity. Melanocytic nevi can be present in patients with albinism, and the nevi may or may not be pigmented. In African Americans, the skin may be tan, the hair may have a yellow or orange color, and freckles can appear on exposure to light. The usual eye findings are photophobia, nystagmus, and a central scotoma with reduced visual acuity. Other associated abnormalities reported in certain types of albinism are small stature and coagulation disorders.

The biochemical defect responsible for oculocutaneous albinism type 1 is a deficiency of tyrosinase, the enzyme responsible for converting tyrosine to dopa, an early step in the formulation of melanin. The range of tyrosinase deficiency correlates well with the spectrum of color seen in affected individuals. Structurally, the melanosomes appear to be normal. In oculocutaneous albinism type 2, however, mutations in the P gene affect function of a melanosomal protein. Molecular analyses of the tyrosinase and P genes are necessary for precise diagnosis. Treatment in all cases is aimed at protection from ultraviolet light because early actinic keratoses and squamous cell carcinoma are common occurrences in these patients.

Partial Albinism

Partial albinism (i.e., piebaldism) is an inherited disease caused by mutations of the autosomal dominant *KIT* gene coding for the tyrosine kinase transmembrane cellular receptor for mast/stem cell growth factor, a critical factor for melanoblast migration and function. This leads to defective cell proliferation and melanocyte migration during embryogenesis.[6] This condition is present at birth but may not be evident in fair-skinned infants because of a lack of contrast in skin color. In piebaldism, the hair and skin are affected. The amelanotic areas usually involve the midline frontal scalp (i.e., widow's peak), resulting in the characteristic white forelock, forehead to the base of the nose, chin, thorax, trunk, back midarm, and midleg. There are normal islands of pigment within the amelanotic areas, and the distribution pattern is fairly constant. Examination of an affected area by electron microscopy shows an absence of melanocytes or melanocytes with markedly deformed melanosomes. Repigmentation does not take place. The differential diagnosis may include vitiligo, achromic nevus, nevus anemicus, and the hypomelanotic macules of tuberous sclerosis.

Phenylketonuria

Phenylketonuria, caused by an absence of phenylalanine hydroxylase, results in a variety of neurologic and cutaneous abnormalities, which include mental retardation, seizures, diffuse hypopigmentation, eczema, and photosensitivity (see Chapter 50).

Chédiak-Higashi Syndrome

The Chédiak-Higashi syndrome is a rare, fatal disorder resulting from mutations in the autosomal recessive lysosomal trafficking regulator (*LYST*) gene.[28] The clinical features include diffuse to moderate reduction in cutaneous and ocular pigment, photophobia, hepatosplenomegaly, and recalcitrant, recurrent infections. Seizures and progressive neurologic deficits have occurred in some patients in early childhood. The leukocytes and other cells contain large granules, and this finding has its parallel in the melanocyte, which produces giant melanosomes. These abnormal granules are unable to discharge their lysosomal and peroxidative enzymes into phagocytic vacuoles. The diagnosis can be made by the characteristic family history, physical findings, laboratory demonstration of abnormal leukocytes and melanosomes, and the usual course, which leads to death in childhood. Death results from a lymphoma-like process (i.e., accelerated phase) or infection. Treatment is palliative, but bone marrow transplantation has been used successfully to reverse the immunologic defects.

Waardenburg Syndrome

Waardenburg syndrome is an auditory-pigmentary syndrome inherited as an autosomal-dominant condition secondary to mutations in the *PAX3* gene controlling neural crest differentiation.[6] The most constant features are lateral displacement of the inner canthi, a prominently broad nasal root, confluent eyebrows, variegation of pigment in the iris (i.e., heterochromia iridis) and fundus, congenital deafness, a white forelock, and cutaneous hypochromia. The clinical picture is quite striking, and the diagnosis usually is not difficult. Although usually limited to small areas, the hypopigmentation may be severe and extensive enough to resemble that of piebaldism.

Nevus Anemicus

Nevus anemicus is a congenital vascular anomaly that appears as a permanently pale, mottled lesion that occurs most often on the trunk. The lesions appear hypopigmented but contain normal amounts of pigment. The nevus is best characterized as a pharmacologic abnormality rather than an anatomic one. Pallor results from increased local reactivity to catecholamines, which results in vasoconstriction and subsequent pallor. When rubbed, the lesion does not redden like the surrounding skin. There is no effective treatment.

Nevus Achromicus

Present at birth but often not visible until 1 to 2 years of age, nevus achromicus is usually a unilateral, hypopigmented, irregularly shaped lesion. The hypopigmented area is quite uniform in color, and, in contrast to nevus anemicus, the vessels within it react normally to rubbing. The melanocytes in the affected epidermis seem to function poorly or not at all.

White Macules in Tuberous Sclerosis

Tuberous sclerosis is a condition with multisystem involvement characterized by hamartomas, often in association with mental retardation and seizures. Between 50% and 90% of infants with tuberous sclerosis have white macules that become apparent at birth or soon thereafter.[33,49] In fair-skinned infants, the hypopigmented areas may be demonstrated more easily by examining the skin with a Wood lamp. These lesions are often leaflet shaped, are variable in number, and occur more frequently on the trunk and buttocks. The melanocytes within areas of macular hypopigmentation contain poorly pigmented melanosomes. A single, hypopigmented macule in an infant without other features of tuberous sclerosis does not warrant extensive investigation.

Hemangiomas and Vascular Malformations

Vascular lesions are a common problem in the neonate.[2,13,29] They can be divided into two major categories: hemangiomas and vascular malformations (Table 52-7). Hemangiomas are benign tumors of the vascular endothelium characterized by a proliferative and an involutional phase. Malformations are developmental defects derived from the capillary, venous, arterial, or lymphatic vessels. These lesions remain relatively static, and growth is commensurate with growth of the child.

HEMANGIOMAS

Hemangiomas are the most common soft tissue tumors of infancy, occurring in approximately 1% to 3% of newborns and up to 12% by the end of the first year, although reported incidences vary.[2,29] True hemangiomas are characterized by a growth phase and marked by endothelial proliferation and hypercellularity and by an involutional phase. Hemangiomas are clinically heterogeneous, with their appearance dictated by the depth, location, and stage of evolution. In the newborn, hemangiomas may originate as a pale macule with threadlike telangiectases (Fig. 52-13A). As the tumor proliferates, it assumes its most recognizable form—a bright red, slightly elevated, noncompressible plaque (see Fig. 52-13B). Hemangiomas that lie deeper in the skin are soft, warm masses with a slightly bluish discoloration (see Fig. 52-13C). Frequently, hemangiomas have superficial and deep components. They range from a few millimeters to several centimeters in diameter and usually are solitary, but up to 20% of infants have multiple lesions. A female predominance (3:1) and an increased incidence among premature infants have been documented. Approximately 55% of these tumors are present at birth, and the remainder develop in the first weeks of life. Rarely, they may appear as fully grown tumors at birth, and these “congenital hemangiomas” resolve rapidly, often leaving pronounced atrophic skin changes in their wake. Generally, superficial hemangiomas have reached their maximum size by 6 to 8 months, but deep hemangiomas may proliferate for 12 to 14 months or, rarely, up to 2 years.

Despite the benign nature of most cutaneous hemangiomas, a significant number cause functional compromise or

TABLE 52–7 Major Differences between Hemangiomas and Vascular Malformations

	Hemangiomas	Vascular Malformations*
Clinical	Variably visible at birth Subsequent rapid growth Slow, spontaneous involution	Usually visible at birth (AVMs may be quiescent) Growth proportionate to the skin's growth (or slow progression); present lifelong
Sex ratio (F:M)	3:1 to 5:1 and 7:1 in severe cases	1:1
Pathology	Proliferating stage: hyperplasia of endothelial cells and SMC-actin+ cells Multilaminated basement membrane Higher mast cell content in involution	Flat endothelium Thin basement membrane Often irregularly attenuated walls (VM, LM)
Radiology	Fast-flow lesion on Doppler sonography Tumoral mass with flow voids on MR Lobular tumor on arteriogram	Slow flow (CM, LM, VM) or fast flow (AVM) on Doppler ultrasonography MR: Hypersignal on T2 when slow flow (LM, VM); flow voids on T1 and T2 when fast flow (AVM) Arteriography of AVM demonstrates AV shunting
Bone changes	Rarely mass effect with distortion but no invasion	*Slow-flow* VM: distortion of bones, thinning, underdevelopment *Slow-flow* CM: hypertrophy *Slow-flow* LM: distortion, hypertrophy, and invasion of bones *High-flow* AVM: destruction, rarely extensive lytic lesions *Combined malformations* (e.g., slow-flow [CVLM = Klippel-Trenaunay syndrome] or fast-flow [CAVM = Parkes-Weber syndrome]): overgrowth of limb bones, gigantism
Immunohisto-chemistry on tissue samples	*Proliferating hemangioma*: high expression of PCNA, type IV collagenase, VEGF, urokinase, and bFGF *Involuting hemangioma*: high TIMP-1, high bFGF	Lack expression of PCNA, type IV collagenase, urokinase, VEGF, and bFGF One familial (rare) form of VM linked to a mutated gene on 9p (*VMCM1*)
Hematology	No coagulopathy (Kasabach-Merritt syndrome is a complication of other vascular tumors of infancy, e.g., kaposiform hemangioendothelioma and tufted angioma, with a LM component)	Slow-flow VM or LM or LVM may have an associated LIC with risk of bleeding (DIC).

*Capillary (C), venous (V), lymphatic (L), arterial (A), and arteriovenous (AV), pure or complex-combined malformation (M).
bFGF, basic fibroblast growth factor; DIC, disseminated intravascular coagulation; LIC, localized intravascular coagulopathy; MR, magnetic resonance; PCNA, proliferating cell nuclear antigen; SMC, smooth muscle cell; VEGF, vascular endothelial growth factor.

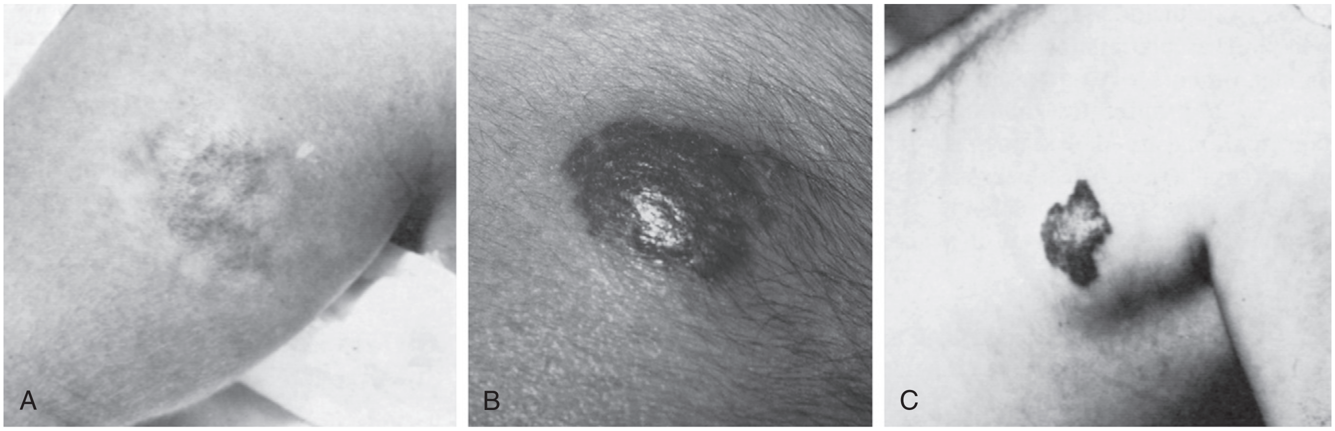

Figure 52–13. **A**, Hemangioma on the thigh of a preterm infant. Areas of pallor, often an initial sign, are still present. **B**, Superficial, bright red hemangioma. **C**, Mixed superficial and deep hemangioma on the back.

permanent disfigurement. Approximately 20% to 40% of patients have residual skin changes; nasal tip, lip, and parotid hemangiomas are notorious for slow involution, and very large superficial facial hemangiomas often leave disfiguring scarring. Ulceration, the most frequent complication, can be excruciatingly painful and carries the risk of infection, hemorrhage, and scarring. Occasionally, hemangiomas manifest as congenital ulcerations with only a very small rim of typical hemangioma, making the diagnosis difficult.

The Kasabach-Merritt phenomenon, a complication of a rapidly enlarging vascular lesion, is characterized by hemolytic anemia, thrombocytopenia, and coagulopathy. The differences between the vascular lesions that induce this phenomenon and classic infantile hemangiomas have been emphasized. These massive tumors are usually a deep red-blue color, are firm, grow rapidly, have no sex predilection, tend to proliferate for a longer period (2 to 5 years), and have a different histologic pattern. Most patients with Kasabach-Merritt phenomenon do not have typical hemangiomas but rather have other proliferative vascular tumors, usually kaposiform hemangioendotheliomas or tufted angiomas.[13] The Kasabach-Merritt phenomenon requires aggressive, often multimodal treatment, such as transcutaneous arterial embolization, and carries a significant mortality rate (see also Chapter 46).

Periorbital hemangiomas pose considerable risk to vision and should be carefully monitored. Hemangiomas involving the ear may decrease auditory conduction, which ultimately may cause speech delay. Multiple cutaneous (i.e., diffuse hemangiomatosis) and large facial hemangiomas may be associated with visceral hemangiomas. Subglottic hemangiomas manifest with hoarseness and stridor, and progression to respiratory failure may be rapid. Approximately 50% of infants with subglottic hemangiomas have associated cutaneous hemangiomas, and "noisy breathing" by an infant with a cutaneous hemangioma involving the chin, lips, mandibular region, and neck warrants direct visualization of the airway. Sixty percent of young infants with extensive facial hemangiomas in the "beard" distribution develop symptomatic airway hemangiomas.

Extensive cervicofacial hemangiomas may be associated with multiple anomalies, including vascular malformations, known as PHACES syndrome (*p*osterior fossa malformation, *h*emangiomas, *a*rterial anomalies, *c*ardiac anomalies, *e*ye abnormalities, *s*ternal anomalies). This syndrome has a marked female predominance (9:1) and is thought to represent a developmental field defect that occurs during the 8th to 10th weeks of gestation. Lumbosacral hemangiomas may be markers for occult spinal dysraphism and anorectal and urogenital anomalies. Imaging of the spine is indicated in all patients with midline hemangiomas in this region.

Most hemangiomas require "active nonintervention" coupled with a careful discussion of the natural history of the lesions and photographic documentation of involution.[13] Ulceration is the most common complication and should be treated promptly. Oral systemic corticosteroids are the mainstay of therapy. Recombinant interferon-α, an inhibitor of angiogenesis, has been used successfully in treating life-threatening hemangiomas, but response is slow, and a particularly worrisome side effect, spastic diplegia, has been reported in as many as 20% of infants. Pulsed dye laser treatment has been approved by the U.S. Food and Drug Administration, but its use is limited by concerns of efficacy and potential scarring.[10]

BLUE-RUBBER BLEB NEVUS SYNDROME

The blue-rubber bleb nevus syndrome is a rare disorder consisting of multiple venous malformations of the skin and bowel.[13] Cutaneous lesions sometimes are present at birth, and their appearance is characteristic as the descriptive name of this syndrome suggests. The lesions are blue to purple, rubbery, compressible protuberances that vary from a few millimeters to 3 to 4 cm in diameter. They are diffusely distributed over the body's surface and may be sparse or may number in the hundreds. Gastrointestinal lesions are common in the small bowel but also may involve the colon. Occasionally, lesions in the liver, spleen, and CNS have been observed. Severe anemia may result from recurrent episodes of gastrointestinal bleeding. Neither the skin nor the bowel lesions regress spontaneously. Surgery is sometimes palliative, but it is frequently impossible to resect all of the affected bowel.

Vascular malformations also have been reported as a congenital feature of Bannayan-Riley-Ruvalcaba syndrome. Maffucci syndrome (i.e., vascular malformations and dyschondroplasia) and Gorham disease (i.e., vascular malformations and disappearing bones) usually are not apparent in the neonatal period.

PORT-WINE STAIN

Port-wine stains (i.e., nevus flammeus), which represent capillary malformations, are almost always present at birth and should be considered permanent developmental defects.[13] These lesions may be only a few millimeters in diameter or may cover extensive areas, occasionally affecting up to half the body's surface. They do not proliferate after birth; any apparent increase in size is caused by growth of the child. A port-wine stain may be localized to any body surface, but facial lesions are the most common. Port-wine stains usually are sharply demarcated and flat in infancy but with time develop a pebbly or slightly thickened surface. Color ranges from pale pink to purple.

The most successful treatment modality in use is the pulsed dye laser, which is effective in fading these lesions, although only 15% to 20% clear completely.[13] Some studies report treatment is more effective if undertaken in infancy, whereas others have found no difference.

Most port-wine stains occur as isolated defects and do not indicate involvement of other organs, but they occasionally may be a clue to the presence of defects in the eye or certain vascular syndromes. Children with facial port-wine stains involving skin innervated by the V1 or V2 branches of the trigeminal nerve should have a thorough ophthalmologic examination in infancy.

STURGE-WEBER SYNDROME

Sturge-Weber syndrome (i.e., encephalofacial angiomatosis) consists of a facial port-wine stain, usually in the cutaneous distribution of the first branch of the trigeminal nerve, a leptomeningeal venous malformation, mental retardation, seizures, hemiparesis contralateral to the facial lesions, and ipsilateral intracortical calcification.[13] Ocular manifestations are frequent and include buphthalmos, glaucoma, angioma of the choroid, hemianoptic defects, and optic atrophy (see Chapter 53). Roentgenograms of the skull of the older child show pathognomonic "tramline," double-contoured calcifications in the cerebral cortex on the same side as the port-wine stain. Magnetic resonance imaging with gadolinium enhancement is the diagnostic modality of choice. Electroencephalography may demonstrate unilateral depression of cortical activity, with or without spike discharges.

The prognosis depends on the extent of cerebral involvement, rapidity of progression, and response to treatment. Anticonvulsant therapy and neurosurgical procedures have been of value in treating some patients.

KLIPPEL-TRÉNAUNAY-WEBER SYNDROME

Klippel-Trénaunay-Weber syndrome is characterized by a cutaneous vascular malformation (usually a port-wine stain), venous varicosities, and overgrowth of the bony structures and soft tissues of the affected part.[13] The vascular lesions are apparent at birth. Some patients with this syndrome also have venous malformations, lymphatic anomalies, and arteriovenous shunts. Complications include severe edema, phlebitis, thrombosis, ulceration of the affected area, and vascular malformations involving the viscera. The prognosis depends on the extent of involvement, which can be assessed by peripheral vascular studies and scans. Management includes careful orthopedic assessment of limb growth. Surgery may be effective in treating severe limb hypertrophy in some patients. Compressive clothing (Jobst garments) may be helpful, but proper fitting is difficult in infants with rapid growth.

Port-wine stains also occur with moderate frequency in Beckwith-Wiedemann syndrome (i.e., macroglossia, omphalocele, macrosomia, and cytomegaly of the fetal adrenal gland) (see Chapter 49, Part 1), Robert syndrome, and Cobb syndrome (i.e., cutaneomeningospinal angiomatosis).

CONGENITAL LYMPHATIC MALFORMATIONS

Lymphangiomas are hamartomatous malformations composed of dilated lymph channels that are lined by normal lymphatic endothelium.[4,13] They may be superficial or deep and often are associated with anomalies of the regional lymphatic vessels. In addition to surgery, recent trials using intralesional injection of sclerosing agents have proven effective.

Milroy's primary congenital lymphedema is present at birth and often affects the dorsal aspects of the feet. The condition arises from a congenital dysgenesis of the lymphatic microvessels possibly secondary to mutation in the *VEGFR3* gene. This condition is rarely associated with significant complications.

Lymphangioma circumscriptum is probably the most common type of lymphangioma and may be present at birth or may appear in early childhood. Areas of predilection are the oral mucosa, the proximal limbs, and the flexures (Fig. 52-14). This malformation consists of clustered, small, thick-walled vesicles resembling frog spawn; it is often skin colored but may have a red or purple cast because of the presence of blood mixed with lymph in the vesicles. Treatment is excision, with attention to removal of the deep component of the lesion. Large lesions may require full-thickness skin grafting. Recurrence has been observed even with full-thickness grafts.

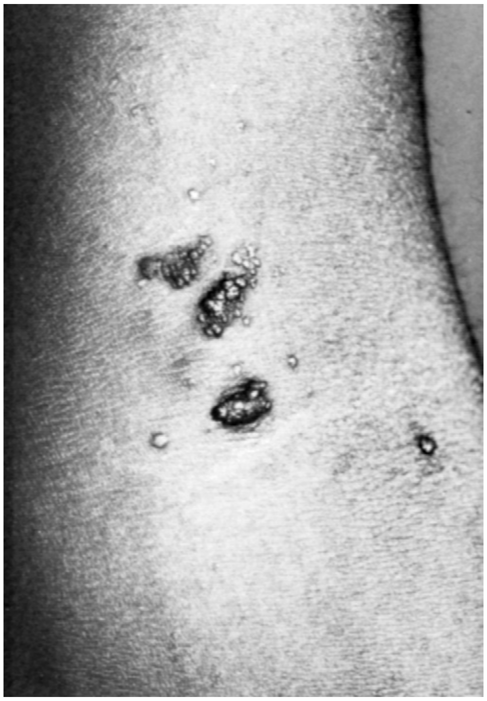

Figure 52–14. Lymphangioma circumscriptum on the upper arm.

Simple lymphangioma appears in infancy as a solitary, skin-colored, dermal or subcutaneous nodule. After trauma, it may exude serous fluid. Occasionally, it has been associated with more extensive lymphatic involvement. Uncomplicated lesions can be removed by simple excision.

Deep lymphangiomas are more diffuse and consist of large, cystic dilations of lymphatics in the dermis, subcutaneous tissue, and intermuscular septa. Surgery is impractical in most cases.

CYSTIC HYGROMA

Cystic hygroma is a benign, multilocular tumor usually found in the neck region. The tumors tend to increase in size and should be treated by surgical excision.

Epidermal Nevi

Epidermal nevi are a group of lesions that are found commonly in the neonatal period. Most of them consist of an overgrowth of keratinocytes and often have an identifiable differentiation toward one of the appendages normally found in skin.[47] They vary considerably in their size, clinical appearance, histologic characteristics, and evolution, depending on their topographic location. Lesions occurring in sites normally rich in sebaceous glands (e.g., the scalp) may look like sebaceous nevi, whereas others, found in areas where the epidermis is thick (e.g., the elbow), look primarily warty.

The most common type of epidermal nevus in the newborn infant is the sebaceus nevus, a hairless, papillomatous, yellow or pink, slightly elevated plaque on the scalp, forehead, or face.[47] These lesions have a characteristic oval or lancet shape. Because a significant incidence of basal cell epitheliomas occurs in these lesions after puberty, they should be removed surgically.

The treatment of large, verrucous epidermal nevi is generally unsatisfactory. The only effective treatment is removal of the lesion together with its underlying dermis. This is only possible in localized lesions, and treatment should be delayed beyond the neonatal period because these lesions may extend over a period of years.

Patients with epidermal nevi may have associated abnormalities, but there are three well-defined entities: Proteus syndrome, CHILD syndrome (i.e., *c*ongenital *h*emidysplasia with *i*chthyosiform nevus and *l*imb *d*efects), and nevus sebaceous syndrome.[47]

Inflammatory Diseases of the Skin

Several inflammatory skin conditions may occur in the neonate. Irritant contact dermatitis, seborrheic dermatitis, and atopic dermatitis are the most frequently encountered.[3] and may be difficult to distinguish because their clinical features have a significant degree of overlap. There are four phases of cutaneous inflammation, any one of which may persist as the dominant feature, depending on the age of the patient, the local physiologic characteristics of the skin involved, and the persistence of the underlying cause. The initial stage is erythema, which proceeds to microvesicle formation, weeping, or oozing. The epidermal response to the injurious process then causes a burst of rapid epidermal mitotic activity that leads to scaling. Lichenification (i.e., thickening of the skin) and pigmentary disturbances supervene. In the young infant, the first three stages predominate; lichenification, which results from scratching or rubbing, is not seen.

IRRITANT CONTACT DERMATITIS

Primary irritant contact dermatitis (as opposed to allergic contact dermatitis) is probably the most common exogenous cause of dermatitis in the newborn. The distribution of the eruption varies somewhat, depending on the precipitating agent. Saliva may be irritating to the face and fecal excretions to the buttocks. Detergent bubble bath, antiseptic proprietary agents, and soap zealously used to clean the perianal area may cause acute eczematous diaper dermatitis, which may become generalized.[56] Obtaining precise information about what has been applied to the skin and how it has been applied is imperative in making an accurate diagnosis. Diaper dermatitis is usually initiated from an irritant but can have a variety of causes. Its proper management should include obtaining a culture for bacteria and yeast, the discontinuance of all ointments containing irritants, and conservative treatment for 1 or 2 weeks. If no improvement follows, a skin biopsy may be indicated.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is characterized by greasy scaling associated with patchy redness, fissuring, and occasional weeping, usually involving the scalp, ears, axillary, and perineal folds (Fig. 52-15). There is controversy about whether seborrheic dermatitis is a distinct entity or presages the advent of atopic dermatitis. Some infants never progress beyond the seborrheic phase of the dermatitis, which in its classic form rarely is seen in the first month. Cradle cap is probably a minor variant of seborrheic dermatitis. Treatment of seborrheic dermatitis consists of a mild shampoo containing selenium zinc with gentle brushing to remove scales. A low-potency topical corticosteroid or antifungal shampoo such as ketoconazole may be efficacious. The usual course of seborrheic dermatitis is one of rapid regression after 1 or 2 weeks of therapy. Occasionally, a seborrheic-like process may affect the entire body, resulting in full-blown exfoliative dermatitis, which has been called *Leiner disease* when associated with failure to thrive and chronic diarrhea.

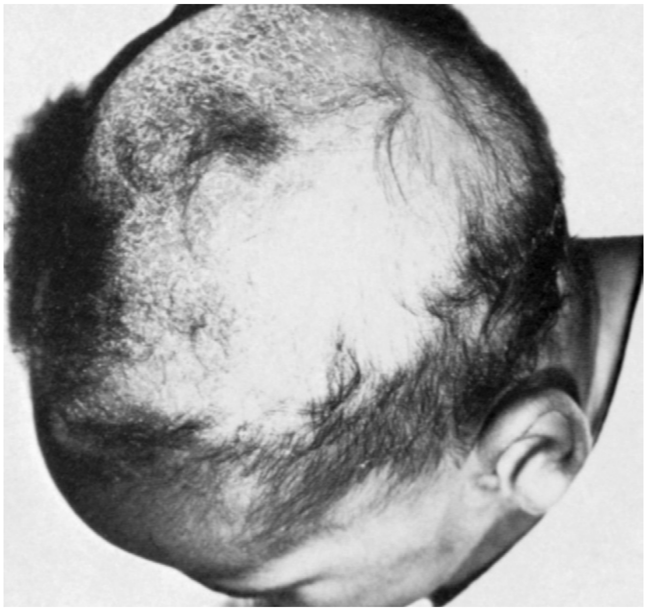

Figure 52–15. Seborrheic dermatitis on the scalp of an infant that resulted in partial alopecia.

ATOPIC DERMATITIS

Atopic dermatitis generally does not appear in the immediate newborn period. Onset during the first year of life occurs in 60% of affected individuals, but most commonly it occurs between 3 and 6 months.[3] Atopic dermatitis is characterized by red, scaling patches and plaques on the face, particularly the cheeks, and on the extensor surfaces of the extremities. Like seborrheic dermatitis, the eruption may be generalized. Infants with atopic dermatitis are often agitated because of the severe pruritus. Clear diagnostic criteria have been established for the diagnosis of atopic dermatitis and include pruritus, chronicity, typical family history, and distribution. Skin barrier dysfunction is prominent in atopic dermatitis, along with an abnormal stratum corneum, increased turnover time, and elevated transepidermal water loss with overproduction of specific cytokines, notably interleukin (IL)-4 and IL-13. Elevated levels of IL-13 in cord blood are associated with increased atopic symptoms during early childhood.[35] Several studies have demonstrated that certain dietary and environmental interventions in the first months of life may decrease the incidence of atopic dermatitis in babies at risk for the disease. These include exclusive breast feeding for 3 months, delayed weaning beyond 6 months, and elimination of house dust mites and passive smoking.

Dermatitis resembling atopic dermatitis may be a feature of a number of systemic conditions, including ataxia-telangiectasia, X-linked agammaglobulinemia, phenylketonuria, gluten-sensitive enteropathy, and long-arm 18 deletion syndrome.[3] Many patients with hypohidrotic ectodermal dysplasia have an eczematous eruption identical to that of atopic dermatitis. Purpura is a frequent additional component of eczema, particularly in Langerhans cell histiocytosis (LCH) and Wiskott-Aldrich syndrome.

Atopic children have a much higher prevalence of staphylococcal colonization than nonatopic children.[3] When bacterial or fungal infection exists, appropriate antibacterial or antifungal therapy is indicated based on the results of culture and sensitivity studies. Weeping lesions should be treated with compresses or bathing in tepid water; protective ointments such as simple zinc oxide paste should be applied after each diaper change; soiled ointments and pastes should be removed with mineral oil. A more extensive eruption may be treated for short periods with a 1% to 2.5% hydrocortisone ointment. A scaly eruption in the scalp may be treated by frequent washing with a shampoo that contains zinc pyrithione or salicylic acid. Bathing should be done in tepid water containing water-dispersible oil. Infants with diffuse dermatitis lose heat readily and are intolerant of even mild changes in environmental temperature or humidity. Humidification of the bedroom in winter and air conditioning in summer is desirable. The efficacy of dietary management of atopic eczema remains controversial.

Subcutaneous and Infiltrative Dermatoses

JUVENILE XANTHOGRANULOMA

Juvenile xanthogranuloma is a benign, non-LCH characterized by solitary or multiple yellow-red cutaneous papules that may enlarge to become nodules.[47] One fifth of infants with juvenile xanthogranuloma are affected at birth, and two thirds have onset of lesions before 6 months of age. There is no predilection for race or sex, and no familial predisposition has been observed for this self-limited disorder, which usually remains confined to the skin. The skin lesions often are restricted to the head, neck, and upper trunk. Involution occasionally leaves a flat atrophic pigmented scar. Serum lipid levels are normal, but histologically, the lesions result from an infiltrate of fat-laden histiocytes, giant cells, and mixed inflammatory cells. Ocular lesions are the most frequent complication (although involvement of other organs may occur rarely) and may result in tumors, unilateral glaucoma, hyphema, uveitis, heterochromia iridis, and proptosis. Ophthalmologic consultation is required for management of the ocular lesions, but the best treatment for the skin lesions is expectant observation.

Several unusual variants may occur, such as giant juvenile xanthogranuloma or bony involvement. There is an increased incidence of juvenile xanthogranulomas among patients with neurofibromatosis type 1, and they may be markers for acute granulocytic leukemia in these patients.

MASTOCYTOSIS

Mast cell disease, or mastocytosis, refers to a spectrum of conditions characterized by mast cell infiltration of the skin or other organs.[48] It may be present at birth and result in a solitary mast cell tumor, a disseminated maculopapular or nodular eruption, a bullous eruption, or a diffuse infiltration of the skin.[25] The disseminated form may be complicated by mast cell infiltrates in internal organs. The diagnosis can be made by demonstration of excessive numbers of mast cells on skin biopsy. Measurement of urinary histamine metabolites or the major urinary metabolite or prostaglandin D_2 can help quantify the total body mast cell load, particularly during systemic symptoms, and may have prognostic significance.

The most common form seen at birth is the firm, solitary mast cell tumor. These tumors usually are ovoid, are pink or tan, and rarely exceed 6 cm in diameter. The lesions are conspicuous by their tendency to form wheals when rubbed (Darier sign) and, in the newborn, to develop overlying blisters. Solitary lesions involute spontaneously within months to years. Urticaria pigmentosa manifests as numerous pink-brown 1- to 2-cm, oval macules and papules. The lesions are usually located centrally and often develop later in infancy. Systemic manifestations of histamine release, such as flushing attacks or generalized pruritus, are caused by mechanical or chemical factors or overheating. Treatment is usually unnecessary, but in symptomatic patients, distressing cutaneous symptoms such as dermatographism and pruritus may be helped with oral antihistamines. Hot water bathing and vigorous toweling must be avoided, as must histamine releasers such as codeine, morphine and its derivatives, aspirin, alcohol-containing elixirs, and certain anesthetics. The prognosis for most infants with mastocytosis, even in its disseminated cutaneous form, is good. The genetics of this condition are unclear. A few pedigrees have been reported with multiple affected family members.

LANGERHANS CELL HISTIOCYTOSIS

LCH is a rare proliferative disorder with skin involvement in 50% of affected children. In 10%, skin is the only affected site, and it is often the first site of involvement. LCH can manifest at anytime from birth to adulthood. Commonly affected areas include the scalp, followed by the skin flexures, including the perineum, but any part of the skin can be affected, including the palms, soles, and nails. The appearance of skin LCH is very diverse with scaly papules, vesicles, nodules, eroded nodules, tumors, and purple plaques.[48] The majority of infants with LCH show multisystem involvement. Single or multifocal bone lesions with lymph node involvement are common, and intracranial disease may manifest with exophthalmos or diabetes insipidus. Definitive diagnosis is made on skin biopsy. CD1a-positive Langerhans cells are seen infiltrating the skin. Langerhans granules (Birbeck granules) within the cells on electron microscopy are also a common finding. LCH with multisystem organ involvement is most often a rapidly fatal disease. Various chemotherapeutic regimens have been used for treatment.

Hashimoto and colleagues described a pure cutaneous form of LCH that occurs only in the neonate or infant.[18] The characteristic features of this congenital, self-healing reticulosis are skin lesions in an otherwise well infant, a histopathology demonstrating Langerhans cell infiltrate, and spontaneous involution of the skin lesions. The pathology is said to be typical with histiocytic infiltration limited to the dermis, sparing of the epidermis, and so-called myelin-dense bodies seen on electron microscopy.

More recently, this entity is considered a mild form of LCH, as progression to severe LCH has now been reported in children who initially met the above criteria. The diagnosis of purely cutaneous LCH should only be made after several years of follow-up.

SUBCUTANEOUS FAT NECROSIS AND SCLEREMA NEONATORUM

Subcutaneous fat necrosis and sclerema neonatorum occur within the first 3 months of life. They may be variants of the same basic disorder of fat metabolism.[7] Sclerema neonatorum usually affects the preterm or debilitated newborn. It manifests by diffuse hardening of the subcutaneous tissue, resulting in a tight, smooth skin that feels bound to the underlying structures. The skin is cold and stony hard. The joints become immobile and the face masklike. The affected infant also may have multiple congenital anomalies or may develop sepsis, pneumonia, or severe gastroenteritis. CNS abnormalities, autonomic dysfunction, and respiratory distress frequently complicate the course of the disease. The mortality rate is high, but the cutaneous changes rarely last longer than 2 weeks if the infant survives. For infants who are severely ill, exchange transfusion and systemic administration of steroids have been used, but their efficacy has not been confirmed.

The lesions of subcutaneous fat necrosis are localized and sharply circumscribed (see Chapters 28 and 49, Part 2). They appear 1 to 4 weeks after delivery as small nodules or large plaques and are found on the cheeks, buttocks, back, arms, and thighs. The affected fat is firm, and the overlying skin may appear reddish or violaceous and occasionally has the texture of orange peel. Histologically, there is a granulomatous reaction in the fat, with formation of needle-shaped crystals, foreign body giant cells, fibroblasts, lymphocytes, and histiocytes. Resolution of the lesion results in fibrosis. Possible precipitating causes of fat necrosis include cold exposure, trauma, asphyxia, and peripheral circulatory collapse. The lesions usually resolve in several weeks or months without complications. Serum calcium levels should be monitored since subcutaneous fat necrosis has been associated with hypercalcemia and its complications.

COLD PANNICULITIS

Cold-induced fat necrosis of the cheeks may occur in the small infant. Warm, red, indurated plaques appear a few hours to a few days after the episode of cold exposure.[7] The lesions resolve in 2 to 3 weeks. An ice cube applied to normal skin of these patients for 2 minutes results in formation of a nodule in 3 to 72 hours at the site of application. The induced nodule parallels the course of the spontaneous lesion. The histologic picture is one of perivascular inflammation and aggregation of lipids from the rupture of fat cells. Postinflammatory hyperpigmentation may mark the site of a healed nodule.

Miscellaneous Congenital Diseases Affecting the Skin

A multitude of hereditary diseases affect the skin. Some of the congenital diseases with prominent cutaneous findings are reviewed here.

APLASIA CUTIS CONGENITA

Aplasia cutis congenita is a rare group of disorders of varying etiology characterized by the focal absence of skin at birth.[32] Most frequently, the lesions are on the scalp in the midline, but other areas of the body may be affected, including the trunk and extremities. Several theories have been proposed to explain the pathogenesis of this disorder, but a single unifying mechanism seems unlikely. Possible etiologies include incomplete closure of the neural tube, localized vascular insufficiency, amniotic membrane adhesions, teratogenic agents, and intrauterine infections. Large scalp defects are associated with trisomy 13. The diagnosis is usually based on clinical findings. Increased levels of acetylcholinesterase and α-fetoprotein have been reported in the amniotic fluid of mothers with children with aplasia cutis. Prognosis and management should be individualized based on the size, location, and presence or absence of ulceration or underlying bony defect. Management strategies include simple observation, prevention of infection in the case of ulceration, and surgical excision or skin grafting in the case of large defects.

CUTIS LAXA

Cutis laxa (i.e., generalized elastolysis) is a heterogeneous group of congenital and acquired disorders and is a feature of several malformation syndromes.[32] There are three major forms of congenital cutis laxa: one inherited as an autosomal dominant trait and two inherited in an autosomal recessive fashion. In all forms of the disease, affected infants have diminished resilience of the skin, which hangs in folds, resulting in a bloodhound appearance. The joints are not hypermobile, and there is no tendency to increased bruising as in Ehlers-Danlos syndrome (EDS). Elastic tissue may be greatly diminished in the dermis and is of poor quality. The collagen has normal tensile properties. In the autosomal dominant form, there are few complications, and the life span is usually normal. In the generalized recessive type of cutis laxa, elastic fibers elsewhere in the body are defective, resulting in inguinal, diaphragmatic, and ventral hernias; rectal prolapse; diverticula of the gastrointestinal and genitourinary tracts; pulmonary emphysema; and aortic aneurysms. Cardiorespiratory complications may cause death during childhood. The other recessive form, cutis laxa with retarded growth and skeletal dysplasia, is typified by intrauterine growth restriction, congenital dislocation of the hips, and a peculiar facies with frontal bossing, antimongoloid slanting of the palpebral fissures, and widening of the fontanelles. Unlike other loose skin syndromes, persons with cutis laxa have almost normal wound healing. These children are good candidates for cosmetic plastic surgery and its attendant psychological benefits.[32]

EHLERS-DANLOS SYNDROME

EDS is a group of inherited connective tissue disorders with the common features of hyperextensible skin, joint laxity, and soft tissue fragility (Fig. 52-16).[43] Bleeding episodes and cardiovascular complications are characteristic of some forms of the disorder. The skin of patients with EDS is hyperextensible when stretched but snaps back with

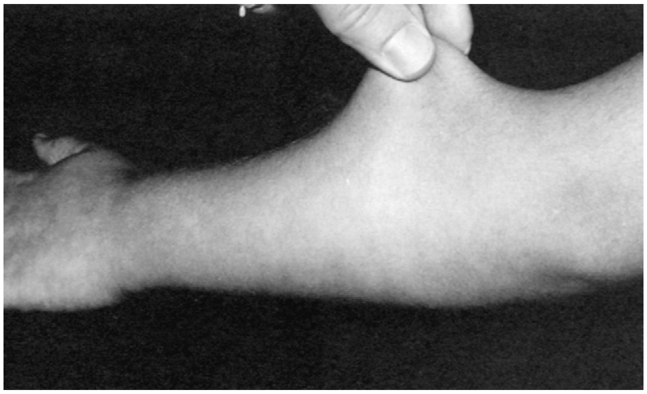

Figure 52–16. Skin hyperextensibility in Ehlers-Danlos syndrome.

normal resiliency, in contrast to the skin of patients with cutis laxa, which hangs in redundant folds. Cutis laxa is not associated with hypermobile joints or easy bruisability. In some forms, the skin also is excessively fragile. Associated findings may include short stature, scoliosis, soft tissue contractures, multiple dislocations, periodontosis, and eye defects. Involvement of the gastrointestinal tract may lead to episodes of acute blood loss or megacolon. Aortic aneurysms also may develop. All forms of the disease are inherited; some are autosomal dominant traits, others are autosomal recessive, and two forms are X-linked. Identified gene mutations include various collagens, collagen-processing genes and tenascin-X, a connective tissue protein. Forty percent of newborns with EDS are delivered prematurely.[43]

ECTODERMAL DYSPLASIA

The term *ectodermal dysplasia* describes a group of more than 100 rare congenital disorders with abnormal development of ectodermally derived tissues, of which the hypohidrotic type is the most common.[43] Diminution or absence of sweating, hypotrichosis, and defective dentition are the most striking features of hypohidrotic ectodermal dysplasia, which usually is inherited in an X-linked recessive fashion. The facies are distinctive because of frontal bossing and depression of the bridge of the nose. Eyebrows and lashes are absent or sparse. The skin around the eyes is wrinkled and frequently hyperpigmented. The skin elsewhere is thin, dry, and hypopigmented, and the cutaneous vasculature is more visible. The scalp and body hair is sparse and the ears and chin prominent. The lips are thick and everted and may show pseudorhagades. Dental anomalies range from total anodontia to hypodontia with peg-shaped teeth.

The most striking physiologic abnormality is the diminution or absence of sweating. Sweat pores usually are decreased to absent on the fingertips. Absence or hypoplasia of eccrine glands can be confirmed by skin biopsy. Other glandular structures also may be absent or hypoplastic. Less constant ancillary findings include conductive hearing loss, gonadal abnormalities, stenotic lacrimal puncta, corneal dysplasia, and cataracts. Mental development is normal. Marked heat intolerance is caused by an inability to regulate the body temperature adequately by sweating. Fever occurs with increases in ambient temperature and exercise and should respond quickly to environmental cooling and rest. Some febrile reactions, however, may be caused by recurrent upper respiratory tract infections. Because the respiratory mucosa also may be deficient in mucus-secreting glands, viral respiratory tract infections in these patients tend to linger and become complicated by secondary bacterial infections in the bronchial tree. It is imperative to diagnose children with ectodermal dysplasia in infancy.

Every effort should be made to moderate extreme environmental temperatures by using air conditioning. Deficient lacrimation can be palliated by the regular use of artificial tears. The nasal mucosa also must be protected by intermittent saline solution irrigations and application of petrolatum. It is imperative that children with this disorder have a thorough dental evaluation during the first years of life, and dental prostheses should be provided even for toddlers so that adequate nutrition is maintained. Reconstructive procedures can be performed later in life to improve the facial configuration. A wig may be required for patients with scant scalp hair.

The incidence of atopic diseases—asthma, allergic rhinitis, and atopic dermatitis—is increased significantly among patients with anhidrotic ectodermal dysplasia. Atopic manifestations should be managed as they would be in otherwise healthy infants and children. Accurate carrier detection and early neonatal and prenatal diagnoses are feasible for many families at risk for this condition.

Numerous other types of ectodermal dysplasia have been defined, including hidrotic ectodermal dysplasia, the ectrodactyly ectodermal dysplasia cleft palate syndrome, the ankyloblepharon ectodermal dysplasia cleft palate syndrome, the ectodermal dysplasia cleft palate midfacial hypoplasia (Rapp-Hodgkin) syndrome, and chondroectodermal dysplasia (Ellis–van Creveld syndrome). Some of these conditions may manifest with scalp erosions or impetiginous lesions in the neonate. Isolated lack of sweat glands occurs in congenital familial anhidrosis.

PORPHYRIAS

The inherited porphyrias are a diverse group of inborn errors of heme biosynthesis, resulting from the deficient activity of a specific enzyme in the pathway. They are classified as hepatic or erythropoietic according to the organ site in which the underlying heme synthetic defect is predominantly expressed. The erythropoietic porphyrias include congenital erythropoietic porphyria and erythropoietic protoporphyria. The erythropoietic porphyrias are present at birth, infancy, or early childhood, whereas the hepatic porphyrias manifest after puberty or in adulthood.[44]

Erythropoietic protoporphyria is the most common childhood porphyria, caused by a deficient activity of ferrochelatase; it usually manifests by age 2 years. Erythropoietic protoporphyria is inherited as an autosomal dominant condition with incomplete penetrance. Clinical diagnosis is made with a history of crying or skin pain following sun exposure. Some patients are photosensitive to fluorescent lighting. Hemolytic anemia is absent. The diagnosis is made by the elevated levels of protoporphyrin in erythrocytes, plasma, and feces. The treatment includes sun avoidance; oral administration of β-carotene, cysteine, and antihistamines to increase tolerance to sunlight; and liver transplantation.

Congenital erythropoietic porphyria, also called Gunther disease, is a rare autosomal recessive disorder caused by deficient activity of uroporphyrinogen III synthase. The gene for congenital erythropoietic porphyria has been mapped to chromosome 10, allowing prenatal diagnosis to be made with chorionic villus sampling. Diagnosis is also suspected when a reddish-brown amniotic fluid is noticed at amniocentesis. Clinical presentation includes severe photosensitivity from birth or early infancy with formation of vesicles and bullae on areas exposed to sun, phototherapy, or fluorescent lighting. There is also marked skin fragility. Diagnosis is made by elevated levels of uroporphyrin I in urine and erythrocytes and increased levels of coproporphyrin I in feces. Treatment modalities include oral super-activated charcoal, hypertransfusion, splenectomy, and bone marrow transplantation.

Transient porphyrinemias have been described in newborns with hemolytic disease with unclear etiology. These infants present with erythema, violaceous discoloration, purpura, erosions, and blisters on areas exposed to phototherapy. The elevated levels of porphyrins normalize spontaneously after the first few months.

NEONATAL LUPUS ERYTHEMATOSUS

Neonatal lupus erythematosus (NLE) is a disease caused by transplacental passage of maternal autoantibodies. Pregnant women whose sera contain anti-Ro/SSA or anti-La/SSB are at risk of having a child with NLE. Permanent congenital heart block and transient skin lesions are the hallmark of this condition. Mean age at the onset of skin rash is 6 weeks, but it may be present at birth.[36]

Clinically, the skin lesions are primarily annular and papulosquamous. They are widespread but most commonly seen on the face and scalp, predominantly affecting the periorbital and malar areas and often causing a "raccoon eyes" appearance. Sun exposure precipitates or aggravates these lesions. Telangiectasia may be a presenting sign and a more permanent sequela. Between 30% and 50% of mothers of infants with NLE have a connective tissue disease, most commonly systemic lupus erythematosus or Sjögren syndrome.

Many questions regarding the pathogenesis of NLE remain unanswered. Serologic studies for autoantibodies are confirmatory for diagnosis. It is unclear why less than 5% of mothers with anti-Ro and anti-La antibodies give birth to affected children and why mothers of affected infants are often asymptomatic despite having the same antibodies. Diagnosis of NLE in the infant, therefore, may lead to diagnosis of lupus in the mother. Treatment of skin lesions is primarily aimed at sun protection along with topical steroids. Development of rheumatic disease later in childhood can occur and warrants long-term follow up. The risk of a subsequent child having any manifestation of NLE is roughly 25%.

PRINCIPLES OF NEWBORN SKIN CARE

It is reported that nearly 80% of normal newborns develop a skin problem, for example, a "rash" during the first month of life. Despite the desire of parents and caregivers to promote good skin care and the ubiquity of skin problems, particularly in the preterm infant, there is a surprising lack of evidence on which to base infant skin care recommendations. Studies, for example, have provided evidence that natural drying of the umbilical cord in term and preterm infants is a safe and effective means of postnatal cord care and results in earlier detachment of the cord compared with the result with alcohol use.[14] Basic principles of skin care were cited earlier in Box 52-2.

The gross appearance of the skin at birth is related in part to the maturity of the infant. The premature infant's skin may be readily distinguished from the term infant's skin. At birth, it is more transparent and gelatinous and tends to be free of wrinkles. The premature infant may be covered with fine lanugo hair. Sexual hormonal effects are less conspicuous in the premature infant; the scrotum is less rugose and pigmented, and the labia majora are less prominent and not approximated, nipples and areolas are less pigmented, and breast tissue is less palpable.

The extremely premature infant ($<$750 g) is at particular risk secondary to a poorly developed epidermal permeability barrier. The stratum corneum becomes multilayered during the third trimester. However, it represents a less effective barrier than adult stratum corneum. Transepidermal water losses may be 10- to 15-fold higher in preterm infants with extremely low birthweight compared with those in term infants. Each milliliter of water lost via evaporation expends 0.58 kilocalories. Epidermal permeability is highest in the premature infant immediately after birth. Heat and water loss can be a significant source of morbidity in the preterm infant and should be prevented beginning in the delivery room. The difference between cutaneous permeability in premature infants and term infants decreases with each postnatal day. At 2 weeks after birth, however, the epidermal barrier of the infant with very low birthweight still has markedly increased transepidermal water loss compared with that in infants born at the same corrected gestational age.[1]

An immature permeability barrier can lead to increased absorption of environmental toxins (Table 52-8). The normal acid mantle of the skin develops more slowly in preterm infants, and the expression of cationic antimicrobial peptides, such as those associated with the protective coating of vernix caseosa at birth, may be diminished.

Strategies for improving epidermal barrier function in preterm infants with very low birthweight are listed in Box 52-4. Studies have shown that postnatal massage of moderately preterm infants with traditional oils reduces infection and mortality.[9] An overview of the complicated interplay between genotype and environment in affecting skin condition is shown in Figure 52-17. This interaction is illustrated in the etiology of common skin disorders such as diaper dermatitis.[56] It is anticipated that increasing understanding of the molecular basis of the skin disorders and diseases covered in this chapter will shed new light on the mechanisms of more common and less serious skin problems in the newborn.

TABLE 52–8 Potential Untoward Effects from Application of Topical Products in Neonates

Compound	Function	Toxicity
Adhesive remover solvents	Skin preparations to aid in adhesive removal	Epidermal injury, hemorrhage, and necrosis
Alcohols	Skin antiseptic	Cutaneous hemorrhagic necrosis, elevated blood alcohol levels
Ammonium lactate	Keratolytic emollient	Possible lactic acidosis
Aniline	Dye used as a laundry marker	Methemoglobinemia
Benzethonium chloride	Skin cleansers	Poisoning by ingestion, carcinogenesis
Benzocaine	Mucosal anesthetic (teething products)	Methemoglobinemia
Boric acid	Baby powder, diaper paste	Vomiting, diarrhea, erythroderma, seizures, death
Calcipotriol	Topical vitamin D_3 analogue	Hypercalcemia, hypercalcemic crisis
Chlorhexidine	Topical antiseptic	Systemic absorption but no toxic effects
Coal tar	Shampoos, anti-inflammatory ointment	Excessive use of polycyclic aromatic hydrocarbons are associated with an increased risk of cancer
Corticosteroids	Topical anti-inflammatory	Skin atrophy, striae, adrenal suppression
Diphenhydramine	Topical antipruritic	Central anticholinergic syndrome
Glycerin	Emollients, cleansing agents (Aquanil)	Hyperosmolality, seizures
Lidocaine	Topical anesthetic	Petechiae, seizures
Lindane	Scabicide (Kwell)	Neurotoxicity
Mercuric chloride	Diaper rinses, teething powders	Acrodynia, hypotonia
Methylene blue	Amniotic fluid leak diagnosis	Methemoglobinemia
Neomycin	Topical antibiotic (Neosporin)	Neural deafness
Phenolic compounds (pentachlorophenol, hexachlorophene, resorcinol)	Laundry disinfectant, topical antiseptic (PHisoHex)	Neurotoxicity, tachycardia, metabolic acidosis, methemoglobinemia, death
Phenylephrine	Ophthalmic drops	Vasoconstriction, periorbital pallor
Povidone-iodine	Topical antiseptic (Betadine)	Hypothyroidism
Prilocaine	Topical anesthetic (EMLA)	Methemoglobinemia
Propylene glycol	Topical vehicles, emollients, cleansing agents (Cetaphil)	Hyperosmolality, neurotoxicity, seizures
Salicylic acid	Keratolytic emollient	Metabolic acidosis, salicylism
Silver sulfadiazine	Topical antibiotic (Silvadene)	Kernicterus (sulfa component), agranulocytosis, argyria (silver component)
Triclosan	Deodorant and antibacterial soaps	Toxicities seen with other phenolic products
Triple dye (brilliant green, gentian violet, proflavine hemisulfate)	Topical antiseptic for umbilical cord	Ulceration of mucous membranes, skin necrosis, vomiting, diarrhea
Urea	Keratolytic emollient	Uremia

Compiled from Gilliam AE, Williams ML: Skin of the premature infant, p 45, and Bree AF, Siegfried EC: Neonatal skin care and toxicology, p 59. Both in Eichenfield LF et al, editors: *Textbook of neonatal dermatology*. Philadelphia, 2008, Saunders.

BOX 52–4 Strategies to Improve Epidermal Barrier Function in Preterm Infants

Topical application of one or more nonphysiologic lipids (e.g., petrolatum)

Topical application of natural oils (e.g., sunflower oil) or mixtures of physiologic lipids (ceramides, cholesterol, free fatty acids)

Topical dressings

- Vapor-permeable: allow metabolic (repair) processes to continue in the underlying epidermis
- Vapor-impermeable (occlusive): delay metabolic responses in the underlying epidermis

Xeric stress: postnatal transition to low-humidity (~60%) environment accelerates barrier development

CHAPTER 53

The Eye

PART 1

Examination and Common Problems

Lawrence M. Kaufman, Marilyn T. Miller, and Balaji K. Gupta

Clinicians should develop the ability to recognize the signs and symptoms of serious eye diseases or complications of diseases early in their course to prevent visual loss and, in some cases, preserve life. For example, early detection and treatment of congenital cataracts and congenital glaucoma are critical for visual rehabilitation. Malignant orbital tumors and intraocular tumors such as retinoblastoma are life threatening. Ocular findings can also assist in the diagnosis of a systemic illness such as type 1 neurofibromatosis (NF1) and CHARGE syndrome (coloboma, heart anomaly, choanal atresia, retardation, genital anomaly, ear anomaly).[68]

The visual system is not completely developed at birth but progressively matures during the neonatal period.[16] The neonatologist must recognize normal ocular findings during different stages of the infant's growth to understand what is abnormal. Some ocular and visual milestones are shown in Table 53-1.

A screening eye examination should be performed during the newborn physical examination and during routine well-baby checkups.[2] The screening examination should include the assessments listed in Box 53-1.[13] Fortunately, the screening examination identifies most problems such as glaucoma, cataract, infection, or tumor. However, if abnormalities are suspected because of the history, presence of systemic anomalies, or abnormal result of the screening examination, a more detailed ocular evaluation is mandatory, preferably by a pediatric ophthalmologist.[23]

NEONATAL EYE EXAMINATION

A screening ocular examination begins with a careful history, especially of ocular diseases in the family.[13] For example, a family history of retinoblastoma necessitates a comprehensive ocular examination of the fundus shortly after birth. Information about maternal diseases (e.g., rubella), injuries, medications, or use of drugs or alcohol during the prenatal period should be obtained. It is also important to document the duration and abnormalities of pregnancy, labor, and delivery. Premature birth suggests potential retinopathy of prematurity (ROP), and difficult delivery with obstetric forceps can result in direct ocular trauma.

The examination should be done under comfortable circumstances and with the proper equipment (Fig. 53-1). Much can be learned if the examiner takes a few moments initially to observe the infant for facial anomalies, the external ocular appearance, and ocular motility while taking the history. The examination is most easily performed with the baby in a parent's arms; the more difficult parts of an examination often can be accomplished while a baby is nursing or sucking on a bottle or pacifier.

The screening eye examination should include an evaluation of visual function, preferably, one eye at a time. For infants less than 4 to 6 weeks of age, visual function is assessed by withdrawal or blinking to light, or pupil constriction to light.[13]

Maintenance of the eyes on an object is called *fixation*. The infant's ability to fixate and follow a target can be an approximate guide to the amount of visual function present. Beyond 4 to 6 weeks of age, visual function is assessed in terms of the quality of the fixation and following. By experience, the clinician must develop an age-appropriate scale that assesses this quality of fixation and following, paying attention to the intensiveness, steadiness, and maintenance of the fixation and the smoothness and duration of the following.

Visual acuity refers to the subjective response from the patient of the ability to discern images of set sizes, such as the tumbling "E" or Snellen letters. Most normally developing children can participate in some form of visual acuity testing by the age of 30 months.

If additional information regarding visual function is desired, some ancillary visual tests are available and used in indicated situations. 1) *Optokinetic nystagmus* describes a reflex ocular response to a moving target. As a target moves across the visual field, a pursuit motion occurs, followed by a rapid return motion in the opposite direction to regain fixation. We experience this response when telephone poles or fence posts are watched from a fast-moving vehicle. With an optokinetic drum, which consists of black and white stripes on a spinning cylinder, if the examiner can elicit optokinetic nystagmus in the infant, this establishes that the child has enough visual function to discern the stripes. The stripe

TABLE 53–1 Visual System Milestones

Description	Age
Pupillary light reaction present	30-wk gestation
Pupillary light reaction well developed	1 mo
Lid closure in response to bright light	30-wk gestation
Blink response to visual threat	2-5 mo
Visual fixation present	Birth
Fixation well developed	2 mo
Visual following well developed	3 mo
Accommodation well developed	4 mo
Visual evoked potential acuity at adult level	6 mo
Grating acuity preferential looking at adult level	2 yr
Snellen letter acuity at adult level	2 yr
Color vision present	2 mo
Color vision at adult level	6 mo
Stereopsis developed	6 mo
Stereoacuity at adult level	7 yr
End of critical period for monocular visual deprivation	10 yr
Conjugate horizontal gaze well developed	Birth
Conjugate vertical gaze well developed	2 mo
Vestibular (doll's eye) rotations well developed	34-wk gestation
Optokinetic nystagmus well developed	Birth
Ocular alignment stable	4 mo
Fusional convergence well developed	6 mo
Eyeball 70% of adult diameter	Birth
Eyeball 95% of adult diameter	3 yr
Cornea 80% of adult diameter	Birth
Cornea 95% of adult diameter	1 yr
Differentiation of fovea completed	4 mo
Myelination of optic nerve completed	7 mo-2 yr
Iris stromal pigmentation well developed	6 mo

BOX 53–1 Screening Assessments

- Reaction to light or visual stimuli to estimate visual function
- Craniofacial dysmorphism
- Orbits
- Eyelids
- Lashes
- Ocular motility
- Globes
- Conjunctiva
- Sclera
- Cornea
- Iris
- Pupils
- Red reflex test

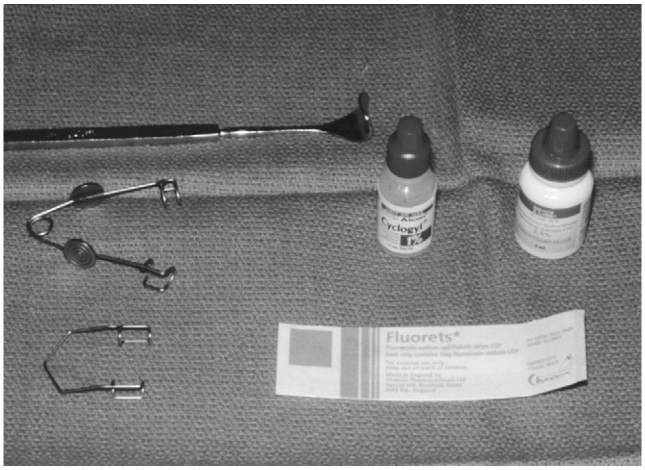

Figure 53–1. Basic equipment for ocular examination: eye speculum or Desmarres retractors, fluorescein strips, 2.5% phenylephrine (ophthalmic), 0.5% cyclopentolate (ophthalmic), and direct ophthalmoscope (not shown).

widths can be calibrated, so as to yield a *visual acuity equivalent*. Optokinetic nystagmus can be evident in term newborns.[55] 2) Another quantitative technique to measure a visual acuity equivalent in the infant older than 3 months is *forced preferential looking*.[84] An infant prefers to look at black and white stripes instead of a uniformly gray target. For the test, infants are quickly shown a card that has stripes on one end and a gray target on the opposite end. The examiner watches the infant's eyes to see whether the baby looks right or left to find the stripes. If the infant's visual function is high enough to distinguish the stripes from the gray target, the infant will look consistently toward the stripes. If the infant's visual function is less than the ability to distinguish the stripes from the gray target, the infant will look randomly right or left. By varying the size of the stripes, the examiner can grade the visual acuity equivalent. The disadvantages of this procedure include the number of people necessary to administer the test, the time involved, and the need for the cooperation of an alert infant. 3) Unfortunately, most estimations of an acuity equivalent in the infant rely heavily on adequate motor responses as part of the visual evaluation. Immature or underdeveloped motor systems can reduce or interfere with eye or head movements and decrease the estimation of the visual acuity equivalent. Visual evoked potentials, which measure the electrical cortical responses to a visual stimulus, eliminate the need for patient cooperation or motor control.[24] Electrodes are placed over the occipital cortex to monitor activity in the brain as the eyes are visually stimulated with graded stripes or checkerboard patterns, and a computer-averaged tracing is made.

Continuing with the screening eye examination, the general facial configuration and the structure of the orbits are inspected next. Note any facial dysmorphism that could affect ocular health, or be part of an ocular syndrome, such as clefts or abnormal head shape. The orbits should be proportional and symmetric compared with the overall craniofacial configuration. Palpation is performed to examine the orbital margin, the contents of the upper and lower lids, and the round contour of the globes. The orbital rims should be sharply outlined. In the newborn infant, the rims are initially round, and increase in vertical diameter with normal growth. The area of the lacrimal sac is palpated for abnormal masses or increased size by pressing the sac against the bones of the nose and medial orbital wall. Mucopurulent material expressed from the lacrimal puncta is a symptom of obstruction of the nasolacrimal system.

The eyelids are examined grossly and are compared for symmetry of horizontal and vertical placement. Spontaneous opening and closing of the lids should be observed. The lid margins should be inspected for regularity of contour, apposition to the globe, and the presence of lacrimal puncta. The punctum, the proximal opening into the nasolacrimal drainage system, is a minute hole in each lid margin a short distance from the inner corner of the eye. A rapid up-and-down movement of the lid during nursing indicates a jaw-winking phenomenon.[44]

The examiner should view the lashes, which normally are directed outward in an orderly row. Abnormalities include distichiasis, an additional row of lashes posterior to the gray line, and trichiasis, an inward turning of the lashes. Epiblepharon is a common condition of the lower lid in which a horizontal fold of skin rotates the lashes of the lid in toward the eye. Lashes that contact the cornea can cause continued irritation and predispose the eye to infection and abrasion of cornea.

The ocular motor system is evaluated with a motility examination. This includes ocular alignment, conjugate ocular movements, and range of movement. Infants younger than 4 months may show small physiologic misalignments of the eyes. Misaligned eyes beyond the age of 4 months should be considered pathologic.[23]

Alignment is tested with the corneal reflex test (Hirschberg test). The examiner shines a well-focused light at the patient's eyes and notes the spot on the cornea where the light is reflected back. If the patient is properly fixating, the light reflex should appear in the same location on each cornea, slightly nasal to the anatomic center of the cornea. If the light reflex is centered in one eye and deviated laterally in the fellow eye, esotropia is present. If the light reflex is centered in one eye and deviated nasally in the fellow eye, exotropia is present. A positive cover-uncover test will support the impression of strabismus.

If the patient does not appear to move the eyes well enough into the periphery, either spontaneously or by following an object, these movements can be driven by the doll's head maneuver (vestibulo-ocular reflex [VOR]). The reflex is tested by turning the infant's head to one shoulder, producing an opposite movement of the eyes (Fig. 53-2). The eyes appear stationary as the head turns. This reflex may be reduced in severely brain damaged infants but normal in blind infants.[9]

Another rotational reflex is elicited by holding the infant vertically and rotating the infant in an arc around the examiner (Fig. 53-3). The infant's eyes will then tonically rotate in the direction of the spin, with short quick movements (saccades) in the direction opposite the spin. This ocular reflex may be a form of optokinetic nystagmus and is reduced in infants with major defects of the vestibular system, lower motor pathways to the extraocular muscles, visual system, or central nervous system.[9]

Examination of the globes may be difficult owing to inability of the examiner to open the neonates' eyelids sufficiently. Various pediatric eye speculums, such as an Alfonso speculum (Bausch and Lomb, STORZ, San Dimas, CA), can be used to maintain the lids open and allow for adequate inspection of the ocular surface, anterior segment, or posterior segment. Before placing the eye speculum, topical ocular anaesthesia can be achieved with a drop of tetracaine 0.5% eye drops. Oral sucrose can also relieve some of the discomfort of an ocular speculum.[25]

The conjunctiva is inspected after the lids are separated with the use of a pediatric ocular speculum or fingers. The bulbar and palpebral conjunctivae are normally moist and

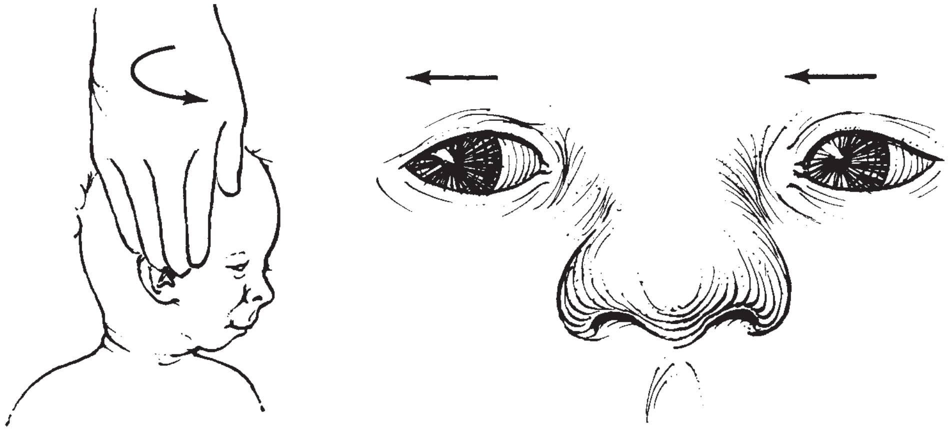

Figure 53–2. Doll's head rotation. As the head is turned toward the shoulder, a tonic neck muscle reflex produces corresponding ocular rotation in the opposite direction as though the eyes were remaining in their original position as the head moves.

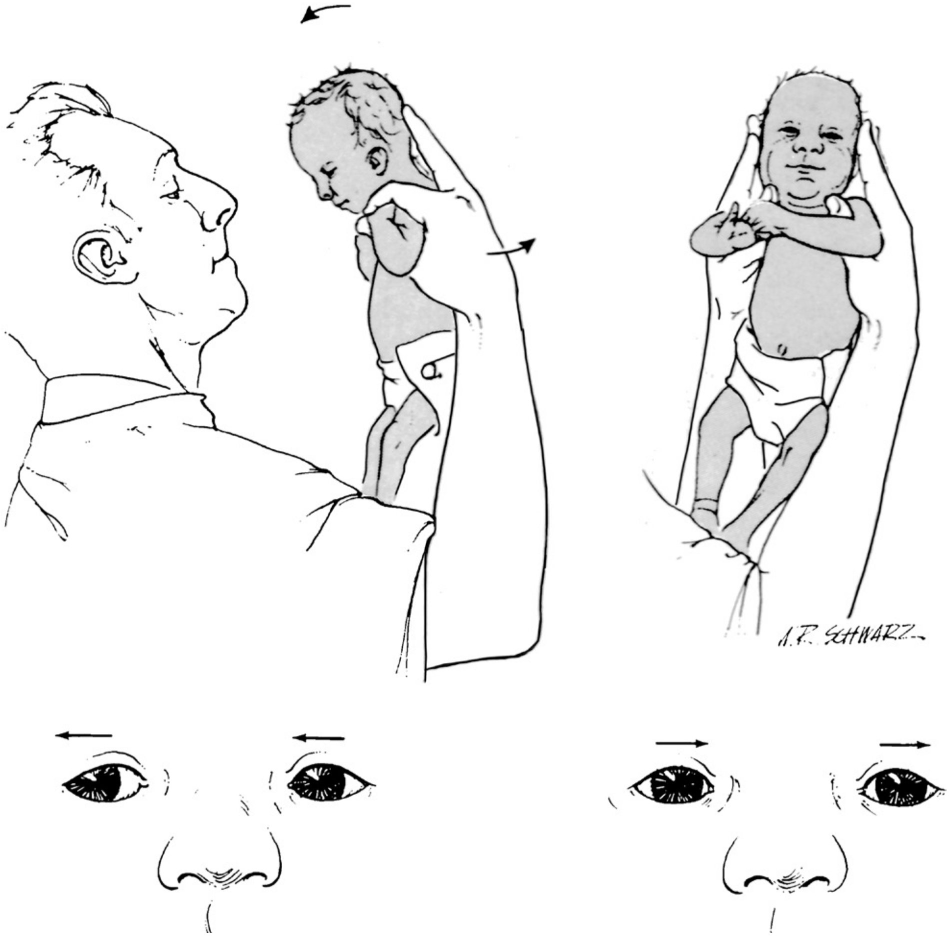

Figure 53–3. Rotational nystagmus. The infant's head is inclined slightly forward with eyes open. With rotation, the eyes move in the opposite direction as in doll's eye rotation. When rotation stops, the recovery movement occurs in the reverse direction.

pinkish. Redness or exudate is abnormal and can indicate infection. The conjunctivae of the lids overlying the tarsal plates should be examined after the lids are everted. Eversion is usually simple to perform with the examiner's fingers, particularly if the infant is attempting to squeeze the lids shut.

The normally white sclera is evaluated for changes of color. A bluish coloration, however, is present in premature infants and in other small babies because of their very thin sclera.

The cornea is inspected with a penlight, paying attention to corneal size, shape, clarity, and luster. Magnification with loupes or an ophthalmoscope with the +10-diopter lens in place may be used. During the first few days of life, premature and term infants might demonstrate a slightly hazy cornea, which is thought to be the result of corneal edema. Thereafter, the surface of the cornea should have good luster and be absolutely transparent even to the extreme periphery. Any opacity or translucency is abnormal after the first few days of life, and referral to an ophthalmologist is indicated. Changes in transparency or opacification in the peripheral cornea may be associated with a local mesenchymal abnormality or glaucoma.

The irides are usually similar in appearance. Although normally incomplete for the first 6 months of life, pigmentation of both irides develops simultaneously. In a normal infant, the iris is often blue or blue-gray for the first few weeks or months of life. However, darkly pigmented babies can show pigmentation at birth or within the first week. Heterochromia (dissimilarity in pigmentation between the two eyes or within one eye) can indicate a normal hereditary pattern, congenital Horner syndrome, or one of several syndromes (e.g., Waardenburg) discussed later in this chapter. These syndromes might not become apparent until the end of the neonatal period or even later in life when the iris is fully pigmented.

The pupils should be central, round, and equal in diameter. The pupillary space should be uniformly black. Any amount of a white reflection is abnormal and could indicate an abnormality within the lens, vitreous, or retina. The neonate's pupils are typically miotic in ambient light, perhaps related to prolonged sleep.[38] A penlight or a transilluminator is used to shine a light at each pupil. Beyond a corrected gestational age of 30 weeks, pupils should constrict to both direct and contralateral stimulation.[38] First, the reaction of the illuminated pupil is observed. It should constrict briskly (although the response in the neonate may be slower than in an older child) and should remain constricted as long as the illumination is maintained. If a poor response is observed, the contralateral pupil's reaction is studied. If the contralateral pupil constricts, the directly illuminated eye must have intact photoreceptors and optic nerve pathways. Failure of constriction in the directly illuminated eye in this instance could result from abnormalities in the iris. If neither pupil constricts on direct illumination to one eye, the first eye may be severely deficient in vision.[51]

The swinging flashlight test is used to check for a relative afferent pupillary defect. Normally, if the light is quickly shifted from one eye to the other, the newly illuminated eye's pupil should show an initial small constriction movement. If illumination is maintained on the eye, small rhythmic constriction and dilation movements may follow—called *hippus*, a normal phenomenon. If, however, the shift of light is followed by dilation of the newly stimulated eye, a Marcus Gunn (or relative afferent pupillary defect) is present. This result indicates decreased vision in the eye that inappropriately dilated. Pupillary reflexes should be completely normal in patients with central (cortical) visual impairment.

The red reflex test is an essential part of the infant screening eye examination.[3,87] Examination starts with a +0 diopter setting in the direct ophthalmoscope, and the child is examined at arm's length, with both pupils illuminated (Fig. 53-4). The red reflex of each eye should be clearly distinct, with no shadows or alterations. Look for any asymmetry of the intensity of the red reflex within each pupil and between the two pupils. If a red reflex cannot be seen, the pupils can be dilated with Cyclomydril eye drops[72] (Alcon Laboratories), and if a clear and equal red reflex is still not seen, the baby should be referred to an ophthalmologist.[23]

Precise viewing of the anterior chamber and crystalline lens requires a slit-lamp examination, instrumentation that is usually not available to the neonatologist or primary care physician. An indirect assessment of the clarity of the cornea, anterior chamber, lens, and vitreous is performed during the red reflex test, which measures the ability of light to enter the eye and reflect back out of the eye off the retina. Similarly, the red reflex test indirectly assesses the intactness of the retina. The adventurous neonatologist or primary care physician can attempt direct viewing of the infant's retina with a direct ophthalmoscope. Viewing the retina of the undilated infant's eye with a direct ophthalmoscope is a challenge, even to the pediatric ophthalmologist. If a view of the retina is required, such as for retinopathy of prematurity screening, the consulting ophthalmologist would dilate the infant's eyes and use more sophisticated examination instrumentation such as the indirect ophthalmoscope.

Certainly, the use of the direct ophthalmoscope to directly view the retina is not considered part of the screening eye examination in the infant.[64] However, if a direct ophthalmoscope examination is attempted, attention should be directed to the clarity of the vitreous cavity and the appearance of the optic disc, major retinal vessels, the macula, and the surrounding retina.

NORMAL OCULAR FINDINGS

The eye of the newborn infant differs from the adult eye primarily in function, although structural differences also exist.[16] The growth of the eye, which parallels that of the brain, continues at a rapid rate for the first 3 years of life, especially during the first year. The anteroposterior dimension of the eye at birth is about 16.5 mm and grows to about 24 mm in adulthood. Normal values in the neonate fall within a very wide range. Suspected abnormalities in size often are substantiated only by comparison with measured values in the fellow eye or by ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI). The horizontal and vertical diameters of the cornea of the newborn are about 9 to 10 mm. Enlarged corneas suggest the diagnosis of congenital glaucoma.

The lid fissures of the term infant are usually narrow and often widely separated horizontally by prominent epicanthal folds. Normal horizontal measurement of the lid fissures in the newborn can range from 17 to 27 mm (Table 53-2). These measurements should be symmetric. The term *telecanthus* indicates a disproportionate increase in the distance between the medial canthal angles. It is particularly noticeable in fetal alcohol syndrome and Waardenburg syndrome. Measurements between the two medial canthi in the term newborn vary from 18 to 22 mm. *Hypertelorism* is defined as an increase in distance between the orbits, observed clinically as a large interpupillary distance, which is often seen in many craniofacial syndromes. A secondary telecanthus is observed in patients with hypertelorism.

Reflex tearing to irritants is evident shortly after birth. However, emotional tearing begins at about 3 weeks of age and is developed at 2 to 3 months. The newborn infant possesses a strong blink reflex in response to light and to stimulation of the lids, lashes, or cornea. The reflex response to a threatening gesture does not appear until 7 or 8 weeks of age in the term infant. Repetitive eye opening is evident at birth.[33]

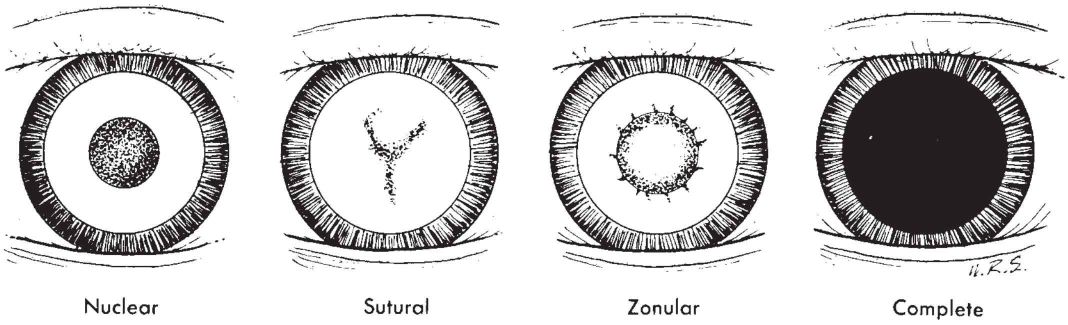

Figure 53–4. Appearance of the red reflex with various types of cataracts. The normal eye has a clear, round red reflex. Lens opacities (cataracts) interrupt the red reflex, producing the black shadows.

TABLE 53–2 Normal Ocular Measurements

Measurement	TERM NEONATE *(mm)*	PREMATURE* *(mm)*
Intermediate canthal distance	18-22	12-16
Medial canthus to lateral canthus	17-27	12-16
Anteroposterior diameter of eye at birth	16	10-16
Horizontal diameter of cornea	10 (average), 9 (lower limits)	7.5-8 (lower limits)

*Neonates weighing 1000 to 1300 g.

After birth, the eyes should appear straight for the most part, although erratic, purposeless, and independent movements can be observed during the first few months of life. Any constant strabismus beyond the age of 4 months requires further evaluation.[4] Conjugate horizontal gaze should be evident in the newborn; vertical conjugate gaze develops by 2 months of age. Convergence spasms are a normal transient phenomenon of infancy.

The ability to maintain a steady gaze or to fixate and follow an object is only weakly initiated at 4 to 6 weeks of age. At first, the eyes pursue a moving visual stimulus with short saccades. By 3 months of age, the infant can fixate and follow in both vertical and horizontal directions. At about 4 months of age, central fixation is associated with the motor activity of grasping. Binocular vision is present at about 6 months of age.

Prematurity

The ocular findings of the premature infant differ from those of the term neonate. At 28 weeks of gestation, the globe is only 10 to 14 mm in diameter. The anterior and posterior hyaloid vascular systems are usually present to some degree, although their involution continues for the next several months (Fig. 53-5). Remnants of this system may be seen in the form of persistent blood vessels or fibrous strands anterior and posterior to the lens. The main hyaloid artery coursing from the optic disc to the posterior lens surface may be patent or appears as a white strand in the vitreous. A moderate amount of vitreous haze is often present at this time, interfering with visualization of the fundus.

Vascularization of the retina begins with the ophthalmic artery entering the eye through the posterior edge of the eye's embryonic fissure at 4 months of gestation. Retinal vessels then grow anteriorly to vascularize the peripheral retina, a process that is not complete until near term. Thus, premature infants have incomplete retinal vascularization, creating the basis for retinopathy of prematurity.

Pupil constriction to light is not seen until 30 weeks of gestational age.[38] Lack of pupil response to light should not be considered abnormal until at least 32 weeks after conception.

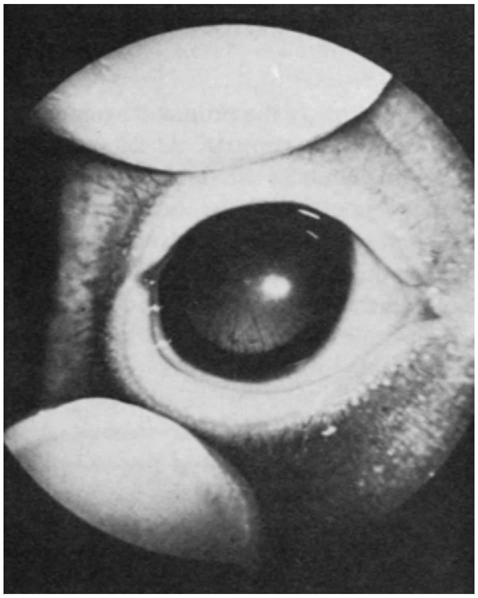

Figure 53–5. Persistent pupillary membrane in a premature infant. Notice the remnants of vascular loops of the anterior hyaloid system anterior to the lens. They will continue to atrophy during the first months of extrauterine life.

Premature infants have a higher incidence of myopia, amblyopia, and strabismus in childhood. Careful follow-up of all children born prematurely is advisable to ensure early detection of these ocular conditions.

REQUESTING OPHTHALMOLOGIC CONSULTATION

Routine ophthalmologic consultation for all infants in the nursery is not warranted.[23] Pathologic ocular findings in normal neonates are sufficiently unusual that evaluation should be requested only after a screening ocular examination indicates the presence of an abnormality or for patients who for some reason are at increased risk for ocular problems. Indications for ophthalmologic consultation include a family history of congenital cataracts, retinoblastoma, congenital glaucoma, or other serious ocular diseases. Intrauterine infectious disease such as rubella, toxoplasmosis, or cytomegalovirus necessitates a thorough eye evaluation. For preterm infants, ophthalmologic consultation is necessary to exclude retinopathy of prematurity.

ORBITAL ABNORMALITIES

The contents of the orbit are confined to a conical shape by its bony walls. At the posterior apex of the orbit, the extraocular muscles originate, and the vascular and nerve structures enter the orbit. The bone structures of the lateral wall do not protect the orbital contents as far anteriorly as do the remaining sides of the orbit, which leaves the eye more susceptible to trauma on its lateral side. In the neonate, the orbital rims form a circular outline at the anterior base of the cone. Box 53-2 lists systemic syndromes with orbital abnormalities.

BOX 53–2 Syndromes Associated with Abnormal Orbits

HYPOTELORISM
Cebocephaly
Oculodentodigital dysplasia
Trisomy 13
Scaphocephaly

HYPERTELORISM
Cerebral gigantism
Cerebrohepatorenal syndrome
Chromosome deletions
Craniosynostosis
Frontonasal dysplasia and median cleft face syndrome
Infantile hypercalcemia
Smith-Lemli-Opitz syndrome
Isolated finding

The terms *proptosis, exophthalmos,* and *exorbitism* are often used interchangeably to describe forwardly displaced eyes. In the strictest sense, proptosis results from an increase in orbital contents within a normal bony orbit, exophthalmos from Graves disease, and exorbitism from shallow bony orbits.

Proptosis

The diagnosis of proptosis can be confirmed if the examiner observes the infant's eyes and lids from above, over the prominence of the eyebrows. A more anterior protrusion of the orbital contents is observed in comparison with the opposite side. In proptosis, the eye frequently also has a widened palpebral fissure.

Masses within the orbital cavity can expand most easily anteriorly, producing proptosis. Those located within the cone of extraocular muscles produce a symmetric anterior displacement, whereas tumors located outside the cone of extraocular muscles displace the eye outward and away from the area of origin of the tumor. A tumor in the inferior portion of the orbit displaces the eye upward and forward, whereas one located medially displaces the eye laterally and forward. A diffuse, extensive tumor can produce sufficient changes to affect the eye's movement, whereas a localized tumor often does not interfere with rotation of the eye. If a tumor is located anterior to the equator of the globe, it can extend anteriorly into the lids without producing proptosis.

An orbital encephalocele or meningocele producing proptosis may be evident at birth or may be delayed until later years. This abnormality results from a defect in the wall between the cranial cavity and the orbit, usually located at the suture lines. Pressure within the cranium causes herniation of brain tissue, meninges, or both into the orbit, most often at the inner angle of the orbit at the root of the nose. Diagnosis is made by identifying the bone defect in association with the area of the orbital cyst. Clinically, an encephalocele is suggested by the presence of a pulsating, fluctuant cyst that can be reduced somewhat with digital pressure or that increases with coughing or crying. Excessive manipulation of the encephalocele can cause pulse and respirations to slow or can cause convulsions. Neurosurgical consultation and intervention are necessary.

Proptosis also can occur from venous engorgement of the orbital cavity such as that produced by a carotid-cavernous fistula. A cephalic bruit is often heard in the infant but is not pathognomonic of a carotid-cavernous sinus fistula.

A false diagnosis of proptosis might be made when there is a slight ptosis of one eye, which gives the opposite, normal eye an appearance of a wide palpebral fissure. Marked enlargement of the eye, as in congenital glaucoma or high myopia, makes the eye appear proptotic because of the increased size of the globe. Facial abnormalities that produce shallow orbits, as in Crouzon disease, simulate proptosis because the normal amount of orbital structure appears to protrude in an abnormally shallow orbit

Hyperthyroid Exophthalmos

Hyperthyroid exophthalmos, a rare neonatal sequela of hyperthyroidism, can occur as the result of maternal Graves disease during the last trimester of pregnancy. The infant is born with classic hyperthyroidism, including exophthalmos, upper lid retraction, and extraocular muscle involvement. Symptoms usually subside during the first 2 months of life.[28]

Enophthalmos

Enophthalmos refers to eyes that look sunken into the orbit. Causes in infants include orbital asymmetry, microphthalmos, trauma resulting in an orbital blow-out fracture, congenital fibrosis of the extraocular muscles, and congenital Horner syndrome.[12] Numerous syndromes, and many infants with unclassifiable facial dysmorphisms, feature deep set eyes, such as Lowe syndrome, Cockayne syndrome and Cornelia de Lange syndrome.

Ocular Hypotelorism or Hypertelorism

Abnormal spatial relationships between the two orbits create excessively wide or excessively narrow intraorbital distances.[54] These abnormalities are caused by a variety of related cranial abnormalities involving the disproportionate growth or lack of development of the body and lesser wing of the sphenoid and ethmoid sinuses and of the maxillary processes. Hypotelorism (narrowing of the intraorbital distance) may be associated with central nervous system malformation.

Ocular hypertelorism is a term indicating increased separation between the bony orbits, usually greater than 2 standard deviations above the mean. It is an anatomic description rather than a diagnostic entity, and is noted with varying severity in many syndromes such as the craniosynostosis syndromes. One condition with marked hypertelorism is frontonasal dysplasia (median facial cleft syndrome), which may be the result of morphokinetic arrest during embryogenesis. Characteristic findings of frontonasal dysplasia are medial cleft nose, lip, and palate, widow's peak, and cranium bifidum occultum. Common other ocular abnormalities include exotropia, dacryostenosis, epibulbar dermoids, palpebral fissure changes, and optic atrophy.[77]A phenotypically similar but probably distinct clinical entity within the frontonasal dysplasia spectrum has been reported with the features of facial midline defects, basal encephalocele, callosal agenesis, endocrine dwarfism, and morning glory disc anomaly.[75]

EYELID ABNORMALITIES

Colobomas

Colobomas of the lids are partial-thickness or complete defects that can range from a small notching of the lid borders to involvement of the entire length of the lid. Most lid colobomas occur in the medial aspect of the upper lid (Fig. 53-6). When the lower lid is involved, the defect is more often in its lateral aspects. The cause of lid colobomas is often unknown unless associated with a craniofacial syndrome. It has been suggested that these isolated colobomas arise from the localized failure of adhesion of the lid folds that results in a lag of growth, or from mechanical effects of amniotic bands. Syndromes with associated lower lid colobomas are mandibulofacial dysostosis (Treacher Collins syndrome), Goldenhar syndrome (more often upper lid), amniotic band syndrome, and Burn-McKeown syndrome.[99]

The treatment of lid colobomas is important when the lid defect prevents adequate lid closure and allows exposure of the cornea. Subsequent thickening, opacification, infection, ulceration, or perforation of the unprotected cornea can occur. Vision can be degraded by the amblyopia that develops. Early surgical correction is often required when the coloboma is greater than one third of the eyelid margin.[81]

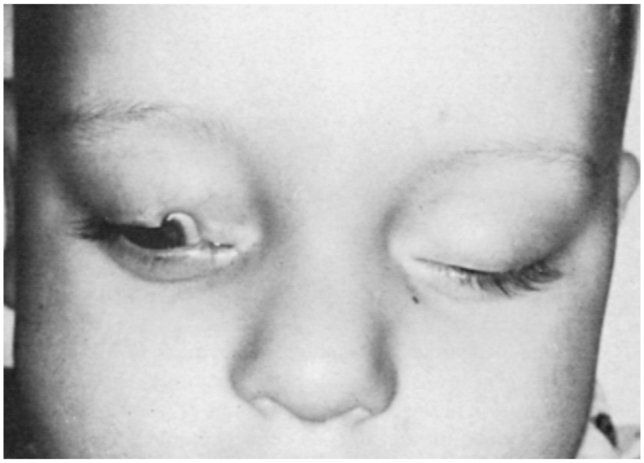

Figure 53–6. Atypical coloboma of the right upper lid.

Congenital Blepharophimosis

The term *blepharophimosis* describes eyelids that are too narrow horizontally and vertically (Fig. 53-7). There is usually an associated ptosis, and strabismus is frequently present. Lid fissure measurements commonly are reduced to about two thirds of normal, whereas the space between the medial canthi is considerably widened. Surgical repair to widen the medial and lateral canthal angles, elevate the upper lid, and correct the strabismus is available.

Blepharophimosis can occur in isolation, as a feature of BPES (blepharophimosis, ptosis, and epicanthus inversus syndrome), or in multiple systemic syndromes such as fetal alcohol syndrome, Saethre-Chotzen syndrome, and van den Ende-Gupta syndrome. BPES has been mapped to the *FOXL2* gene encoding a fork head transcription factor. BPES is divided into type 1 and type 2, with and without premature ovarian failure, respectively.[5]

Epicanthus

Epicanthus is the most commonly encountered lid abnormality. A skin fold originating in the upper lid extends over the medial end of the upper lid, the medial canthus and the caruncle, and ends in the skin of the lower lid. It gradually disappears with the growth of the bridge of the nose as the child loses its baby face. Epicanthal folds can give a false appearance of crossed eyes (pseudostrabismus). Epicanthus inversus is similar except that the predominance of the skin fold arises in the lower lid and runs diagonally upward toward the root of the nose to overlie the medial canthus. These folds are benign and generally do not require treatment.

Congenital Ectropion, Entropion, and Epiblepharon

Congenital ectropion is an eversion of the lid margin, most commonly of the lower lid. It may be associated with other eye abnormalities or syndromes such as Duane syndrome. If the ectropion is mild, no treatment is necessary. A more severely everted lid might require surgical correction. The integrity of the cornea requires monitoring and will determine the treatment.

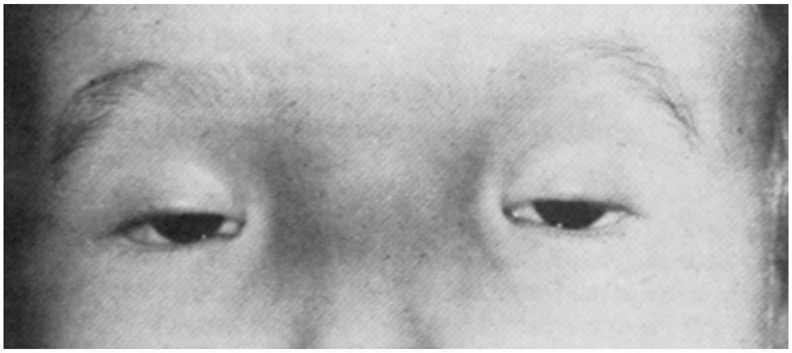

Figure 53–7. Congenital blepharophimosis, ptosis, and epicanthus inversus (bilateral).

Often associated with other lid or ocular abnormalities, congenital entropion is an in-turning of the lid margin, most often of the lower lid. If the lashes on the lid margin rub the cornea and cause corneal abrasions, surgery is necessary.

Epiblepharon is an extra fold of skin along the lower lid that can cause lashes to turn inward. This condition usually requires no treatment and is most often seen in infants of Asian ancestry. This condition usually improves spontaneously during the first 4 years of life, but if it persists, consideration should be given to surgical correction.[12a]

Blepharoptosis

Blepharoptosis, often shortened to *ptosis*, is defined as an upper lid that cannot or does not rise to a normal level (Fig. 53-8). When looking straight ahead, the normal lid should elevate to a point at least midway between the pupil and the upper margin of the cornea. Neonates may have a transient self-limited droopy or closed lid as a result of facial edema or lid trauma during normal vaginal delivery. A temporary, simulated ptosis (protective ptosis or guarding) can result from irritation or infection of the cornea or conjunctiva.

Congenital ptosis most often results from the dysfunction of the levator palpebrae muscle, mostly seen as an idiopathic or familial disorder. Although occlusion of the pupil is rare, the ptotic lid can induce a corneal astigmatism and refractive amblyopia. Occlusive patching and glasses may be needed.

Mild, unilateral ptosis should prompt a comparison of pupil size to evaluate for Horner syndrome. Congenital Horner syndrome is often a result of trauma at birth, although it may be associated with mediastinal disease or neuroblastoma. The involved iris may be hypopigmented.

Ptosis also may be associated with a jaw-winking phenomenon. This syndrome is caused by anomalous motor innervation of the levator palpebrae muscle from nerve twigs to the pterygoid, masseter, or lingual muscles. The affected patient has an up-and-down rhythmic movement of the upper lid during nursing activity. The jaw-winking portion of the syndrome is thought to decrease or disappear in early adulthood, but the ptosis remains. Many surgical procedures have been designed to mitigate the ptosis.

Two forms of myasthenia gravis can produce ptosis in the neonatal period. In about 15% of neonates born to mothers with myasthenia gravis, a transient form of myasthenia occurs shortly after birth. Affected children have a weak cry and poor suck and can develop weakness in all muscle groups. Ocular symptoms are rare and most commonly involve ptosis.[31] A variety of congenital myasthenia syndromes linked to genetic disorders of the neuromuscular junction or acetylcholine production can display ptosis and ophthalmoparesis, which are often variable and related to the level of fatigue.

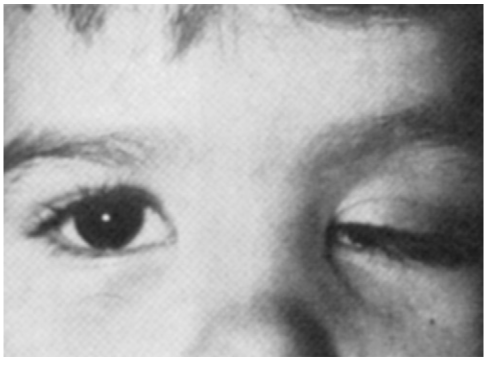

Figure 53–8. Congenital ptosis of the left upper lid.

Pseudoptosis, or false ptosis, may be apparent when the globes are of different sizes or if enophthalmos or proptosis is present. Microphthalmia is a common congenital defect that can be mildly expressed. In such situations, the lid will look drooped even if it is functioning properly. A unilateral large globe due to monocular myopia can produce a relative ptosis in the contralateral normal eye.

EYELASH ABNORMALITIES

Excessive eyelash growth can result, as a side effect, from multiple medications, including topical prostaglandin analogues and epidermal growth factor receptor inhibitors.[18] The term *distichiasis* describes an additional row of lashes posterior to the center of the lid margin. This condition usually results in contact of the lashes with the cornea, producing corneal irritation and abrasions. Trichiasis is a lash that grows from a normal location but is misdirected toward the ocular surface.

Hypertrichosis

Excessive hair on the lids and forehead can occur as a dominant characteristic in male infants and, on occasion, may be extreme. Hypertrichosis involving the eyebrows, forehead, and upper lid appears in the Cornelia de Lange syndrome, a pathologic dwarfism associated with multiple congenital anomalies. Hypertrichosis lanuginosa is transmitted as an autosomal dominant condition. The fetal lanugo persists into adult life, creating an abundant covering of hair on the eyebrows, forehead, eyelids, and other areas of the body.

LACRIMAL ABNORMALITIES

Watery Eye

Epiphora (excess tearing) usually does not occur until after the first 3 weeks of life, when the major portion of the lacrimal gland has become functional. Although the usual cause of epiphora is a blockage of the nasolacrimal ducts (dacryostenosis), the possibility of congenital glaucoma is the most important consideration in the differential diagnosis. Less commonly, tearing can result from an obstruction of the common canaliculus, from congenital absence of the lid puncta, or from dacryocystitis. Congenital absence of the entire lacrimal drainage apparatus is extremely rare. Reflex tearing may be produced by any stimulation of the fifth cranial nerve. Epiphora can occur as the result of corneal abrasion, corneal foreign body, or nasal and facial lesions that irritate the fifth cranial nerve. Chronic nasal congestion also may produce epiphora by mechanically blocking the nasolacrimal duct.

Dacryostenosis may be present in up to 7% of neonates and creates a stagnant pooling of tears in the lacrimal sac that contributes to chronic or recurrent dacryocystitis. The inflammation is marked by a purulent exudate in the medial canthal area of the conjunctiva. Severe dacryocystitis can produce swelling and induration of the lacrimal sac medial and inferior to the medial canthus.

Treatment of mild nasolacrimal infection consists of topical antibiotic drops or ointment. If surrounding cellulitis is suspected, systemic administration of medication and locally applied heat may be required. Repeated massage of the lacrimal sac at the medial canthal area serves to flush out the stagnant tears, decrease the risk for infection, and "pop" open the nasolacrimal obstruction. If the epiphora continues, a lacrimal probe passed through the nasolacrimal duct to the nose usually creates an adequate opening. Probing before 6 months of age is sometimes performed in an office setting under topical anesthesia with the baby swaddled in a sheet. In children with extensive purulent discharge and frequent infections, office probing can be considered as early as 2 months of age.

In more than 90% of children with congenital dacryostenosis, the obstructions spontaneously correct during the first year of life. If persistent, treatment is then offered, but requires general anesthesia because these children are too large to swaddle for an office probing. Surgical options include simple probing, silicone tube intubation, or balloon dilation of the lacrimal system.[53]

Dacryocystocele

A congenital dacryocystocele presents within the first week of life as a bluish mass adjacent to the medial canthus. The distended lacrimal sac is filled with clear fluid, feels firm or fluctuant to palpation, and does not pulsate like a frontal encephalocele. Initiating oral antibiotics is recommended as soon as a dacryocystocele is identified to prevent infection of the dacryocystocele, which can occur in up to two thirds of these patients.[101] If the patient presents with signs of a dacryocele infection, admission to a pediatric intensive care unit for intravenous antibiotics is required. Surgical treatment with a nasolacrimal probing should be considered within the next 2 to 4 days.

Dry Eye

The normal newborn will have moist eyes from basal secretion of tears. Reflex tearing from ocular irritation or psychogenic (emotional) tearing may not develop for weeks to months after birth. Infants do not usually have symptoms from dry eyes unless in rare conditions such as alacrima from a congenital lack of tear glands or Riley-Day syndrome. Recognition of alacrima in the infant is important in preventing corneal abrasions, infections, and perforations, the inevitable sequelae of dry eye. During the first month of life, an infant with alacrima from any cause might not appear different from the normal infant because tear production is minimal during this period. The usual time of discovery is at 6 to 12 months of age after the lack of tears has produced changes such as scarring or ulceration of the cornea.

At 1 to 2 months of age, early symptoms of dry eye are conjunctival hyperemia and photophobia. Instead of the ample tears expected with conjunctival irritation, a sticky mucoid secretion is produced, and the cornea shows punctate staining with fluorescein solution application. Treatment includes frequent use of artificial tears (as often as every 15 to 30 minutes), punctal occlusion, or tarsorrhaphy.

Isolated congenital lack of tears, usually bilateral, is a rare anomaly. The cause is unknown, but it has been suggested to result from hypoplasia of the lacrimal gland or from an absence of innervation of the lacrimal gland structures.

The ocular findings in familial dysautonomia (Riley-Day syndrome) are characteristic and can produce the initial criteria for diagnosis. They include alacrima and corneal anesthesia. These ocular changes and constriction of the pupil by instillation of 0.125% pilocarpine should establish the diagnosis. The onset of major systemic symptoms occurs when the child is about 2 years old. An abnormal swallowing mechanism, inappropriate blood pressure and respiratory control, decreased sensitivity to pain, deficient taste perception, and abnormal ocular findings in this syndrome are the result of sympathetic, parasympathetic, and sensory neuronal abnormalities. Additional ocular findings are myopia, anisometropia (different refractive error in the two eyes), exotropia, tortuosity of the retinal vessels, and occasionally ptosis. Familial dysautonomia results from a mutation in the *IKBKAP* gene encoding elongation protein 1, resulting in defective splicing.[66]

GLOBE ABNORMALITIES

Anophthalmia

Anophthalmia is a rare sporadic phenomenon in which there is total absence or a minute rudiment of the globe, and it can present either unilaterally or bilaterally. It occurs as a developmental failure of the optic vesicle. It is often accompanied by other congenital anomalies, such as central nervous system defects and mental retardation, and has been observed in isolation, in genetic defects (e.g., *SOX2, STRA6, PAX6* genes), and in chromosomal syndromes (e.g., trisomy 13).[96] Because lid formation does not depend on ocular formation, the lids are fully formed. However, the lids remain closed and can be partially fused, and they are smaller and sunken without the support of the eye.

Treatment involves reconstruction of the orbit to improve the appearance of the face. Plastic molds of the conjunctival sac of gradually enlarging sizes are used to stretch the lids and sac sufficiently to hold an ocular prosthesis. In unilateral situations, orbital reconstruction using tissue expanders can dramatically improve the overall facial appearance.

Cryptophthalmia

In cryptophthalmia, the eyelids fail to cleave, and uninterrupted skin runs from the forehead to the malar area. The eyelids and eyelashes usually are absent; however, the eye can be palpated beneath the skin and might even be observed to move with the stimulation of a strong light.

The anterior segment of the eye is invariably disorganized into fibrovascular tissue adherent to the subcuticular tissue of the lids. Because the conjunctival sac is absent or small, attempts to separate the lids from the ocular structures are usually unsuccessful, and surgical correction is not advisable

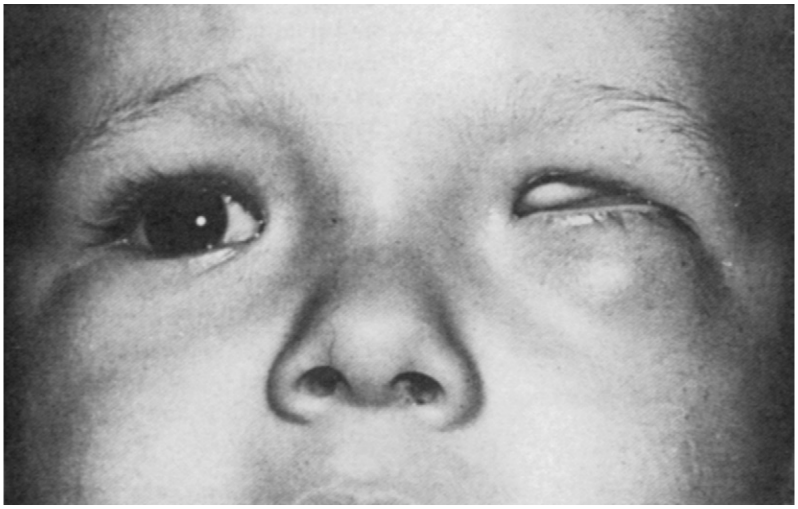

Figure 53–9. Congenital microphthalmia with a large cyst of the left eye.

in most circumstances. Although a globe is present, only rarely is vision obtainable.

Cryptophthalmia is frequently associated with systemic abnormalities such as urogenital malformations (Fraser syndrome) linked to defects of the *FRAS1* and *FREM2* genes, and a thorough genetic evaluation is indicated.[37,95]

Microphthalmia

Microphthalmia describes a variety of conditions in which the axial length of the neonatal eye is less than two thirds of the normal 16 mm. Causes include familial, syndromic, and chromosomal abnormalities and environmental influences during gestation. Simple microphthalmia is a condition in which there is an abnormally small eye but with intact internal organization. It may be associated with other ocular features of importance: a high degree of hypermetropia, retinal folds, a tendency for choroidal effusions, and the late occurrence of glaucoma.[98]

Complex microphthalmia describes small eyes with internal disorganization, such as anterior segment dysgenesis, cataract, coloboma, or persistent fetal vasculature.[97] Colobomatous microphthalmia occurs when the embryonic cleft of the optic vesicle fails to close. Typically, this form is associated with other ocular anomalies such as colobomas of the iris, ciliary body, fundus, or optic nerve, or colobomatous orbital cysts.

Microphthalmia can also be associated with other ocular and systemic syndromes, including intrauterine infections such as rubella and cytomegalovirus, craniofacial anomalies, anterior segment dysgenesis syndromes, or chromosomal abnormalities. Because of the heterogenicity of associated findings, infants with microphthalmia should be evaluated by both an ophthalmologist and geneticist.

Large Eye

An abnormally enlarged eye in the neonatal period is rare but is extremely important to recognize. An apparently enlarged eye may be caused by colobomatous microphthalmia with an associated large cyst (Fig. 53-9), congenital megalocornea (see later), or congenital glaucoma (see later). Colobomatous microphthalmia results when the embryonic optic vesicle fails to close. Tissue that originally should have become intraocular is encased in a cystic structure outside the eye in the orbit. If the cyst becomes sufficiently large that proptosis occurs, the microphthalmic eye simulates an enlarged eye.

SCLERA ABNORMALITIES

The normal term neonate has a glistening white sclera. The overlying conjunctiva and the conjunctival vessels superimpose a filmy, vascular pattern. A generalized bluish discoloration of the underdeveloped sclera is normal in premature infants. Rarely, a congenital weakness in a small area of the sclera produces a bluish bulge called a *staphyloma*. The light-blue color is caused by thinness of the sclera that transmits the darker color of the underlying uveal tissue. Osteogenesis imperfecta may be associated with a similar bluish discoloration of the sclera in the term neonate because of inadequately developed scleral collagen. Blue sclera may also be seen in other systemic diseases such as Marfan syndrome, Ehlers-Danlos syndrome, and Crouzon syndrome.

Pigmentation of the conjunctiva and sclera is common in darkly pigmented people. Intrascleral nerve loops appear as darkly pigmented dots about 3 to 4 mm from the limbus. Congenital ocular melanosis and oculodermal melanosis (nevus of Ota) occur as a unilateral slate-blue pigmentation in infancy.

CORNEA ABNORMALITIES

Cloudy Cornea

The normal premature infant might have a slightly hazy cornea for the first few weeks of life, caused by temporary excess hydration of the cornea. In the normal term infant, a similar appearance may be seen for the first 48 hours after delivery.

A persistently hazy or cloudy cornea suggests congenital glaucoma or birth injury. Anterior segment dysgenesis syndromes, corneal dystrophies, infection, or systemic disease should also be considered.

Enlarged Cornea

Most newborn infants have a corneal diameter of about 9 to 10 mm. If this measurement exceeds 12 mm, congenital glaucoma must be considered, especially if corneal haze, tearing, and photophobia are present.

Megalocornea is an enlarged cornea exceeding 13 mm in diameter. The cornea is usually clear, with distinct margins and thin iris stroma. There are no other features of congenital glaucoma, such as elevated intraocular pressure, tearing, photophobia, or conjunctival injection. Megalocornea as an isolated finding is usually inherited in an autosomal dominant manner. Megalophthalmia, which is commonly inherited as an X-linked recessive trait, is characterized by deep anterior chambers, subluxation of the lens, hypoplastic iris, and cataract formation in early adult life.

A corneal diameter of less than 10 mm may be an isolated finding or may be associated with other ocular anomalies. Cases of autosomal dominant and recessive inheritance of microcornea have been described.

Anterior Segment Dysgenesis Syndromes

A wide spectrum of clinical findings is observed in the anterior segment dysgenesis syndromes, including abnormalities of the cornea, anterior chamber, iris, and lens. Corneal opacities, adhesions of the iris, and glaucoma can occur. Although a continuous spectrum of findings can be evident in a family pedigree, or between the two eyes of one patient, eyes are often assigned into the distinct subgroups of posterior embryotoxon, Axenfeld anomaly, Rieger anomaly, or Peters anomaly.

Corneal Dystrophies

Most corneal dystrophies become apparent in adolescence or early adult life. However, congenital hereditary endothelial dystrophy may be present at birth. This condition is characterized by bilateral cloudy corneas, normal corneal diameter, and normal intraocular pressure. Early cornea transplantation may be helpful, but the prognosis is guarded.

Corneal Manifestations of Systemic Disease

Corneal opacities and haze can occur because of inborn errors of metabolism. Most are not associated with corneal opacities in the neonatal period. Systemic diseases that cause corneal opacities include the mucopolysaccharidoses, mucolipidoses, Fabry disease, hypophosphatasia, cystinosis, and Wilson disease.

CONGENITAL GLAUCOMA

Although congenital glaucoma is uncommon, the devastating effects of uncontrolled ocular pressure are sufficiently important to keep this disease uppermost in the mind of the examining physician. The classic symptoms of congenital glaucoma include epiphora, photophobia, and blepharospasm. As the disease progresses, the increased intraocular pressure produces stretching of the eye, creating an increased corneal diameter greater than 12 mm (buphthalmos, Fig. 53-10), cloudy cornea, progressive myopia, and loss of vision. Symptoms can be apparent at birth or weeks to months later.

Congenital glaucoma can occur as a primary disease or secondary to numerous other ocular conditions or systemic syndromes. A list of diseases associated with congenital glaucoma is shown in Box 53-3.

In addition to visual impairment from glaucomatous damage, amblyopia from visual deprivation or anisometropia can prevent a successful visual outcome. The prognosis depends on the age of onset, time to diagnosis, and associated ocular and systemic conditions.

IRIS ABNORMALITIES

Aniridia

Aniridia (absence of the iris) is a rare congenital anomaly, usually bilateral, that is almost invariably associated with poor vision and nystagmus. A small rudimentary cuff of peripheral iris can be observed grossly or microscopically. Associated ocular findings include glaucoma, corneal pannus, cataract, abnormal optic discs, and foveal hypoplasia. Because the fovea subserves our best vision, its maldevelopment causes the nystagmus and poor visual acuity.

Aniridia is caused by a defect in the *PAX6* gene on chromosome 11 at 11p13.[33] *WAGR* syndrome, a contiguous gene syndrome, results from a larger deletion in the area that involves the Wilms tumor gene (*WT1*), and includes Wilms

tumor, aniridia, genitourinary abnormalities, and mental retardation.[22]

All infants with nonfamilial aniridia should undergo chromosomal analysis to detect small deletions; if a deletion exists, the infant should be carefully monitored for early detection of Wilms tumor.[49]

Coloboma

Iris coloboma is one of the most common congenital abnormalities of the eye. It can occur as a single ocular finding, have a mendelian mode of inheritance, be associated with a chromosomal abnormality, or be associated with other malformation syndromes (Box 53-4). Typical colobomas occur in the inferonasal quadrant, where the embryonic fissure closes (Fig. 53-11). Because typical iris colobomas result from an abnormal closure of the embryonic fissure, they also may be associated with a coloboma of the ciliary body, fundus, or optic nerve. Associated microphthalmia is common. When the optic nerve or macula is involved in the coloboma, visual difficulty occurs. It is always wise to evaluate the fundus for a pathologic condition when an iris coloboma is detected.

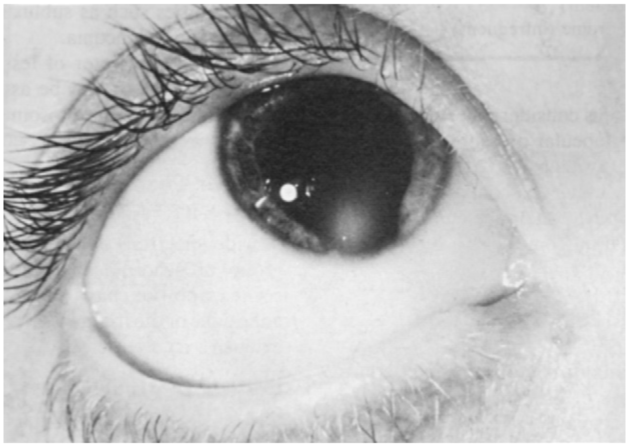

Figure 53–11. Typical iris coloboma with an inferonasal iris defect.

Atypical iris colobomas occur away from the inferonasal quadrant. Atypical colobomas, which vary from a small notch in the pupil to the absence of an entire segment of the iris, are not usually associated with visual difficulties.

Coloboma of the iris, uvea, or retina, with or without microphthalmia, is a feature of CHARGE association.

Persistent Pupillary Membrane

Persistent pupillary membranes are common in the neonate, particularly in the premature infant. The membranes are remnants of the anterior fetal vascular supply of the lens that failed to atrophy in the seventh month of gestation. If these persistent vessels adhere to the lens, a localized cataract can form.

Iris Heterochromia

Heterochromia indicates a difference in pigmentation in the irides. For example, one eye may have a blue iris, and the other iris may be brown; or one iris may have a wedge of lighter or darker pigmentation. The heterochromia itself does not affect ocular health or vision but may secondarily result from other pathologic ocular conditions, such as trauma or inflammations.

Heterochromia can occur as an isolated autosomal dominant trait. It also is associated with several syndromes such as Waardenburg syndrome. Congenital Horner syndrome produces heterochromia, usually after the neonatal period, resulting from the failure of normal pigmentation to develop in the iris on the sympathetically denervated side. Aganglionic megacolon (Hirschsprung disease) can also be associated with iris heterochromia.

ABNORMAL RED REFLEX

This is one of the most important abnormalities that requires immediate evaluation. The term *leukocoria* is used to describe a white pupil seen by the naked eye or during the red reflex test. Leukocoria is not a diagnosis but rather a description of an observation. Because the infant sleeps much of the time and because the pupils are small, a white pupil often is not noticed until the infant becomes more alert and active. False-positive red reflex test results are commonly due to small pupils, shifting gaze, limited patient cooperation, poor illumination from the ophthalmoscope, and examiner inexperience. Regardless, these patients should be over-referred to the ophthalmologist to ascertain the true-positive results.

Causes of leukocoria in infants include opacities of the cornea, lens, and vitreous, as well as retinal diseases such as retinoblastoma, chorioretinal coloboma, persistent hyperplastic primary vitreous, endophthalmitis, Coats disease, congenital retinal fold, retinoschisis, or scarring from ROP.

Abnormal red reflexes can also result from misaligned eye or from high or asymmetric refractive errors.

LENS ABNORMALITIES

Cataract

The size and shape of a cataract depends on the area of the lens that is being formed at the time the damage or developmental defects occur. The lens grows continuously during life, laying down new lens fibers on its external surface much as an onion does. Damage that occurs in the early embryonic period produces opacifications in the center of the lens. Such nuclear cataracts have clear layers in the periphery of the lens. Later periods of damage produce ringlike opacifications surrounded by central and peripheral clear areas (zonular cataracts). Recent damage produces peripheral opacifications near the surface of the lens (cortical cataracts). Dense opacities near the central axis cause greater visual disturbance, especially if they are located in the central visual axis.

Cataracts may be grouped according to cause: idiopathic, genetic, viral, inborn errors of metabolism, trauma, association with other eye malformations, and generalized syndromes. However, most congenital cataracts are genetic or isolated and idiopathic. A list of causes of juvenile cataracts is shown in Table 53-3.

Genetically determined cataracts often are isolated abnormalities and bilateral. Many genetic loci have been mapped.[80] The lens opacities are often present at birth but occasionally become evident later in childhood. The primary mode of transmission is autosomal dominant. Recessive transmission and X-linked transmission have been recorded. Because there is variable expressivity, parents should be examined for mild cataracts.

The rubella embryopathy syndrome is rare in the era of rubella vaccination but is still seen in developing countries. The syndrome comprises multiple congenital anomalies that result from maternal viremia during the first trimester of pregnancy. Cataracts are present in about 20% of children with the congenital rubella syndrome (Fig. 53-12). The rubella virus may remain dormant in lens material in the offspring for as long as several years. Microphthalmia, pupil abnormalities, congenital glaucoma, and anterior uveitis also may result. A cloudy, edematous, or white cornea may be found with normal intraocular pressure as part of the rubella embryopathy. Rubella retinopathy is a pigmentary disturbance of the retina without demonstrable effect on visual function. A TORCH (*t*oxoplasmosis, *o*ther agents, *r*ubella,

Rieger anomaly	Infrequent

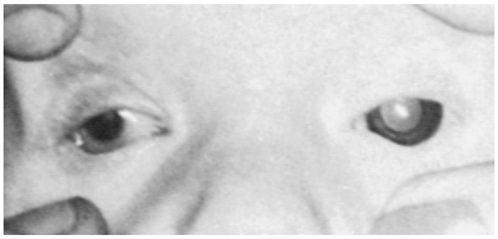

Figure 53–12. Congenital rubella syndrome with a cataract of the left eye, microphthalmia of the right eye, and exotropia.

*c*ytomegalovirus, *h*erpes simplex) titer should be obtained from all infants with nongenetic congenital cataracts.

Galactosemia is a hereditary inborn error of metabolism with deficiency of the enzymes responsible for galactose metabolism: galactose-1-phosphate uridyltransferase, galactokinase, or uridine diphosphategalactose-4-epimerase. The affected neonate may appear normal at birth. Cataracts usually develop during the first 2 months of life. The cataracts may be zonular or may appear as vacuoles (classically described as "drop of oil") in the center of the lens owing to an accumulation of galactose and galactitol. Early diagnosis and a regimen of a galactose-free diet can prevent development or further progression of cataracts.

All congenital forms of infantile cataracts require a prompt evaluation by an ophthalmologist. Dense cataracts are treated surgically to prevent irreversible amblyopia and strabismus. Removal of the lens, followed by optical correction and amblyopia therapy, provides the best hope of restoring vision. The prognosis for vision is poorer in the involved eye when the cataract is monocular. Intraocular lens implantation, especially in older infants, is often used to restore the focusing ability of the eye.[83] Long-term follow-up is necessary to monitor vision development, treat strabismus and amblyopia, and detect glaucoma.

Subluxed Lens

The discovery of a subluxed lens (ectopia lentis) in an eye helps in identifying systemic disease processes associated with this abnormality. Although lens dislocation may be present during the neonatal period, it typically develops in the first or second decade of life. Marfan syndrome is the most common cause, but homocystinuria, sulfite oxidase deficiency, hyperlysinemia, Ehlers-Danlos syndrome, Weill-Marchesani syndrome, and trauma can also produce this finding. There is also an isolated genetic form. The dislocation results from a laxity, absence, or defect of the zonular attachments that suspend the lens from the ciliary body. A subluxed lens usually is not treated during the neonatal period unless there is the complication of cataract formation or glaucoma.

By dilating the pupil, the examiner can visualize the edge of a dislocated lens in the pupillary space (Fig. 53-13). Ectopia lentis may also be suggested by iridodonesis (shaking of the iris), which occurs when the posterior surface of the iris lacks the normal support of the lens.

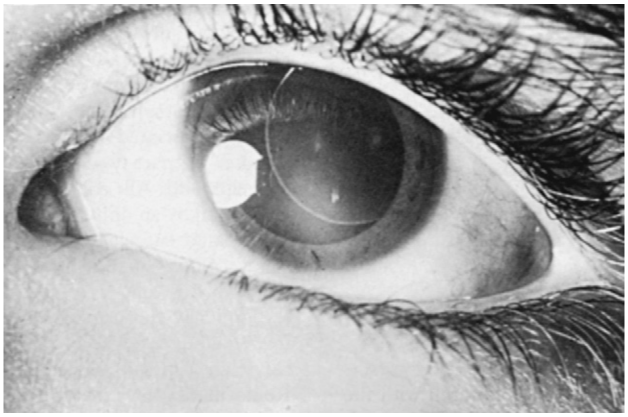

Figure 53–13. Ectopia lentis (dislocated lens) of the left eye.

RETINAL AND VITREOUS DISEASES

During the neonatal period, nonvascular structures of the fundus are nearly transparent because uveal pigmentation is not fully developed. The neonatal retina does have a sheen to its inner surface, but the macular region appears flattened. Retinal transparency is disturbed when abnormalities are present. The retina resembles a pale, ghostlike sheet when it is detached. Retinal edema gives a slightly raised, opalescent appearance. Infection obscures the underlying structures with a fuzzy, white thickening of the retinal tissue. In pathologic processes characterized by a lack or an excess of pigment, retinal abnormalities may become evident only after the first few months of life. The choroid is the deepest layer normally visible with the ophthalmoscope. Pathologic processes that prevent its development or that destroy areas of choroid expose areas of bare sclera, which appear glistening white.

Persistent Hyperplastic Primary Vitreous

Persistent hyperplastic primary vitreous (PHPV), also known as *persistent fetal vasculature*, is a congenital anomaly that produces a white pupil usually evident at birth. It results from the failure of the embryonic vitreous to regress. The embryonic vitreous system develops as a complex network of vessels that grows anteriorly from the disc to surround the developing lens, and normally involutes during the third trimester.

At birth, PHPV may appear as a strand or plaque of white tissue immediately behind a clear lens. Vessels are frequently seen to radiate from the plaque's center, and the retrolental mass may therefore be pinkish white. When the pupil is dilated, the ciliary processes are often drawn centrally along the posterior surface of the lens toward the central mass.

Almost always unilateral, PHPV occurs in term infants without a history of oxygen therapy. The involved eye is commonly microphthalmic. The anterior chamber is shallow owing to fibrous contraction of the primary vitreous, which pulls the ciliary body centrally, forcing the lens forward. With continued organization and contraction of the primary vitreous, the lens capsule may be involved, and a cataract may form. At this stage in the development of the disease, glaucoma, posterior chamber hemorrhages, or hemorrhages into the lens may occur. Retinal detachment occurs in the final stages, with continued vitreous traction. Persistent hyperplastic primary vitreous should be suspected in the neonate with a rapidly progressive unilateral cataract.

Differentiation of PHPV from ROP is usually possible because of the unilateral involvement and occurrence of PHPV in a term infant. Differentiation from retinoblastoma is important. The absence of calcification within the eye, as occurs in retinoblastoma, is a critical finding. A persistent embryonic iris vessel or one that notches the pupil suggests the presence of PHPV, even when an opaque lens obscures its presence. CT, MRI, and ultrasound can help in the diagnosis of difficult cases. Surgical removal of the lens and vitreous with optical correction and amblyopia treatment must be attempted very early to achieve any degree of success in recovering vision.

Retinal Dysplasia

Retinal dysplasia is a usually bilateral, congenital anomaly of term infants showing congenital retinal folds and retinal detachments. Histopathologically, the retina shows disorganization and dysplasia. The retinal detachments may clinically resemble a mass and should be considered in the differential diagnosis of retinoblastoma. Rather than a distinct clinical entity, retinal dysplasia may represent a common final pathway of many different developmental disorders of retinal differentiation and organization. Retinal dysplasia can occur as part of a group of congenital anomalies—including defects of the central nervous system, cardiovascular system, and skeletal system—that are sufficiently severe to produce early death of the infant. Specific conditions that result in retinal dysplasia include trisomy 13, Norrie disease, and Walker-Warburg syndrome.

Norrie Disease

A rare genetic disorder transmitted as an X-linked recessive trait, Norrie disease is characterized by the presence of bilateral total retinal detachments that result in a white pupil. Organization of the retinal detachment can disrupt the lens, producing cataract, or can affect the anterior chamber angle, producing congenital glaucoma. The usual result is atrophy of the globe. Norrie disease maps to the *NDP* gene on chromosome Xp11.4, most commonly due to mutations of the cysteine-knot motif.[102] Patients with Norrie disease may also develop progressive mental disorders often with psychotic features, and about one third of patients develop sensorineural deafness.

Mutations of the *NDP* gene away from the cysteine-knot motif often result, not in Norrie disease, but in a clinically distinct entity termed *familial exudative vitreoretinopathy* (FEVR). FEVR is characterized by avascularity of the peripheral retina, abnormal retinal neovascularization, retinal traction, and detachment. FEVR is actually a genetically diverse disorder, having been also mapped to the *FZD4* and *LRP5* genes, both of which encode for receptors for the *NDP* gene product.[7]

Retinoschisis

Retinoschisis is a hereditary abnormality in which the superficial layers of the retina are split from the deeper layers and are elevated into the vitreous. This splitting creates a veil-like appearance in front of the retina. Visual function is absent in the affected tissue. Juvenile X-linked retinoschisis is a progressive, degenerative disorder that has an X-linked recessive transmission. Macular changes and vitreous hemorrhages can occur as associated findings. Both lead to loss of vision. Early diagnosis offers a better chance in improving prognosis.

Leber Congenital Amaurosis

Leber congenital amaurosis often produces symptoms of blindness shortly after birth. Children with this disorder sometimes rub or poke their eyes excessively, called *blindism* behavior. Nystagmus usually appears after a few months. The fundus often has a normal appearance in the neonatal period. Electroretinography is a diagnostic test that measures the electrical responses of the photoreceptors to light stimulation and can confirm the severely deficient retinal function in this disorder. Leber congenital amaurosis is most commonly transmitted as an autosomal recessive disease and represents a similar phenotype in response to many different known genetic defects.[30]

Albinism

The diagnosis of albinism in the neonatal period is difficult to substantiate because the uveal pigment is underdeveloped during this period. The diagnosis may be suggested when pigmentation of the skin, hair, and irises fails to progress during the first several months in comparison with that of parents and siblings. Lack of pigmentation is more apparent earlier in darker races. The fundus remains blonde, and choroidal vessels are prominent. Photophobia, nystagmus, and abnormal transillumination of the irides are characteristic features of albinism. Moderately to severely reduced vision is characteristic as a result of foveal hypoplasia.

Chorioretinal Coloboma

A coloboma of the fundus is visible as a defect in the retinal and choroidal layers through which the underlying sclera is visible. Leukocoria may result. Typical coloboma occur inferonasally, which is the site of the closure of the embryonic fissure. The fissure usually begins to close at the globe's equator and then extends posteriorly toward the optic disc and anteriorly toward the periphery. Any part or all of this region may be involved in the colobomatous defect. The visual prognosis depends on how much of the macula or optic disc is involved.

Abnormal Macula

Several of the lysosomal storage diseases alter the appearance of the macula, a fact that may be useful in detecting these disorders (Table 53-4). The stored material accumulates in

TABLE 53–4 Neonatal Macular Changes

Condition	Defect
Tay-Sachs disease	Cherry-red spot
Niemann-Pick disease	Cherry-red spot
GM1 gangliosidosis	Cherry-red spot
Neuraminidase deficiency	Cherry-red spot and corneal clouding
Farber disease	Gray macula
Best vitelliform degeneration	Cystic macula (rare)
Toxoplasmosis	Chorioretinal scar
Coloboma	Absence of retina and choroid

the ganglion cells of the retina, which decreases the transparency of the retina except at the very center of the macula, where no ganglion cells exist. The center of the macula retains its normal cherry-red appearance, in sharp contrast to the surrounding grayish involved fundus.

Sphingolipidoses that may produce a cherry-red spot are Tay-Sachs disease, in which a cherry-red spot may be present shortly after birth or may develop during the first year, and Niemann-Pick disease (infantile), in which about 50% of patients have a cherry-red spot in the macula during the neonatal period. Of the lipidoses, Farber disease shows a grayish discoloration of the macula at 6 to 8 weeks of age, and GM1-gangliosidosis demonstrates a cherry-red spot in the macula in about 30% of patients before 2 months of age. The mucopolysaccharidoses are characterized by the abnormal deposition of mucopolysaccharides in the cornea, but the macula appears normal.

Persistence of Hyaloid Artery

Persistence of the central hyaloid artery is a common but clinically insignificant developmental abnormality. Its presence in the premature infant is sufficiently common to be considered normal. It is most often seen as a fine thread of nearly transparent tissue extending from the optic disc toward the posterior surface of the lens; it rarely may be patent and contain blood. The artery commonly continues to atrophy during the neonatal period, with rare persistence into adulthood.

Bergmeister Papilla

The persistence of the mesodermal supporting elements of the hyaloid vascular system at the disc might leave a small protuberance of gray-white tissue extending from the disc forward into the vitreous—a so-called Bergmeister papilla. A small retinal artery might course into this area and return to the disc before supplying the retina, or the papilla may be associated with one or several small, round, pearl-gray cysts of glial tissue. Vision and optic nerve function are unaffected.

Myelinated Nerve Fibers

Normal myelinization of the optic nerve fibers occurs in fetal development in reverse direction to the growth of the axons themselves. Development of myelin sheaths progresses from the geniculate bodies through the optic tracts, optic chiasm, and optic nerves to end just posterior to the optic disc. This process is usually complete at birth or within the first month of life.

Myelination of the nerve fibers occasionally proceeds aberrantly through the disc and into the retina, seen as a glistening white, opaque area involving the peripapillary retina. The edges of the myelinated areas are feathered, and the involved areas are sometimes arcuate. This process is stable after the first several months of life, and vision is unimpaired except for an enlarged blind spot or scotoma of the involved retinal area. Small areas may sometimes be confused for the cotton-wool spots seen in retinal vascular diseases. A large area of myelinated nerve fibers may result in leukocoria.

OPTIC DISC ABNORMALITIES

The optic disc should appear flat and pink, even in the newborn. Mild degrees of pallor or hypoplasia can be difficult to establish in the neonate because of a lack of patient cooperation with the examination. Disc margins should, however, be clear and distinct. The sharp margins of the optic disc are created by the abrupt ending of the choroid and retinal pigment epithelium at the disc borders. Occasionally, as a variation of normal, these structures fail to extend to the immediate edge of the disc, creating a peripapillary crescent of visible underlying sclera. This crescent is sometimes bordered by a darkly pigmented line.

Coloboma of the Optic Disc

Coloboma of the optic disc is another manifestation of failure of the globe's embryonic fissure to close adequately, in this case at its posterior limit. The optic disc might appear enlarged and elongated, usually inferiorly. The coloboma may include adjacent retina and choroid. The blood vessels may be distributed normally, or they may be displaced to the periphery of the optic disc and appear disorganized. Colobomas of the optic disc often are associated with defective vision, but the appearance of the optic disc does not correlate with potential acuity. Coloboma of the optic nerve should be differentiated from optic nerve cupping due to glaucoma, requiring a more extensive evaluation by an ophthalmologist and consideration of associated genetic syndromes.

Morning Glory Disc Anomaly

Morning glory disc describes a congenital anomaly of the optic disc showing a colobomatous-like excavation of the optic disc but with the additional findings of central glial hyperplasia, peripapillary depigmentation, and anomalous retinal vasculature. It can be distinguished from other congenital optic disc lesions, such as optic nerve coloboma, by pattern recognition. Morning glory discs can be associated with intracranial and systemic disorders such as basal encephalocele, agenesis of the corpus callosum, and moyamoya disease.[48]

Optic Pit

The surface of the optic disc occasionally shows a sharply defined hole or pit. This pit usually is situated near the lower temporal quadrant of the optic disc at its border and can vary in size, shape, and depth. It is thought to be a minimal expression of an optic disc coloboma. Visual defects may be present with this finding.

Oblique Discs

The optic nerve commonly enters the posterior aspect of the eye from a slightly nasal angle. If this angle is accentuated, the nerve head or disc may be tilted obliquely, with its temporal margin considerably more posterior than its nasal margin. This gives the optic disc an ovoid appearance.

Optic Nerve Hypoplasia

Hypoplasia of the optic nerve is a congenital anomaly in which there are a reduced number of axons within an optic nerve. The optic disc is smaller than normal and may be pale, but the retinal vessels usually are normal. A hypopigmented ring around the hypoplastic nerve creates the double-ring sign. Optic nerve hypoplasia can occur unilaterally or bilaterally. Visual impairment can range from mild to severe. In bilaterally severely affected patients, the nystagmus that develops makes the retinal and optic nerve examination difficult.

Optic nerve hypoplasia can occur as an isolated finding or in association with other ocular or systemic abnormalities. CT or MRI of the brain can reveal midline abnormalities, a disorder referred to as *septo-optic dysplasia* (de Morsier syndrome) if there is absence of the septum pellucidum. Endocrine abnormalities can occur in patients with this syndrome because of coexisting defects of the infundibulum or pituitary gland.[39] Neonatal hypoglycemia has been reported in these patients resulting from growth hormone deficiency.[73]

Most cases of optic nerve hypoplasia occur sporadically and idiopathically. Minor associations include young maternal age, nulliparity, maternal diabetes, fetal alcohol syndrome, or other maternal ingestions.[93]

Optic Nerve Atrophy

Optic nerve atrophy is a condition in which the nerve fibers have formed and subsequently atrophied in response to some insult. The optic disc shows regional or diffuse pallor, but has a normal size and configuration. Significant visual impairment is common and may be associated with nystagmus if the atrophy occurs before 6 months of age. The most common cause in the infant is perinatal hypoxia. Many other causes have been described (Box 53-5).

BOX 53–5 Causes of Childhood Optic Atrophy

- Compressive intracranial lesions
- Compressive bony disorders
  - Craniosynostosis
  - Fibrous dysplasia
- Hydrocephalus
- Post–papilledema optic atrophy
- Infectious
- Hereditary
  - Leber hereditary optic neuropathy
  - Dominant optic atrophy (Kjer)
  - Recessive optic atrophy
  - Behr optic atrophy
  - DIDMOAD (diabetes insipidis, diabetes mellitus, optic atrophy, deafness) (Wolfram) optic atrophy
- Toxic or nutritional optic neuropathy
- Hypoxia
- Trauma
- Postoptic neuritis
- Radiation optic neuropathy
- Paraneoplastic syndromes
- Neurodegenerative disorders with optic atrophy
  - Krabbe disease
  - Canavan disease
  - Leigh disease
  - Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like (MELAS) episodes
  - Neonatal adrenoleukodystrophy
  - Metachromic leukodystrophy
  - Riley-Day syndrome
  - Lactic acidosis
  - Spinocerebellar degeneration
  - Mucopolysaccharidosis
- Ocular disorders
  - Glaucoma
  - Retinal disease
  - Vascular disease
  - Uveitis
  - Optic nerve hypoplasia

PUPIL ABNORMALITIES

Abnormalities of the pupil can result from structural disease of the iris or from neurologic abnormalities. Neurologic abnormalities may be described in terms of pupil size (i.e., miosis or mydriasis) or abnormal function.

Miosis can result from paralysis of the sympathetic pathways, as in Horner syndrome, or from irritation of the parasympathetic pathways, as in central nervous system inflammation.

Mydriasis most often is caused by a paralysis of the parasympathetic pathways, which can occur in third-nerve palsy or with increased intracranial pressure. Local trauma, such as that caused by a difficult forceps delivery, can also damage the iris sphincter and result in mydriasis.

Anisocoria describes a difference in the size of the two pupils. When this condition is seen, the physician should examine the patient in bright and dim illumination to determine the abnormal pupil. If more anisometropia is evident in dim light, the pathologic pupil is the more miotic pupil because this pupil has failed to fully dilate. If more anisometropia is evident in bright light, the pathologic pupil is the more mydriatic pupil because this pupil has failed to fully constrict. Many infants have a small degree of “physiologic” anisocoria.[76]

A relative afferent pupillary defect, as detected by the swinging flashlight test, occurs when an optic nerve defect is present anterior to the lateral geniculate body.

NEUROMUSCULAR ABNORMALITIES

Strabismus

Strabismus refers to any type of ocular misalignment or inability to move the eye fully. Various classification schemes have been proposed to help organize the different forms to aid diagnosis and treatment. We favor a system that considers etiology in the first order of the classification scheme. These etiologic groups include the following:

Comitant strabismus—sometimes referred to as *benign childhood strabismus*. This is the most common type of strabismus, with onset typically from 4 months to 6 years of age. The globes, extraocular muscles, and cranial nerves to the eye are normal. The cause is idiopathic, but the fault lies in purported central nervous system ocular alignment centers.

Sensory strabismus—the oculomotor system requires a certain level of vision in both eyes to maintain ocular alignment. If vision is lost in one or both eyes, an ocular misalignment may follow.

Paralytic strabismus—resulting from lower motor neuron lesions of the third, fourth, or sixth cranial nerve.

Restrictive strabismus—resulting from lesions within the orbit that limit free movement of the extraocular muscles; for example, orbital blow-out fractures and orbital tumors

Syndromic strabismus—this group includes a variety of entities, each with distinct and stereotypical patterns, with causes that may overlap the aforementioned four groups, such as for Duane syndrome and Brown syndrome.

Central nervous system strabismus—due to lesions of the oculomotor pathways above the level of the lower motor neuron[9]

Small horizontal ocular misalignments, but with full right and left gaze movements, are a common transient feature of infancy. Persistent abnormalities in alignment beyond 3 to 4 months of age should be referred for a complete ophthalmic assessment.[4] A more prominent strabismus and a lack of full movement of an eye are suggestive of a congenital palsy of the extraocular muscles, typically a lower motor neuron lesion of the sixth or third cranial nerve.

Pseudostrabismus is present in infants who appear cross-eyed because the bridge of the nose is wide and the epicanthal folds cover some of the medial sclera. True strabismus is excluded when the corneal light reflex is found to be symmetrically placed in both pupils and alternate cover testing reveals no deviation. It is important to remember that epicanthal folds may exist with true esotropia, and if there is an intermittent esotropia, the eye may be straight on one examination. Infants with severe ROP causing a dragging of the macula may appear to have strabismus when the dystopic maculae are aligned.

Treatment of strabismus begins with a complete ocular examination and a careful cycloplegic refraction. Treatment includes prevention of amblyopia, reconstruction of the normal ocular alignment and movement, and development of binocular vision. The chances of diagnosing and successfully treating amblyopia and strabismus are better the earlier therapy is begun. Treatment should be undertaken well before the child is of school age to eliminate a visual or cosmetic disability.

Nystagmus

Nystagmus refers to an oscillation of one or both eyes. It may be horizontal, vertical, or torsional (rotary). Nystagmus is described by its waveform, direction, rate, amplitude, laterality, and intensity in different positions of gaze.[8] The most common types of nystagmus are pendular and jerk nystagmus. Pendular nystagmus is a to-and-fro movement of the eyes of equal amplitude and velocity in both directions. Jerk nystagmus is characterized by a slow component in one direction and a fast component in the opposite direction. Patients may maintain an abnormal head posture as an adaptation to the nystagmus.[1]

Physiologic nystagmus, usually a jerk nystagmus, may be seen in several situations. The optokinetic phenomenon of a target moving past the eyes causes a slow-moving component as the eyes fixate on an object, followed by a rapid refixation movement in the opposite direction. Vestibular nystagmus occurs with rotation of the body or with irrigation of the ear, causing a movement of the fluid within the semicircular canals. Positional or end-gaze nystagmus is seen in extreme gaze, usually in a horizontal direction.

Pathologic forms of nystagmus can result from ocular, neurologic, or vestibular defects. If onset is before 6 months of age, it is classified as congenital nystagmus; later onset is classified as acquired. Nystagmus due to ocular pathology (termed *sensory nystagmus*) results from a primary, profound bilateral loss of vision in an infant younger than 6 months. It can be caused by a lesion in the eyes or in the pathways leading back to the lateral geniculate. Common ocular defects causing sensory nystagmus include optic nerve hypoplasia or atrophy, macular scars, retinal disorders, cataracts, aniridia, and albinism.[50] Infants born blind typically start to show sensory nystagmus at 1 to 2 months of age.

Nonsensory congenital nystagmus (commonly called *motor nystagmus*) requires a workup that includes central nervous system imaging and a neurologic evaluation to exclude an identifiable etiologic lesion. Most cases of congenital motor nystagmus are either idiopathic in otherwise neurologically intact infants or familial.

An interesting form of benign acquired nystagmus, called *spasmus nutans*, usually develops within the first 2 years of life and disappears within months to several years after its onset. The nystagmus of spasmus nutans is often very fine and rapid and may be asymmetric or even monocular. The classic triad of spasmus nutans includes nystagmus, head nodding, and torticollis, although the diagnosis is often made when one or two of the features are absent. Optic pathways gliomas can have similar characteristics.[27] Careful follow-up is essential, and further diagnostic studies may be advisable.

AMBLYOPIA

Amblyopia is a decrease in vision in one or both eyes that is not caused by organic disease. This is a central process, an expression of brain plasticity, in response to any ocular condition that prevents a clear image from reaching the retina. The main causes are strabismus, refraction, occlusion, and deprivation. Amblyopia can develop at any time during the "sensitive period" of visual development, usually during the first 7 years in humans, and can be treated if discovered within this same time frame of plasticity.

Strabismic amblyopia occurs in children who first develop strabismus and then favor one eye. The constantly deviated eye will then develop amblyopia; hence, strabismic amblyopia is always unilateral. Refractive amblyopia results from large refractive errors that create significant blurry vision. This can be a bilateral or unilateral process. Occlusion amblyopia is caused by opacities in the visual axes, such as cataracts or corneal scars. Deprivation amblyopia is a special form of occlusion amblyopia in infants younger than 3 months. If the visual obstruction is not cleared by 3 or 4 months of age, the amblyopia becomes very dense and unresponsive to treatment—hence the urgency to identify and treat congenital cataracts.

Treatment of amblyopia is accomplished by patching or optically penalizing the better-seeing eye and prescribing the appropriate optical correction. The patching regimen is tapered as visual improvement is noted. If bilateral amblyopia is present because of high refractive error, glasses are prescribed.

EYE FINDINGS IN CHROMOSOMAL SYNDROMES

Any alteration of gene dosage often results in multiple systemic anomalies. Many ocular abnormalities have been reported in patients with chromosomal aberrations; often they are not diagnostic of a specific chromosomal syndrome. The following are examples of common chromosomal syndromes or defects associated with ocular findings of particular importance.

Trisomy 13

Ocular findings are very common in trisomy 13, with iris coloboma and underlying sectoral cataracts very suggestive of the syndrome. Other eye findings include hypotelorism, microphthalmia or anophthalmia, synophthalmia, colobomas of the iris or choroid, corneal opacities, persistent hyperplastic primary vitreous, retinal dysplasia, cataracts, and many low-incidence anomalies.[52]

Trisomy 18

Trisomy 18 is characterized by micrognathia, flexed fingers with the index finger overlapping the third finger, generalized hypertonicity of skeletal muscles, mental retardation, ventricular septal defect, umbilical hernia, rocker-bottom feet, and malrotation of the gut. Ankyloblepharon filiforme adnatum (strands joining the upper and lower lids together) are very suggestive of trisomy 18.[11] Other ocular abnormalities include retinal folds, cornea and lens opacities, ptosis, strabismus, epicanthal folds, abnormal orbital ridges, hypertelorism, microphthalmia, glaucoma, myopia, and congenital optic atrophy.

Trisomy 21

Down syndrome is a well-recognized entity comprising typical facies, mental retardation, small but obese habitus, large tongue, and cardiac, genitourinary, and gastrointestinal abnormalities. The ocular findings associated with this entity are extensive. They include epicanthus, hypertelorism, and upward slant of the palpebral fissures. Brushfield spots might be found on the unusually thin, lightly colored irises. Because strabismus, nystagmus, cataracts, glaucoma, high refractive errors, keratoconus, and blepharitis are also seen, children with Down syndrome should be examined by an ophthalmologist during infancy. Systemic or topical therapy with atropine may result in unusual and sometimes dangerous systemic responses in infants with Down syndrome.[61]

Turner Syndrome

Strabismus, ptosis, congenital cataracts, and occasionally corneal nebulae and blue sclerae in the neonatal period have been described associated with Turner syndrome.

11p Abnormalities

Infants with a deletion of the short arm of chromosome 11 involving the *PAX6* gene and the adjacent *WT1* gene on the 11p13 band have the WAGR syndrome of aniridia, genitourinary abnormalities, and mental retardation.[22] Wilms tumor has been diagnosed in a significant percentage of children with this chromosomal deletion and must be evaluated with periodic ultrasounds of the abdomen for a number of years.

13q Abnormalities

Patients with a deletion of 13q often have a characteristic facial anomaly with microcephaly, micrognathia, large malformed ears, a wide nasal bridge with hypertelorism, and protruding upper incisors. Other findings include urogenital, thumb, and congenital cardiac defects. Ocular abnormalities are almost always present and severe, including microphthalmia, iris and choroidal colobomas, ptosis, cataracts, and down-slanting palpebral apertures and epicanthus. However, the most important possible finding that requires a comprehensive retinal examination is retinoblastoma.

EYE FINDINGS IN CRANIOFACIAL SYNDROMES

Eye abnormalities associated with congenital anomalies of the face, skull, or head can occur as an isolated finding or in conjunction with well-recognized syndromes.

Craniosynostosis Syndromes

Premature closure of the cranial sutures can occur in the embryonic period or early childhood. The involved suture determines the shape of the skull because growth is inhibited perpendicular to the closed suture. Compensatory growth occurs at the open sutures and in weakened areas of the cranial vault. Premature craniosynostosis can exist as a primary isolated anomaly or may be associated with systemic or metabolic malformations. If more than one suture is involved, there is a greater chance for increased intracranial pressure resulting in papilledema or optic nerve atrophy.

Crouzon syndrome is an autosomal dominant craniosynostosis syndrome characterized by maxillary hypoplasia, shallow orbits, parrot-beak nose, moderate hypertelorism, highly arched palate, and a variety of abnormal skull conformations depending on the pattern of suture involvement. Ocular complications are stereotypic, mostly resulting from the abnormalities of the bony orbit or skull: shallow orbits, compression of the optic nerves, and papilledema from elevated intracranial pressure.[60] Visual acuity may be reduced because of amblyopia, optic nerve atrophy, or exposure keratitis.[92] Strabismus is common, as a mechanical limitation of ocular rotations within the abnormal orbit, or from anomalous or missing extraocular muscles. Shallow orbits produce exorbitism, leading to exposure keratopathy and globe subluxation. Eyelids may be ptotic or retracted. Midface abnormalities often result in symptomatic dacryostenosis. Infrequent anomalies include iris and corneal malformations, cataracts, and retinal pigmentary changes.

Because of similar cranial and orbital anomalies, eye findings can be similar in the other craniosynostosis syndromes such as Apert syndrome, Saethre-Chotzen syndrome, and Pfeiffer syndrome.[41,45]

Cornelia de Lange Syndrome

The typical facial appearance in infants with Cornelia de Lange syndrome is a low hairline, eyebrows that are joined in the middle (synophrys), long eyelashes, and a small upturned nose. Skeletal deformities ranging from syndactyly to phocomelia may be present. Eye disorders, which are less frequently encountered, include hypertelorism and downslanting palpebral fissures, dacryostenosis, strabismus, nystagmus, ptosis, severe myopia, and pupillary abnormalities.[65] Some patients with this diagnosis resemble children with fetal alcohol syndrome.

Hemifacial Microsomia

Hemifacial microsomia describes a group of patients with microtia, macrostomia, and mandibular anomalies. Most patients show unilateral involvement. Ocular manifestations can range from clinical anophthalmia to minor fissure asymmetry. Goldenhar syndrome is probably a variant of this group, with characteristic dermoids of the limbus (interface between the sclera and the cornea) or lipodermoids of the lateral canthal angle.[88] Limbal dermoids are reported more frequently than lipodermoids and are occasionally bilateral. Another common finding is an upper eyelid coloboma almost always on the more affected side. Less frequent findings are Duane syndrome and microphthalmia. Children with Goldenhar variant should have a comprehensive eye examination.

Hallermann-Streiff Syndrome

Oculomandibulofacial dyscephalia (Hallermann-Streiff syndrome) is characterized by hypoplasia of the mandible, a thin, prominent nose (parrot-beak nose), and congenital cataracts. Other common eye findings include spontaneous resorption of the crystalline lens, microphthalmia, and glaucoma.[6]

Terminal Transverse Defects with Orofacial Malformations and Oromandibular-Limb Hypogenesis

These are a heterogeneous collection of syndromes with a wide variety of facial and limb anomalies probably resulting from a variety of etiologies.[59] They include the aglossia-adactylia syndrome, Hanhart syndrome, ectrodactyly with orofacial malformations, ankyloglossia syndrome, Möbius syndrome, and a few others. The pattern of craniofacial anomalies noted in this complex includes oral and facial clefts, micrognathia, microglossia, pectoral muscle malformations with ipsilateral hand malformations (Poland syndrome), dental and oral anomalies, and hypoplastic limb anomalies. The minimal findings of Möbius syndrome are abduction weakness (sixth cranial nerve palsy) and facial nerve palsy, with frequent limb and tongue anomalies. Möbius syndrome has been reported frequently in South America following unsuccessful abortion attempts using misoprostol (Cytotec).[14]

Pierre Robin Sequence

The Pierre Robin sequence is characterized by micrognathia, glossoptosis, and cleft palate. Pierre Robin sequence can occur in isolation or in a variety of multiple-defect syndromes. About 10% of patients with Pierre Robin sequence have Stickler syndrome as well, with the additional features of high myopia, propensity for retinal detachment, cataracts, deafness, and arthritis.[20] Stickler syndrome is further subdivided into types 1 and 2, linked to defects of the genes *COL2A1* and *COL11A1*, respectively.[17]

Waardenburg Syndrome

Waardenburg syndrome is transmitted as an autosomal dominant trait and has been divided into four types based on clinical attributes. The most common is Waardenburg syndrome type 1. It is associated with lateral displacement of the medial canthi (i.e., telecanthus), abnormal position of the lacrimal puncta, coalescing of eyebrows, white forelock, heterochromia irides, retinal pigmentary changes, and sensorineural deafness.

EYE FINDINGS IN NEUROCUTANEOUS DISODERS

Sturge-Weber Syndrome

Port-wine stains (capillary angiomas or nevus flammeus) can occur in isolation or as a feature of Sturge-Weber syndrome, with the additional finding of leptomeningeal angiomas, hemiparesis, epilepsy, mental retardation, and other ocular problems.[71] Patients with port-wine stains of the upper or lower lids have a very high likelihood of having Sturge-Weber syndrome.[90] Ocular complications of Sturge-Weber syndrome include glaucoma and chorioretinal angioma. The associated choroidal angioma is usually indistinct and difficult to visualize without indirect ophthalmoscopy. If present, it may lead to macular edema and decreased visual acuity. There is no apparent hereditary pattern. Congenital glaucoma frequently occurs and can lead to blindness.

Neurofibromatosis Type 1

NF1 (von Recklinghausen disease) is a congenital, autosomal dominant disease that is characterized by hamartomatous growths of neural crest origin. It is rarely diagnosed in the neonate. Lid abnormalities in NF1 can include neurofibromas, plexiform neurofibromas (sometimes presenting early in life), or café-au-lait spots. A plexiform neurofibroma of the upper lid greatly increases the chances of developing glaucoma. Other ocular findings in NF1 include Lisch nodules of the iris, retinal astrocytic hamartomas, sphenoid wing dysplasia resulting in pulsatile exophthalmos, and thickened corneal nerves. About 20% of NF1 patients develop optic glioma. The characteristic Lisch nodules are rarely present at birth but develop in more than 90% of affected individuals by puberty.[68] NF1 results from a germline mutation of the tumor suppressor *NF1* gene on chromosome 17q11.2.[94]

OCULAR TRAUMA

Birth trauma to the eyes is associated with the duration of labor and difficulty of delivery.[74] Lid petechiae and hemorrhages, observed more often with face presentations than with vertex presentations, usually resolve rapidly without treatment. Subconjunctival hemorrhages are also common and require no treatment. Such findings, however, should increase the suspicion of associated intraocular injuries. Retinal hemorrhages are common after delivery, occurring in 78% of newborns after vacuum delivery, 30% after normal vaginal delivery or with forceps assists, and only 8% after cesarean delivery.[35] These retinal hemorrhages are usually small, multiple, and scattered throughout the retina, but they may persist for months and must be considered in the differential diagnosis of later suspected intentional injury or shaken baby syndrome.[35] More profound retinal and vitreous hemorrhages requiring treatment with vitrectomy can also occur from birth trauma.[82]

Bleeding into the orbital contents (retrobulbar hemorrhage) can result from birth trauma. This bleeding produces a unilateral proptosis that tends to increase gradually in size during the first 3 or 4 hours after birth. Ecchymoses of the lids can be associated findings at birth or can occur 1 or 2 days later. The differential diagnosis includes dermoid cysts, teratomas, and other congenital tumors of the orbit. The hematoma usually absorbs spontaneously over 1 to 2 weeks. It is important during this time to ensure that the cornea is not abraded and that the retinal circulation is not compromised. A detailed examination of ocular findings is indicated, and if it shows compression of the arterial or venous supply at the optic disc, immediate surgical decompression of the orbit is required.

Rarely, the eye may be completely dislocated during birth, resulting when the orbit is shallow in conditions such as the craniosynostosis syndrome. This condition constitutes an emergency because the cornea is exposed.

Forceps deliveries, particularly when associated with improper application, can produce bruises and lacerations of the lid or globe.[34] A forceps mark or lid laceration requires a careful and complete examination of the orbit and globe for associated injuries.[56] Forceps application can produce a rupture in the cornea's endothelial basement membrane (Descemet membrane). Seen with magnification, these ruptures appear as diagonal lines in the posterior portion of the cornea. They are rapidly followed by excess hydration of the cornea, with a subsequent cloudy appearance that must be differentiated from congenital glaucoma, infections of the cornea, or diseases associated with cloudy cornea such as the mucopolysaccharidoses. Children with Descemet membrane ruptures can rapidly develop astigmatism and dense amblyopia. Traumatic forceps delivery has been known to cause a variety of other ocular injuries, including Purtscher retinopathy, choroid ruptures, and traumatic optic neuropathy.[40]

Ocular injury in the newborn has also been reported as a result of fetal monitors,[46] surgical instruments,[62,86] phototherapy lights,[70] prenatal maternal injury, and amniocentesis.[67]

Blunt trauma from any cause to the ocular area of the infant can produce blood in the anterior chamber (hyphema), rupture of the globe, dislocation of the lens, vitreous hemorrhage, contusion cataract, traumatic retinal detachment, retinal hemorrhage or edema, rupture of the choroid, and arterial or venous occlusion in the retina. A history of minimal trauma with extensive multilayer retinal hemorrhages may be an indication of shaken baby syndrome.

Shaken baby syndrome can result in devastating and blinding ocular injuries. The examiner might see vitreous, preretinal, intraretinal, or subretinal hemorrhages. Peripheral, dome-shaped hemorrhagic lesions with white retinal borders could represent peripheral retinoschisis. The retina can even be folded in a circumferential manner around the macula. Retinal hemorrhages may resolve without sequelae, but involvement of the optic nerve, macula, or occipital cortex can produce profound lifelong visual loss.[43] The extent and type of retinal hemorrhages that occur in shaken baby syndrome can be pathognomonic of the syndrome and may support the legal prosecution of the offender.[91] Accidental head trauma and cardiopulmonary resuscitation in infants do not result in the type and extent of retinal hemorrhage seen in shaken baby syndrome.[69,89] Thermal and chemical burns around the eyes must be treated with extreme care. Treatment by an ophthalmologist is required after the usual first-aid measures of cooling and providing protective covering. Of immediate priority in the first-aid management of a chemical burn of the eye is copious irrigation with tap water or normal saline solution.

Abrasions of the cornea are suggested by tearing, redness, or protective forced closure of the eyes. Diagnosis is made by observing an irregularity in the smooth corneal surface or by staining the cornea with a fluorescein-impregnated strip. This is done by moistening a sterile fluorescein strip with a drop of sterile saline solution and touching it to the lower conjunctival fornix. The area of corneal abrasion turns light green in ordinary illumination but is best seen with a cobalt-blue filter. Treatment can include antibiotic ointment, cycloplegic eye drops, and oral analgesics. Prolonged patching of an injured eye should be avoided to prevent the development of amblyopia.

Lacerations can involve the conjunctiva, the cornea, or the sclera. All conjunctival lacerations should be assumed associated with a laceration of the globe until proved otherwise. Treatment of ocular lacerations requires a full and careful evaluation of the extent of damage, particularly of the globe. Treatment usually requires microscopic evaluation and repair, with the infant under general anaesthesia. Lid lacerations should be repaired properly to minimize permanent deformity. Involvement of the lacrimal canaliculi, the lid margin, and the lacrimal gland requires special attention. Avulsion of or tissue loss from the lids necessitates urgent treatment to prevent exposure injuries to the cornea.

Orbital or ocular foreign bodies require specialized and precise localization to determine the proper therapeutic approach. Fortunately, they occur rarely in the neonate.

NEONATAL OCULAR INFECTIONS

Conjunctivitis

Neonatal conjunctivitis may be caused by a variety of agents, including chemical, bacterial, chlamydial, and viral. If the condition is undiagnosed and untreated, permanent scarring and loss of vision may occur. If chlamydia or *Neisseria gonorrhoeae* is in the differential diagnosis, it is essential to culture the conjunctiva and to perform whatever chlamydia test is available at your facility.

One cause of a red eye in the neonate can occur after the instillation of silver nitrate, or other antibiotic, for gonorrhea prophylaxis into the eyes at birth. In this chemical conjunctivitis, the conjunctiva is congested and edematous, but purulence is not present, and the redness clears spontaneously in 3 or 4 days. Alternative treatments for neonatal prophylaxis other than silver nitrate include erythromycin and tetracycline ointments.

A bacterial infection is suspected if the conjunctivitis persists or progresses, or if discharge develops. Cultures with sensitivity tests identify the organism and suggest appropriate treatment. Conjunctivitis caused by *N. gonorrhoeae* is an acute, severe, purulent conjunctivitis with an incubation period of 2 to 5 days. If *N. gonorrhoeae* is the cause of the conjunctivitis, immediate treatment with systemic and topical antibiotics is necessary. In cases of infection with organisms resistant to penicillin, a third-generation cephalosporin is indicated.[79]

Ophthalmia neonatorum also can result from other common pathogens such as staphylococci, pneumococci, streptococci, or gram-negative bacteria. These bacterial infections usually appear several days after birth. Most respond well to topical antibiotics or ointment.

Chlamydial conjunctivitis is now a common infection in the neonatal period. The infection is typically acquired from the mother as the child passes through the birth canal. The usual cultures and Gram staining are unhelpful in the diagnosis of chlamydia. Diagnosis can be made by Giemsa staining of a conjunctival scraping or by a variety of commercially available antibody tests.

Chlamydial conjunctivitis is treated with erythromycin or sulfacetamide ointment three times a day for 2 to 3 weeks. Systemic antibiotics are necessary because chlamydia can cause pneumonia, otitis, and persistent nasolacrimal duct obstruction.[78] The mother may also require treatment.

Older infants with chronic or recurrent conjunctivitis usually have a blocked nasolacrimal duct as the underlying cause. The duct frequently opens spontaneously during the first year of life. Treatment with topical antibiotics and massage of the lacrimal sac can help resolve the problem.

Intrauterine Ocular Infections

Intrauterine ocular infections result from maternal infections that cross the placental barrier. Neonates with a TORCH infection should have a complete eye examination to identify ocular involvement. One of the most common is congenital toxoplasmosis, which can result in chorioretinal scars in the retina in response to an in utero chorioretinitis. These scars appear as white areas of exposed sclera, with prominent, darkly pigmented borders. When seen in the neonatal fundus, scars are usually a sign of inactive disease. A significant number of these patients have bilateral blinding macular lesions.[57]

Congenital syphilis may involve the eye with chorioretinitis, interstitial keratitis, uveitis, and optic atrophy. Typically, the corneal changes of interstitial keratitis are not apparent until after the age of 5 years. Neonatal herpes infection is most often acquired during passage through the birth canal and can cause typical herpetic eye disease such as blepharoconjunctivitis, keratitis, iritis, or chorioretinitis. Ocular involvement with either congenital cytomegalovirus disease or varicella is unusual but can result in chorioretinitis, keratitis, or cataract. Ocular involvement in congenital rubella was discussed previously.

Transmission of the human immunodeficiency virus (HIV), causing acquired immunodeficiency syndrome (AIDS), may occur prenatally or postnatally. Chorioretinitis may occur in an HIV-infected child as a result of secondary infection with herpes zoster or simplex. Other causes of retinitis in HIV/AIDS patients, such as toxoplasma, *Mycobacterium avium–intracellulare*, cryptococcus, histoplasma, nocardia, and *Treponema pallidum* and cytomegalovirus are uncommonly seen in children.[15]

Orbital Cellulitis

Cellulitis of the orbital tissue is rare in the neonate but is a common cause of proptosis in children. In children, the infection most often originates in the paranasal sinuses and produces swelling of the orbital contents. Infections caused by penetrating orbital wounds or endogenous spread from remote locations are much less common in children.

The disease is characterized by the rapid onset of progressive proptosis, often with erythema of the lids, chemosis of the conjunctiva, limited motility, and systemic signs of toxicity and hyperpyrexia. Rapid loss of vision caused by compression of the orbital structures can occur.

Diagnosis is made by clinical appearance and radiologic evaluation of the orbits and sinuses. Treatment includes admission to a hospital, CT scan of the orbits, intravenous administration of antibiotics, application of warm compresses, and surgical drainage of persistent orbital abscesses if necessary.[21]

In preseptal cellulitis, the infection is limited to the lids and does not extend past the orbital septum to involve the orbital contents. It is usually caused by streptococcal and staphylococcal bacteria and can be treated on an outpatient basis with oral antibiotics. Widespread vaccination has dramatically decreased *Haemophilus*-associated orbital and preseptal cellulitis.

OCULAR TUMORS IN INFANTS

Ocular tumors of the lids and conjunctivae are often easily diagnosed based on clinical history and pattern recognition. Diagnosing intraocular tumors requires a more detailed examination, often under anesthesia, and ancillary testing such as fluorescein angiogram and MRI. Biopsy is only rarely considered in these circumstances. Diagnosing orbital tumors can be more challenging.

Orbital tumors may be benign or malignant and can develop from ectodermal, mesodermal, and neural crest tissues or by metastasis from distant sites. They also can originate from the intracranial cavity or paranasal sinuses and enter the orbit by growing through natural or acquired bone defects in the orbital walls. Ultrasound, MRI, and CT are particularly valuable in the diagnosis of orbital disease.

Hemangioma

Infantile hemangioma is the most common primary orbital tumor that produces proptosis. In infants, the hemangioma usually is not well encapsulated and often involves the lids as well as the orbit. Although observation of lid involvement assists in making the diagnosis, a biopsy might be required to exclude other orbital tumors if the hemangioma lacks a superficial component. Crying or straining by the infant often causes the mass to increase in size and assume a bluish coloration.

Treatment initially should be confined to expectant observation because spontaneous resolution is the rule. However, some tumors require therapy because of growth that produces a refractive error (astigmatism) or obstruction of the pupillary axis, resulting in amblyopia. Glasses and patching might be necessary to prevent or treat amblyopia. Promising new therapy with oral propranolol has recently been described.[47] In the past, treatment involved systemic, injectable, or topical corticosteroids, or other drugs.[19] Occasionally, surgery is indicated.[85]

Another type of hemangioma is the port-wine stain of the face (nevus flammeus) associated with Sturge-Weber syndrome.

Lymphangioma

Lymphangiomas are slowly progressive, diffuse, soft tumors that may be present at birth or gradually develop during the first several years of life. They tend to enlarge slowly and cease growing by early adulthood. An upper respiratory tract infection may be associated with an increase in the size of the lesion. Spontaneous hemorrhage into an orbital lymphangioma can cause sudden proptosis. Lymphangiomas are composed of thin-walled vascular channels that can involve the orbit and lids as well as other tissues in the body. The tumors can cause proptosis, ptosis, strabismus, or anisometropia. Amblyopia is common and must be aggressively treated. The lesion itself is difficult to treat because it does not regress spontaneously or respond to radiation or corticosteroid therapy. Although surgery is the treatment of choice, results are not always satisfactory.

MRI can be exceedingly helpful in diagnosing a lymphangioma. Surgical removal of the tumor might be necessary for cosmetic or functional reasons, but recurrence is common. Picibanil (OK-432), a sclerosing agent, can be injected directly into lympangiomas.[103]

Dermoid Cysts

Dermoid cysts are thought to arise from a congenital rest of primitive ectoderm at the site of closure of a fetal cleft. They usually contain connective tissue, sebaceous glands, and hair follicles. Cysts are often located near the orbital rim, where they are attached to bone at suture sites. The most frequent location is in the lateral third of the brow or upper lid. The skin overlying the soft cyst is freely movable, although the cyst remains attached to the periosteum at the site of the embryonic cleft. The cysts can connect with the cranial cavity, paranasal sinuses, or orbit, and can produce local bone changes. Cysts located within the orbit produce proptosis and vertical or horizontal displacement of the globe. Radiographic examination might document bone erosion where the cyst is attached. Local trauma can produce a hemorrhage into a dermoid cyst or cyst rupture, leading to a clinical picture resembling cellulitis. Surgical excision is recommended and is usually curative, especially for the dermoids external to the orbit.

Teratoma

Teratoma is a primary orbital tumor composed of the three embryonic cell layers. It can differentiate into a variety of tissues containing cartilage, connective tissue, skin, hair, and sebaceous glands or into endodermal epithelium. Bone is a common component and can be identified by orbital roentgenograms. Orbital teratomas that are present at birth produce a striking massive proptosis. Treatment is early excision of the teratoma. Malignant transformation can occur but is rare in the orbit.

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common malignant tumor of the orbit in children (Fig. 53-14). Although it may be found in the neonatal period, the average age of occurrence is 6 to 10 years. Rhabdomyosarcoma develops in the orbit more often than elsewhere in the body. Orbital involvement produces proptosis that develops over a few weeks. Diagnosis is made by biopsy. Treatment in the past involved orbital

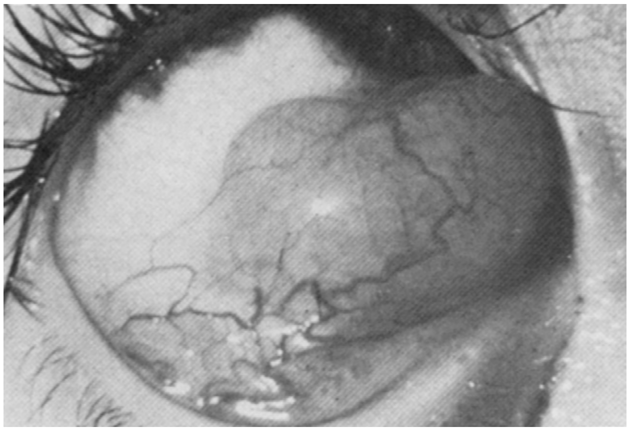

Figure 53–14. Rhabdomyosarcoma of the right orbit.

exenteration, but this is now replaced by chemotherapy and radiation therapy.

Histiocytoses

Children with histiocytoses (eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease) may have proptosis or ptosis. Involvement is usually painful, with features of inflammation.

Retinoblastoma

Retinoblastoma is the most frequent malignant intraocular tumor affecting the neonatal eye. In the United States, about 50% of retinoblastoma cases are diagnosed by leukocoria detected by primary care physicians or a parent (Fig. 53-15).

Retinoblastoma occurs in about 1 in 20,000 births, with no predilection for race or sex. The tumor arises sporadically or may be familial.

The genetic basis for retinoblastoma has been widely studied. The gene, located on the q14 band of chromosome 13, is a tumor suppressor gene. Mutation or inactivation of both alleles in a vulnerable retina cell results in transformation of the cell into retinoblastoma.[100]

The tumor originates in the retina and grows anteriorly into the vitreous or posteriorly into the choroid. If the tumor disrupts vision, a sensory strabismus may result. Hence, all infants with strabismus require a fundus examination with dilated pupils to exclude retinoblastoma. With further enlargement, the tumor produces secondary glaucoma, which may be associated with pain and photophobia or symptoms identical to those of congenital glaucoma. With extension into the anterior chamber, an opaque layer of leukocytes (pseudohypopyon) or spontaneous bleeding (hyphema) can occur.

The diagnosis of retinoblastoma is supported by the detection of one or more solid white masses in the fundus of the eye. Small, whitish opacities in the vitreous, representing an anterior seeding of the tumor, may be present. Calcification identified within the eye on CT scan, ultrasound, and MRI findings help to confirm the diagnosis. The differential diagnosis may be exceedingly difficult if the tumor is advanced or atypical, and enucleation may be required for histologic study and positive identification. Other lesions that rarely can simulate retinoblastoma are coloboma of the fundus, congenital retinal fold, retinal dysplasia, persistent hyperplastic primary vitreous, retinoschisis, organizing vitreous hemorrhage, or scarring from ROP.

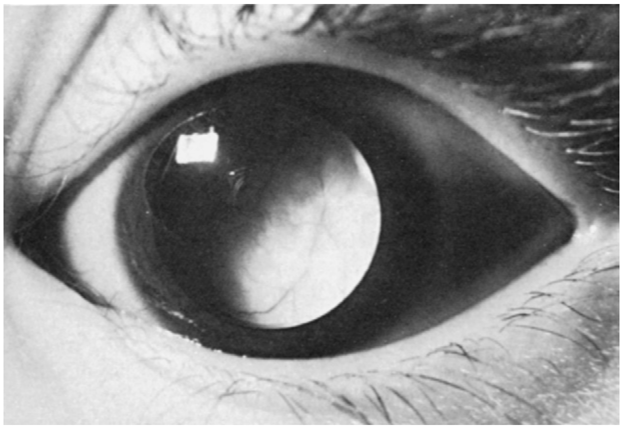

Figure 53–15. Leukokoria in a patient with advanced retinoblastoma.

The treatment of retinoblastoma is determined by its size and location. Examination should be performed with the infant under anesthesia, and accurate documentation of all lesions should be done with drawings or photography.

The treatment of retinoblastoma involves a team approach between pediatric oncologists, radiologists, and ophthalmologists. A variety of chemotherapeutic regimens are now used with increasing success.[10,42] Other local treatment modalities for unilateral and bilateral retinoblastoma include external-beam irradiation, plaque radiotherapy, thermotherapy, photocoagulation, and cryotherapy.

The most significant factor in the prognosis is the stage of disease when treatment is instituted. When retinoblastoma is limited to the eye, 98% of patients can expect a 5-year disease-free survival.[10] With extension beyond the globe, the cure rate is reduced. Because radiation therapy has many side effects, adjuvant chemotherapy is increasingly being used to avoid enucleation and to prevent metastatic disease.

Patients with the familial form of retinoblastoma also are at risk for developing secondary malignancies.[63] The most common secondary malignancy is osteogenic sarcoma, usually occurring in the teen years. Pinealoblastoma forms the third part of what is called *trilateral retinoblastoma*. This malignancy usually occurs during the first 4 years of life.

OCULAR CHANGES FROM MATERNAL SUBSTANCE ABUSE

An increasing number of infants are born bearing the physical, mental, and social consequences of maternal drug and alcohol abuse. Miller and colleagues described many of the ocular findings of fetal alcohol syndrome, including refractive errors, strabismus, anterior segment abnormalities, cataract, ptosis, long eyelashes, telecanthus, and optic nerve hypoplasia.[58] Maternal ingestion of cocaine can result in optic nerve abnormalities, delayed visual maturation, and prolonged eyelid edema.[26] Maternal cigarette smoking has been identified as a risk factor for strabismus.[29] As more information is gathered, additional evidence of the teratogenicity of various illicit drugs may be obtained.

PART 2

Retinopathy of Prematurity

Dale L. Phelps

Retinopathy of prematurity (ROP) is a postnatal disorder of the retinal vessels that develops only in the incompletely vascularized retinas of premature infants. It leads to a wide range of outcomes from normal vision to blindness. First described in the early 1940s, *retrolental fibroplasia*, as it was first named, almost disappeared between 1954 and 1970, when oxygen use for preterms was severely restricted,[41] but it returned in a second epidemic in the 1970s to plague neonatal intensive care units (NICUs) as one of the major causes of disability in surviving infants with extremely low gestation.[12,26] Effective interventions have reduced its toll of vision loss in developed countries, but worldwide, ROP now appears as a third epidemic in developing countries as they begin to provide neonatal intensive care.[13]

INCIDENCE

ROP is common among extremely low gestation infants (especially those <29 weeks), but severe ROP causing vision loss is fortunately the minority of cases. The Cryotherapy for Retinopathy of Prematurity Natural History Study of 4099 infants born in the late 1980s and weighing less than 1251 g at birth prospectively followed these infants in the NICU and importantly after discharge until the final outcome of their ROP was known. The overall incidence of ROP of any severity was 66%; moderately severe ROP, 18%; and severe ROP, 6%.[26] The rates by gestational age are shown in Figure 53-16.[8,28] Among studies with similarly complete follow-up, little changed in the 1990s[36] or early 2000s.[15]

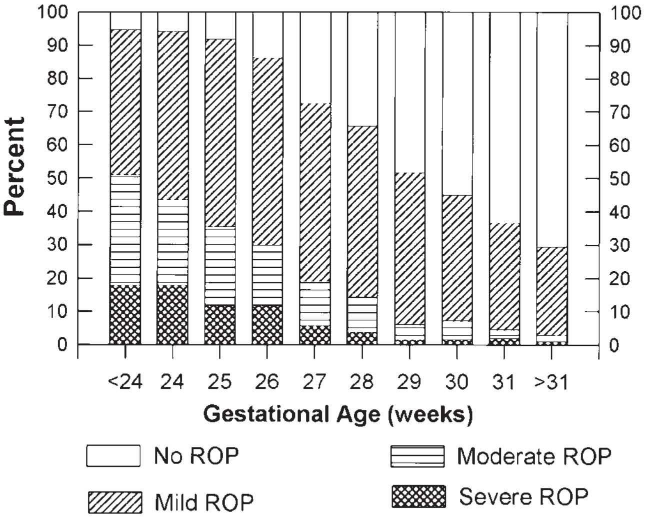

Figure 53–16. Incidence of mild (less than prethreshold), moderately severe (prethreshold), and severe (threshold) retinopathy of prematurity (ROP). *(Data from Phelps DL: Retinopathy of prematurity: history, classification, and pathophysiology,* Neoreviews *2:e153, 2001; and the ROP definitions from Cryotherapy for Retinopathy of Prematurity Cooperative Group: Multicenter Trial of Cryotherapy for Retinopathy of Prematurity: 32-year outcome-structure and function,* Arch Ophthalmol *111:339, 1993.)*

Lower gestational age and birthweight have always been the strongest predictors of ROP. After controlling for these parameters in regression analyses, the strongest additional risk factors for severe stages of ROP are prolonged administration of oxygen, duration of mechanical ventilation, and other indicators of a complicated hospital course, such as hypotension (e.g., hypovolemic shock, pneumothorax, severe intraventricular hemorrhage, septic shock), number of transfusions, multiple birth, out-born status, nonblack race for the more severe stages of ROP, and small for gestational age status at birth.[3,4,16,23,24,26,34]

PATHOGENESIS

Only infants whose retinal vessels have not yet completed their centrifugal growth from the optic disc to the ora serrata may develop ROP. Retinal vessel growth begins from the optic disc at 14 to 18 weeks' gestation, proceeding outward as the retina differentiates. Primitive future endothelial cells form cords that canalize into a network of evenly spaced primitive capillaries, which further remodel into primitive and then mature arterioles and venules. Each of these steps can be seen simultaneously at any moment in time because they are sequentially proceeding from the disc outward toward the ora serrata in the immature retina (Fig. 53-17A).

When any injury occurs to these developing vessels, the natural progress is arrested. Prolonged hyperoxia, shock, asphyxia, hypothermia, acidosis, and vitamin E deficiency are among the factors that have been implicated as possible reasons for the initial injury. Inhibition of vascularization in this early phase 1 of ROP has been attributed to suppression of vascular endothelial growth factor (VEGF), and possibly erythropoietin, by hyperoxia. Lack of insulin-like growth factor-1 (IGF-1) in this phase of ROP and associated poor postnatal growth may also prevent normal retinal vascular growth.[17,18] After initial injury, vessel growth can resume in a near-normal fashion (i.e., no ROP), or for poorly understood reasons, the progress of primitive vessels can remain arrested, piling up within the retina, growing without forward progress, and forming a ridge of tissue that can become quite thick (see Fig. 53-17B). This tissue might subsequently regress or resolve, and the vessels again progress toward the periphery, or the ROP can worsen through the growth of fibrovascular tissue into the vitreous cavity, leading in some cases to retinal detachment.

In phase 2 of ROP, pathologic vascular proliferation appears to be associated with hypoxia-induced rising levels of VEGF, erythropoietin, and IGF-1.[17] This is consistent with the recent clinical observation that a higher incidence of intermittent hypoxemic episodes is associated with severe retinopathy of prematurity.[8a] In some infants, the regrowing vessels become inflamed, with vitreous haze, exudate along the retinal vessels, and engorgement and tortuosity of the

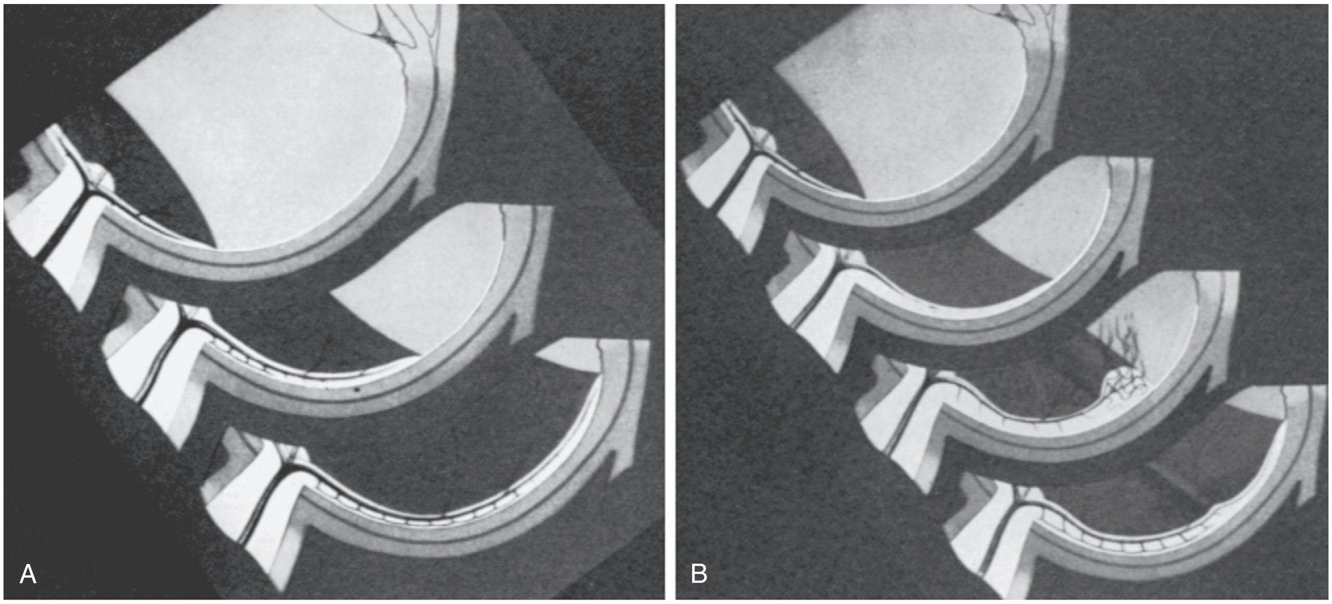

Figure 53–17. A, Cross sections of normally developing retina and retinal vasculature. From the *top left* to the *bottom right*, the area of the normally vascularizing retina increases with age from 24 weeks' gestation to term as the retina centrifugally differentiates. Retinal thickness and vessels have been exaggerated for illustration. B, Cross sections of the retina across time as the retinal vessels ablate after preterm delivery, revascularize to an excessive degree with intravitreal extension (retinopathy of prematurity), and finally regress, leaving a residual visible ridge of tissue (mild cicatrix) where the retinopathy had been. *(From Phelps DL: Retinopathy of prematurity. In* Mead Johnson Symposium on Perinatal and Developmental Medicine: the tiny baby, *held at Marco Island, Florida, Nov. 16-20, 1988; No. 33. Printed in 1990.)*

posterior pole vessels as well as the remnants of the tunica vasculosa lentis on the lens and in the iris. This condition is called *plus disease*, and recent data suggest it is linked to high levels of VEGF and associated growth factors in the retina and vitreous cavity.[1,2,5] As infants mature, rising levels of IGF-1 may allow VEGF-stimulated neovascularization to occur. When extraretinal neovascularization and plus disease occur, this "threshold" ROP can still heal spontaneously in nearly 50% of infants[7]; however, in the others, the tissue forms a scar (cicatrix) that contracts and distorts the retina, leading to a displaced macula, retinal folds, or retinal detachments. This sequence occurs as early as 8 to 10 weeks after birth but most often 3 to 5 months after birth. (An animated illustration of this sequence can be viewed at http://www.nei.nih.gov/photo.)

Oxygen was inexorably linked to ROP with the publication of the randomized, cooperative trial of oxygen restriction published in 1956. It showed that the then-common practice of administering more than 50% inspired oxygen for longer than 4 weeks resulted in an incidence of severe retinopathy of 23% in survivors, compared with just 7% in infants given oxygen just sufficient to relieve cyanosis.[22] That study randomized subjects weighing less than 1500 g at 48 hours after birth and occurred at a time when ventilators, continuous positive airway pressure, and even intravenous fluids had not yet entered the nursery. In the era that followed this study, oxygen use was severely restricted without the benefit of blood gas determinations, resulting in an increased preterm mortality rate; however, ROP was nearly eliminated for a time.[41] The resurgence of ROP in the second epidemic was attributed to the increased survival rate of infants with retinas so immature at birth that the controlled use of oxygen did not appear to contribute to disease, and other complications of the perinatal period, in addition to the extreme immaturity, were believed to be primarily responsible.[12]

The oxygen story, however, continues to haunt us. Case series restricting oxygen at the turn of the century suggested that further restriction or control of oxygen in the modern intensive care unit could further reduce the incidence of ROP.[6,44] Although some quietly questioned whether these reports had merely demonstrated that giving oxygen carefully with attention to controlled saturation at all times around the clock would reduce ROP (i.e., were we finally just doing what our policies said we should do), others were pointing out that we did not know whether lowering pulse oximetry goals below 95% or 90%, or even 85%, was safe. Today, solid evidence is still lacking on the safe upper and lower limits of oxygenation in the preterm infant who has left in utero conditions of 60% to 70% saturation for ex utero conditions of 80% to 100% saturation.[45] Ongoing research aimed at answering those questions is being conducted cooperatively around the world.

In developing countries, however, the third epidemic of ROP is appearing as, for the first time, extremely preterm infants begin to survive. The beginning intensive care units do not initially have technology or sufficient staffing to carefully monitor oxygen administration.[13,47] The effect on vision loss is further complicated by lack of organized ophthalmic examination and treatment programs for a disorder previously unrecognized because such immature infants had not survived.

CLASSIFICATION

In 1984 and 1987, the International Classification of Retinopathy of Prematurity (ICROP) was developed to facilitate communication about ROP among physicians and investigators. It was published in two parts after years of work by ophthalmologists studying this disorder throughout the world[19,20] and was revisited in 2005.[21]

The classification has three novel new features. First, it locates the disease (anterior to posterior) by defining three zones that have strong prognostic significance (Fig. 53-18). ROP located in the most immature zone I has a much worse prognosis. Second, the extent of the disease is described by the number of clock hours (maximum of 12) involved within the zone. Third, the change in posterior pole venous dilation and arterial tortuosity that occurs in aggressive disease is identified by the designation of plus disease (or "preplus disease" if it is not normal, but does not meet criteria for plus disease).

As in previous classifications, the degree of vasculopathy at the vascular-avascular transition is divided into stages 1 through 5. Stages 1 through 3 are increasing degrees of abnormal blood vessel growth (neovascularization) at this transition, with vessels actually leaving the retina and growing in the vitreous in stage 3. Stage 4 is partial retinal detachment, and stage 5 is complete retinal detachment, both of which carry a grim prognosis for normal vision.

The international classification captures these degrees of disease and permits some early prognostication. For instance, ROP occurring in zone I (the most immature or posterior zone) has a greater chance of progressing to retinal detachment than does zone II disease, and rarely does zone III disease ever result in any permanent damage.[26,37] For investigators, the classification has been critical for improving communications and standardizing entry criteria for multicenter studies.

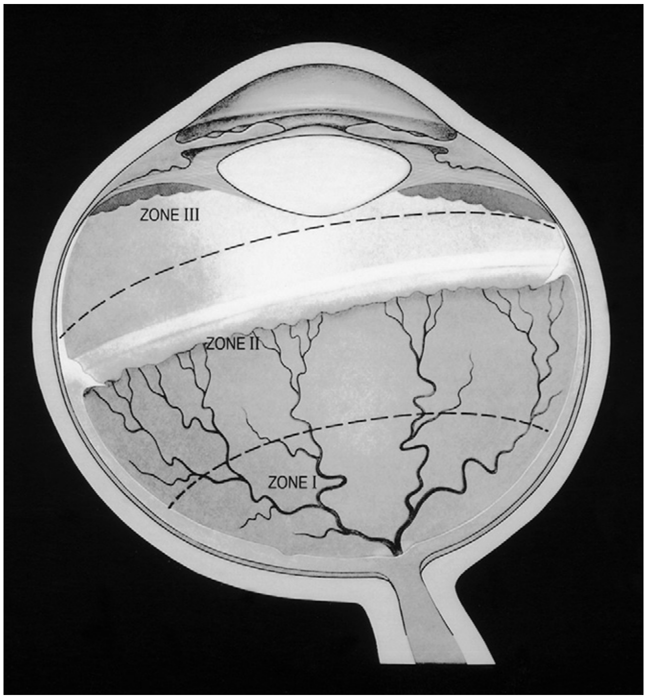

Figure 53–18. Artist's rendering of half of the eye with zone II, stage 3, retinopathy of prematurity with plus disease. The view is from the top of the head, with the temporal side of the retina to the reader's left, and the nasal side to the right. Zones I, II, and III are drawn onto the retina to assist in visualizing their positions within the eye.

CLINICAL COURSE

When infants with ROP are examined regularly from 31 to 33 weeks' postmenstrual age (PMA), they demonstrate the sequential development of the stages of ROP until they reach a turning point when the ROP regresses (heals) or goes on to advanced disease. This turning point can occur after just stage 1, 2, or 3, and most often has turned by 36 to 42 weeks' PMA.[35]

Rates of progression are variable, and the worst prognosis is associated with onset in zone I (most immature) followed by rapid progression in time through stages 1, 2, and 3 to plus disease and retinal detachment. When this progression proceeds over a few weeks, the Japanese named it *rush disease*. Onset in zone II, or a slower evolution of the disorder, leads more often to complete resolution or to just a partial cicatrix (retinal scar). This slower resolution can take as long as a year to stabilize, but most often results in full recovery. ROP with an onset in zone III has a good prognosis for full recovery.[37]

Infants who develop only mild ROP (i.e., stage 1 or 2 without plus component) and heal without a residual cicatrix have a slightly increased incidence of myopia, strabismus, and amblyopia compared with term infants.[38] However, for those infants who develop threshold ROP and receive cryotherapy or laser ablation, severe myopia, glaucoma, and associated sequelae are common.[32] The infants who have a residual cicatrix without retinal detachment are also more likely to have any of these problems and are at risk for very slowly progressive retinal degeneration that can lead to retinal detachment and acuity loss in later decades.[27,42,43]

Infants who develop total retinal detachment are at risk for secondary glaucoma, entropion, and infections caused by eye rubbing. Even if they have no vision, they may benefit from referral for cosmetic treatment if phthisis (shrunken eye) begins to develop. Physicians must refer infants to early intervention programs and support their families.

THERAPY

The only completely effective prophylaxis for ROP is the prevention of premature deliveries. Meticulous oxygen monitoring is necessary to reduce the incidence of ROP to a minimum, but it cannot eliminate ROP,[11] nor has early administration of vitamin E[33] or restricting light exposure prevented ROP.[30,36] Lower oxygen saturation goals might prove useful in the future in reducing severe ROP.[6,44,45] These approaches are being investigated in controlled trials. The SUPPORT trial showed that management with oxygen targets of 89-91% vs 92-95% reduced ROP, but resulted in a statistically significant increase in mortality.[41a] Two additional trials are in progress and will further clarify optimal targets.

Fortunately, established ROP of a moderately severe degree (see new definition in Box 53-6) can be arrested effectively in

BOX 53–6 Criteria for Peripheral Ablative Therapy for Retinopathy of Prematurity

Zone II: Plus disease with stage 2 or 3 ROP
Zone I: Plus disease with stage 1 or 2 ROP
Zone I: Stage 3 ROP

ROP, retinopathy of prematurity.
Adapted from Early Treatment for Retinopathy of Prematurity Cooperative Group: Revised indications for the treatment of retinopathy of prematurity: results of the Early Treatment for Retinopathy of Prematurity Randomized Trial, *Arch Ophthalmol* 121:1684, 2003.

many cases by applying laser therapy or cryotherapy to ablate the entire peripheral avascular retina, which we believe is overproducing the angiogenic factors driving the vessels to grow abnormally. One of these factors has been identified as VEGF,[1,9] which is almost certainly representative of a group or cascade of factors involved in the control of retinal vascularization.[17] Although this treatment does not always succeed in preventing retinal detachment, it reduces the incidence of poor retinal outcomes at 2 years from 15.4% to 9.1%,[14] a further improvement from the poor outcome rate of 26% in the treated eyes in the CRYO-ROP study.[8] At 15 years' follow-up, the benefit of cryotherapy persists, although the effect on the appearance of the fundus is again greater than the benefit for visual function.[27] The criteria for laser treatment established by the ETROP multicenter trial first published in 2003 are shown in Box 53-6.

Use of supplemental oxygen to reduce the hypoxic stimulus for neovascularization has been studied in a multicenter trial. Although there was no harm to eyes that already had moderately severe ROP, there was no clear ophthalmic benefit, and there was increased pulmonary morbidity from maintaining oxygen saturations at 96% to 99% compared with 89% to 94%.[29]

With the development of effective humanized mouse antibody fragments that block VEGF in colorectal cancer and wet macular degeneration[48] (intravitreal injection), this approach has been tried in small case series of ROP patients with promising short-term results.[25] Controlled trials to study the effectiveness, and most importantly the short- and long-term safety, of an antiproliferative drug in the rapidly growing infant are needed.

When total or subtotal retinal detachment occurs, the usual prognosis is that there will be no useful vision, even when heroic vitrectomy is performed to reattach the retina.[31,46] With these discouraging results, some retinal surgeons perform scleral buckle procedures, early lens-sparing vitrectomy, or both, in an attempt to stabilize a partial detachment. However, there are no controlled trials of such interventions, and long-term follow-up outcomes are not yet available.

RECOMMENDATIONS FOR EXAMINATION SCHEDULE

Examinations to identify infants who have ROP must be done by a clinician skilled with indirect ophthalmoscopy of premature infants and must begin early enough to permit the application of laser therapy (or cryotherapy) to prevent progression of the disease if it meets treatment criteria.[10,39,40] The ophthalmic and pediatric societies periodically publish joint recommendations for the screening guidelines (Box 53-7).

Each infant at risk (i.e., those weighing less than 1500 g or born at 30 weeks' gestation or less, and those more mature preterm infants with birthweight of 1500 to 2000 g who had an unstable medical course) should be examined initially by the later of 31 weeks' PMA, or 4 weeks' chronologic age. If the retinal vasculature is complete to the ora serrata, repeated examinations are not needed. If the vessels are in zone III, ROP could develop or might be present but likely will be only mild, and repeated examinations are done at 2- to 4-week intervals to ensure complete vascularization. Infants with retinal vessels that have grown only into zone II should be followed at least every 2 weeks to observe for the development of ROP, which may require therapy. Infants with vessels only as far as zone I are at greatest risk for severe ROP and should be followed closely on the basis of the presence, severity, and rate of progression of any ROP.

Neonatologists and ophthalmologists must work closely together to ensure an efficient tracking system for timely examination of these infants and to be certain that follow-up examinations occur at the best times both in the hospital and after discharge or transfer. The examinations are technically challenging to perform, and vitreal cloudiness or poor dilation of the pupil can result in an imprecise judgment of the zone where vessels end. Moreover, the diagnosis of "no ROP" must be regarded as incomplete and vigorously followed with the question, "In what zone, or mature?" An infant can have zone I vessels and no ROP but be blind 6 weeks later because of ROP. Generally, because ROP develops in more than 90% of infants born at less than 26 weeks' gestation, the index of suspicion must be high, and follow-up examinations must be particularly adhered to in these babies. At 26 to 28 weeks' gestation, 70% develop ROP, and at 29 to 30 weeks' gestation, the incidence is lower (45%). The goal is to ensure that infants who reach criteria for surgery are offered this opportunity to minimize vision loss.

BOX 53–7 Schedule for First Indirect Ophthalmoscopy in Premature Infants

WHO
All infants 30 weeks' gestation or less, or weighing less than 1500 g at birth
Infants born at 1500 to 2000 g who have a medically unstable course

WHEN
By the later of 31 weeks' postmenstrual age* or 4 weeks after birth
Recommend first examination before discharge from the hospital

---

*Postmenstrual age in weeks is equal to the gestational age at birth plus the chronologic age in weeks after birth.
Adapted from American Academy of Pediatrics, American Association for Pediatric Ophthalmology and Strabismus, and American Academy of Ophthalmology: Screening examination of premature infants for retinopathy of prematurity, *Pediatrics* 117:152, 2006 and 118:1324, 2006.

After the acute process has resolved, continued follow-up is dictated by the worst degree of ROP that occurred in the acute course. For infants who have had laser or cryotherapy for ROP, close observation of the retina is usually provided by the retinal surgeon who has treated the infant. Pediatric ophthalmic care for corrective eyeglasses and possible strabismus or amblyopia therapy is also extremely important, and such treatment is often needed in the first year for infants with moderate ROP who did not need laser treatment, and frequently for those who needed such treatment.[32] Patients who have significant residual retinal scars (cicatrix) require regular ophthalmologic follow-up care for life because of the incidence of late retinal detachments that can sometimes be effectively treated.[42]

Neonatologists and ophthalmologists can offer hope of preserving vision in most premature infants with severe acute ROP. However, this requires an organized system of tracking each preterm birth and arranging examinations in a timely fashion both in the intensive care unit and its associated referral units to which infants return after initial care, and when infants are discharged home without full resolution of their ROP. Research must continue in order to learn about the basic mechanisms involved in the control of retinal vascular development and neovascularization. When understood and applied in appropriate clinical settings, such knowledge may permit the ultimate complete control of ROP.

CHAPTER 54

Neonatal Orthopedics

Musculoskeletal abnormalities of the extremities, spine, and pelvis are common in the neonate. Some are pathologic and others physiologic in origin from normal in utero positioning. The congenital absence of all or part of a limb, deformities of the feet or hands, and abnormalities of the spine are rarely diagnostic problems, whereas others, such as developmental dysplasia of the hip (DDH), may escape diagnosis even after repeated screenings by experienced examiners. Bone and joint infections in the neonatal period produce few of the diagnostic signs and symptoms present in the older child and require a high index of suspicion and careful diagnostic evaluation. When an infection is diagnosed early and prompt treatment rendered, the growth potential of the neonate yields an excellent prognosis for normal development and function.

PART 1

Musculoskeletal Disorders

Daniel R. Cooperman and George H. Thompson

NORMAL EMBRYOLOGY

Because many neonatal musculoskeletal disorders are congenital in origin, it is important to understand the basic aspects of musculoskeletal embryology. Prenatal development is divided into two major stages: the embryonic period, consisting of the first trimester, and the fetal period, consisting of the middle and last trimesters of pregnancy. The components of the musculoskeletal system differentiate during the first trimester; the second and third trimesters are periods of further growth and development.[28,37,50,74] Abnormalities during the embryonic period produce congenital malformations, whereas the fetal period produces deformations and alterations in the configuration of essentially normal parts.

Embryonic Development

The early embryonic development of the musculoskeletal system is oriented around the notochord, a tubular column of cells running cranially and caudally along the long axis of the embryo. During the third week of gestation, the neural crests develop dorsally and on either side of the notochord. These crests fold over and are joined dorsally to produce the neural tube, from which the spinal cord and associated spinal nerves develop. At the same time, paraxial collections of mesodermal tissue develop on either side of the notochord and segment cranially and caudally into 44 distinct condensations called *somites*. From the primitive mesodermal tissue comprising the somites, the skeletal tissues, muscle, and dermal elements of the body develop.

EXTREMITIES

The upper and lower extremities develop from the limb buds. They become recognizable during the fourth week of gestation. These buds grow and differentiate rapidly in a proximal to distal sequence during the next 4 weeks. The cells differentiate into three segments: the dermatomes, which become skin; the myotomes, which become muscle; and the sclerotomes, which become cartilage and bone. By the fifth week, the hand plate forms, and mesenchymal condensations occur in the limbs. By the sixth week, the digits become evident, and chondrification of the mesenchymal condensations occurs. Notches appear between the digit rays during the seventh week. The failure of the rays to separate at this time results in syndactyly. Also during the seventh week, the upper and lower limbs rotate in opposite directions. The lower limbs rotate internally to bring the toes to the midline, whereas the upper limbs rotate 90 degrees externally to the position of the thumb on the lateral side of the limb.

SPINE

The differentiation of the spinal column begins during the fourth week of the embryonic period. The somites first appear in the occipital region of the embryo; further development occurs simultaneously in a cranial-to-caudal direction. Dorsal and anterolateral migrations of the mesodermal tissue derived from the somites give rise to the connective tissue elements of the trunk and limbs. Anteromedial extensions of the somatic mesoderm migrate to surround the notochord, separating it from the neural tube and forming the primitive anlage of the vertebral bodies. The differentiation of the neural and vascular elements of the spinal column occurs simultaneously to somite development.

Definitive formation of the spinal column occurs from the fourth through the sixth week of gestation. The somatic mesodermal tissue surrounding the notochord differentiates into a less cellular and dense upper portion and a more dense and cellular lower portion. The somites cleave together, the lower portion of the superior somite joining with the upper portion of the inferior somite. The intervertebral disc develops at the site of the cleavage. The notochord, which is contained within the newly joined primitive vertebral bodies, degenerates, and those portions at the site of cleavage become the nucleus pulposus of the intervertebral disc. The neural arches and ribs develop from the dense portions of the somite, and the vertebral body develops from the less dense portions.

Chondrification begins in the primitive mesodermal vertebrae during the sixth week of pregnancy. It progresses rapidly to form cartilaginous models of the vertebral body by the end of the first trimester. Ossification of the cartilaginous models begins during the second trimester. The ossification of each side of the neural arch and of the body at each level proceeds separately. In the neonate, the ossified vertebral body and neural arches at each level are clearly visible radiographically, separated as they are by the nonossified synchondritic junctions. The ossification centers of the neural arches and body coalesce during the first 3 years of postnatal development.

The first and second cervical segments are embryologically and anatomically distinct from the remainder of the spinal column. The first cervical vertebra—the atlas—lacks the physical form characteristic of other vertebrae, having instead only a narrow anterior arch. This arch is not ossified at birth or during the neonatal period but is most often visible by 1 year of age.

The most striking feature of the second cervical vertebra—the axis—is the prominent odontoid process, derived from the caudal portion of the first cervical somite. The odontoid process joins with the remainder of the C2 body through synchondritic links with each neural arch and the vertebral body. The synchondrosis with the centrum lies below the level of the neural arches and may be radiographically confused with a fracture line; it closes by 3 years of age. The vertical synchondroses separating the centrum from the neural arches of C2 close by 7 years of age.

The radiographic evaluation of the neonatal spine requires experience. In the lateral view, the vertebral bodies are often notched at their waists and are trapezoidal rather than rectangular. In the anteroposterior view, the synchondritic links between the neural arches and vertebral bodies are not ossified and may give the false impression of a fracture. In the cervical region, the odontoid process may be confusing to those not familiar with the normal developmental anatomy of the region. Fortunately, fractures of the cervical spine are uncommon in the neonatal period and, when present, are usually associated with a suggestive history and other signs on physical examination.

Fetal Development

The appendicular and axial skeletons are preformed in cartilage. By the end of the first trimester, primary ossification centers are present in the long bones of the extremities. Further increases in length occur through endochondral growth at the ends of the long bones. This growth continues in the postnatal period until the end of adolescence, when growth plates close and the epiphyseal regions fuse with the remainder of the long bone.

CONGENITAL ABNORMALITIES

Teratogenic influences and genetic abnormalities occurring during the embryonic period can adversely affect the normal differentiation of the musculoskeletal system, resulting in malformations of the extremities or spine. Other organ systems differentiating at the same time are often concomitantly affected, such as the association of cardiac and genitourinary abnormalities with congenital spinal deformities (see also Chapter 29).

Teratogenic Abnormalities

It has been estimated that 5% of all malformations are the result of the action of known teratogens on the developing embryo. Irradiation, industrial chemicals, therapeutic drugs, and certain maternal infections produce primary musculoskeletal malformations or secondarily affect the growth and development of the musculoskeletal system. Thalidomide is the best known cause of musculoskeletal malformation. Rubella, cytomegalic inclusion disease, and congenital herpes produce lesions of the central nervous system that may secondarily affect the musculoskeletal system.

Genetic Disorders

Genetic disorders that affect the musculoskeletal system may be divided into three categories: mendelian, chromosomal, and multifactorial.

MENDELIAN DISORDERS

Mendelian disorders are characterized by an abnormality in a single gene obeying the rules of mendelian inheritance. Skeletal dysplasias, such as achondroplasia and diastrophic dwarfism, Marfan syndrome, hemophilia, and rickets resistant to vitamin D, are examples of mendelian disorders. Skeletal dysplasias are usually diagnosed in the neonate, whereas other entities do not become clinically recognizable until later in childhood.

CHROMOSOMAL ABNORMALITIES

Chromosomal abnormalities are characterized by morphologic changes detectable on ultrastructural analysis. Trisomies are common examples. Although they are striking, the musculoskeletal manifestations of these conditions are frequently the least serious of the child's problems.

MULTIFACTORIAL CONDITIONS

These conditions are determined by a combination of genetic predisposition and intrauterine environmental influences. Such conditions typically occur in families with a frequency that is greater than expected but do not follow the obvious rules of mendelian inheritance. Talipes equinovarus (clubfoot) is such a disorder. The overall incidence of clubfoot is 1 case per 1000 live births, but the incidence of deformity among first-degree relatives is 20 to 30 times higher than that in the general population. Three percent of dizygous twins and 40% of monozygous twins share the deformity. An increased incidence of clubfoot occurs among breech and twin births.

Congenital Limb Malformations

Congenital limb malformations are relatively common among neonates. Some are grossly obvious, such as a congenital amputation, whereas others are subtle and perhaps unrecognizable for years, such as a congenital proximal radioulnar synostosis (fusion). Congenital limb malformations are classified according to the parts that have been primarily affected by embryologic failure. Swanson and colleagues[102] developed a seven-group classification system.

1. Failure of formation of parts (i.e., arrested development)
2. Failure of differentiation (i.e., separation) of parts
3. Duplication
4. Overgrowth (i.e., hyperplasia, gigantism)
5. Undergrowth (i.e., hypoplasia)
6. Congenital constriction band syndrome
7. Generalized skeletal abnormalities

These various malformations are caused by alterations in the organization of the limb mesenchyme; the time of the insult, the sequential development of the part, and the location of the destructive process determine the type of ensuing deformity. The presentation, diagnosis, and treatment of the more common congenital limb malformations are discussed in later sections.

FAILURE OF FORMATION OF PARTS

This group of failures of part formation is subdivided into transverse and longitudinal deficiencies. A transverse deficiency is manifested as an amputation type of stump that is classified by naming the level at which the remaining limb terminates. All elements distal to the level are absent. Longitudinal deficiencies represent all other skeletal limb deformities. In identifying longitudinal deficiencies, all completely or partially absent bones are named. Bones not named are considered to be present. These deficiencies are separated into preaxial and postaxial divisions of the limb and include longitudinal failure of the formation of an entire limb segment, such as phocomelia, or of the preaxial (i.e., radius, tibia), central, or postaxial (i.e., ulna, fibula) components of the limb. The more common deformities include phocomelia, an absent radius (i.e., radial clubhand), and an absent fibula (i.e., fibular hemimelia).[13,36,41]

FAILURE OF DIFFERENTIATION OF PARTS

In failure of the differentiation of parts, the basic units of the extremity developed, but the final form was not completed. The common disorders of this group include an undescended scapula (i.e., Sprengel deformity), proximal radioulnar synostosis, and syndactyly of the fingers and toes.

DUPLICATION

Duplication occurs as the result of a particular insult to the limb bud at an early stage such that the splitting of the original embryonic part occurs. Polydactyly of the thumb, fingers, great toe, and lesser toes represents duplications of this most common of the neonatal musculoskeletal disorders.

OVERGROWTH

Overgrowth can result from an excess of skeletal growth or soft tissues. The overgrowth frequently increases in size because of the asymmetric growth of the involved part.

UNDERGROWTH

Undergrowth usually represents the defective or incomplete development of parts. It can involve an entire extremity or only a portion of it. Overgrowth disorders, such as congenital hemihypertrophy, are more common than undergrowth disorders.

CONGENITAL CONSTRICTION BAND SYNDROME

Congenital constriction band syndrome may represent focal necrosis of the limb after the embryonic period or an acquired deformity due to amniotic bands. Deformity resulting from amniotic bands is thought to be the most common cause.

GENERALIZED SKELETAL ABNORMALITIES

Generalized skeletal abnormalities manifest generalized disorders, some of which may be inherited. Examples include skeletal dysplasia and syndromes such as Marfan syndrome and neurofibromatosis.

Spinal Defects

Errors in the embryologic derivation of the spine cause a number of congenital defects of the spine and spinal cord. These errors range in severity from isolated hemivertebrae to the complex errors of vertebral formation and segmentation associated with massive defects of the neural tube or spinal cord. When such errors result in asymmetric vertebral formation or produce asymmetric vertebral growth potential, structural spinal curves such as congenital scoliosis or kyphosis develop. Partial or complete failure of the formation of a vertebra (i.e., hemivertebra) or errors in the normal pattern of vertebral segmentation and recombination (i.e., unsegmented bars and trapezoidal, butterfly, and block vertebrae) may occur as single anomalies or be associated with other malformations of the osseous, neural, and organ systems. When vertebral defects are unbalanced and have growth potential, striking spinal deformities may occur. The nature of the deformity depends on the growth potential of the abnormal segments and their positions in the spinal column. For example, lateral abnormalities produce congenital scoliosis, and anterior or posterior midline defects result in congenital kyphotic or lordotic deformities.

Malformations of the head and neck, especially the internal and external auditory apparatuses, maxillae, and mandibles, occur frequently in patients with high thoracic and cervical curves. The association of a short neck, low posterior hairline, and restriction in neck motion caused by the congenital fusion of cervical vertebrae represents Klippel-Feil syndrome. Renal anomalies, the congenital elevation of the scapulae (i.e., Sprengel deformity), impaired hearing, and congenital heart disease are common associated anomalies in affected patients. The VATER syndrome (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia), in association with limb defects, underscores the complex nature of the relationships between the rapidly evolving organ systems and the musculoskeletal system during the first trimester of pregnancy.

The association of vertebral anomalies with neural tube or spinal cord defects is to be expected, given the intimate relationships of their embryonic development. Spina bifida occulta is the most common and least serious and myelomeningocele the most severe of such anomalies. Not all anomalies are easily identified on physical or radiographic examination. McMaster[69] reported a 20% incidence of occult intraspinal abnormality in patients with congenital scoliosis. Possible anomalies included intradural and extradural lipoma, cysts, teratoma, spinal cord tethers, diplomyelia, and meningocele. In some instances, the spinal cord may be split by a bony, fibrous, or cartilaginous bar extending from the posterior aspect of the vertebral body to the vertebral arches. This condition, known as diastematomyelia, commonly occurs in association with defects at the thoracolumbar junction. Unless the spurs are ossified, they are not easily visualized by conventional radiographic techniques. The physical signs of underlying spinal dysraphism include hairy patches, midline dimpling, nevi, inequality in the length of the lower extremities or circumferential asymmetry, and asymmetry in foot size.

IN UTERO POSITIONING

The imprint of in utero positioning is frequently seen in the neonate. It can produce joint and muscle contractures and torsional and angular variations in the long bones, especially those of the lower extremities. It can also produce craniofacial distortion and positional contracture of the neck. The upper extremities are usually less affected.

The expression of in utero positioning depends on fetal position and the amount of compressive force applied. Intrinsic and extrinsic factors contribute to these variables. The intrinsic factors include oligohydramnios, multiple fetuses, a large fetus, and uterine deformities (i.e., bicornuate). The extrinsic factors may include a small maternal pelvis, abnormal fetal positioning (i.e., breech and transverse), and abnormal fetal muscle tone. These factors can lead to increased uterine compression and secondary changes in the neonate. Some of the more common problems related to in utero positioning include DDH, metatarsus adductus, the calcaneovalgus foot, tibial bowing, internal and external tibial torsion, and hyperextended knees. Craniofacial abnormalities, which are much less common, may include plagiocephaly, mandibular asymmetry, flattened facies, and crumpled ears. Therefore, most of these abnormalities are physiologic rather than pathologic in origin and resolve with normal growth and development. Others, such as DDH, may not resolve and may cause significant disability unless they are recognized and appropriately managed. The speed of resolution depends on the severity of the deformity and the rate of growth of the involved area.

It is a common misconception that the bowed appearance of the neonate's lower extremities is an abnormality. All term neonates have 20- to 30-degree hip and knee flexion contractures that decrease to the neutral position by 4 to 6 months of age. The newborn hip is externally rotated in extension to 80 to 90 degrees and has a limitation of internal rotation of 0 to 10 degrees. Metatarsus adductus results from the tucked-under position, in which each foot is wrapped around the posterolateral aspect of the opposite thigh. The same position also produces lateral tibial bowing and inward (internal) rotation of the tibia. Tibial bowing and internal tibial torsion contribute to the bowed appearance of the lower extremity during the first year of life as well as a mild pigeon-toed or in-toed gait during the second year. However, this condition must be recognized as a normal variation resulting from the in utero position; it resolves with normal growth and development.

TRAUMA

See also Chapter 28.

Neonatal musculoskeletal injuries are frequently the result of a difficult or traumatic delivery. An abnormal intrauterine presentation and forcible extraction are associated with clavicular fractures, brachial plexus injuries, and occasionally long-bone fractures or epiphyseal separations (i.e., proximal humeral epiphysis) in otherwise healthy term infants. Prematurity, low birthweight, and underlying systemic disease may also predispose an infant to birth trauma and neonatal injury. Sometimes the minimal force involved in the daily care of a significantly premature infant is sufficient to produce a long-bone fracture. Infants receiving total parenteral alimentation may develop disorders of ossification that lead to pathologic fractures. These fractures are not usually associated with neurologic injury, and the prognosis for healing and subsequently normal function is excellent. Those fractures associated with neurologic injuries are more complex and have a more guarded prognosis.

Neonatal fractures resulting from abuse are uncommon but do unfortunately, occur. Long-bone fractures in association with vague histories or suspicious causes must be investigated.

Spine

Neonatal spinal trauma may be classified as an injury directly to the spine (i.e., vertebrae, intervertebral discs, and supporting ligamentous structures) or indirectly to the surrounding structures. The latter includes injuries to the brachial plexus and the sternocleidomastoid muscle (i.e., muscular torticollis) of the neck.

SPINAL INJURY

Difficult delivery is the most frequent cause of neonatal spinal injury. Breech presentation, especially when associated with intrauterine neck hyperextension, excessive traction during delivery, and forceps traction, puts the spine and enclosed neural elements at risk for injury. Injuries of the cervical spine are more common in neonates than those of the thoracic or lumbar spine; upper cervical injuries are more common than lower ones.

Spinal cord injury may occur with or without vertebral fracture. Excessive ligamentous laxity and the relative weakness of supporting musculature predispose the neonate to stretch injuries of the spinal cord without obvious skeletal damage. This stretch can produce spinal cord ischemia due to vertebral artery or segmental vessel injuries and result in neurologic abnormality in some neonates. Extensive areas of vascular damage in the spinal cord have been reported in neonates who died as the result of obstetric trauma.

Fractures, dislocations, and subluxations of the occipitoatlantal, atlantoaxial, and second and third cervical articulations have been reported. The neonatal spine is incompletely ossified, and skeletal injury may be difficult to detect on routine radiography. Radioisotope scanning or magnetic resonance imaging maybe useful for documenting injury in questionable cases.

Injuries of the brainstem and spinal cord may be fatal if the respiratory centers are compromised. For infants who survive, the goal of treatment is to improve function. When fracture or dislocation is documented, reduction and immobilization may be necessary to achieve segmental stability. Unfortunately, reduction rarely improves neurologic function.

BRACHIAL PLEXUS INJURY

See also Chapter 28.

Injuries of the brachial plexus have long been recognized as a consequence of difficult labor and delivery.[90] In this kind of paralysis, the arm falls motionless alongside the body and is rotated inward; the forearm remains extended, but the movements of the hand are preserved.

In 1877, Wilhelm Heinrich Erb described isolated upper plexus palsy and localized the site of damage to the junction of the C5 and C6 nerve roots, known thereafter as the *Erb point*. Erb's description remains an accurate assessment of the most common variety of plexus injury, with traction damage to spinal nerves C5, C6, and C7.

Other patterns of brachial plexus injury are less common but well documented. Isolated injuries to the lower portion of the brachial plexus described by Klumpke are uncommon in infants. Wickstrom[114] reported 11 such cases in his series of 87 patients. Hoffer and associates[47] observed four cases of posterior plexus damage in their series of 39 patients. Total or mixed plexus involvement is reported to be the most common pattern of injury after isolated upper plexus palsy.

The incidence of brachial plexus injury at birth is 0.1% to 0.3% of live births. Risk factors include elevated birthweight, prolonged labor, shoulder dystocia, and breech presentation, as well as high maternal body mass index and fetal asphyxia. Additionally, a humerus fracture is a risk factor for brachial plexus injury, whereas a clavicle fracture is not. Cesarean delivery does not fully protect children from birth palsy[2]; 10% of the affected patients have a history of cesarean delivery.

Upper brachial plexus injury is the most common pattern of damage. Combined upper and lower plexus injuries occur in a small percentage of patients. Isolated lower plexus injuries and posterior plexus injuries occur much less commonly.

Traction damage of the plexus may occur at any level from the origins of the cervical nerve roots at the spinal cord to the terminal branches of the plexus and may range in severity from stretch with intact neural tissues to avulsion of nerve roots. The physical findings at birth reflect the degree of involvement. The affected limb shows little or no spontaneous motion and is held in a position of elbow extension, internal rotation, and adduction. With lesions of the upper plexus, active wrist flexion and finger flexion may be present. In complete injuries, these motions are absent. The injury must be differentiated from other causes of decreased active motion in the neonatal period, such as fracture of the clavicle or upper humerus and septic arthritis or osteomyelitis. The diagnosis can usually be established from a history of difficult delivery, physical examination, and radiographic evaluation of the upper limb and trunk.

The prognosis varies with the extent of damage to neural tissues. Up to 90% of patients with incomplete lesions involving the upper plexus can expect full recovery with no treatment. In general, these children recover biceps function within 1 month of life and quickly become normal. Patients with complete injuries or injuries of the lower plexus do not fare as well. Most recovery occurs within the first 3 months of life, but continued slow improvement for up to 5 years after birth has been reported by Tada and colleagues[103] for patients with complete injury. Partial recovery occurs in most cases. Surgical repair of the brachial plexus has been recommended by Waters[112] for children who have no return of biceps function by 6 months of age. Compared with the natural history of the lesion, improved but not normal function is possible. Shoulder contracture and osseous deformity (nonspherical humeral heads and abnormal glenoids) are common in patients with birth palsies. They commonly occur in children who have incomplete recovery and are also seen in those who have eventually complete neurologic recovery if that recovery does not start within the first 3 weeks of life.[46]

Infants with nerve root avulsion have the worst prognosis; no motor recovery can be expected in such cases, although some sensory recovery may occur. Fortunately, such injuries are uncommon. Surgical repair of nerve root avulsion has been recommended by some investigators, including Solonen and coworkers,[97] who reported good results in three infants with complete avulsion of the cervical nerve roots who underwent surgery within the first 3 months of life. Such an approach is theoretically justified when there is convincing evidence of complete avulsion on examination and no recovery has been seen on repeated examination, although such cases are uncommon.

In most cases of neonatal brachial plexus palsy, no treatment is necessary. Abduction splinting of the limb in the first few months of life is unnecessary and may further complicate lower plexus injury. Gentle range-of-motion exercises may be used to prevent adduction and internal rotation contracture. Infants with incomplete recovery may require later reconstructive surgery to minimize deformity and functional disability. In young children without fixed contractures and secondary bony deformities, tendon transfers may be used to balance asymmetric forces.[47,110] In older children, humeral osteotomy is occasionally necessary to correct internal rotational deformity.[58]

MUSCULAR TORTICOLLIS

Torticollis, or wryneck, in the neonatal period is most commonly associated with abnormalities of the sternocleidomastoid muscle. Shortening of the sternocleidomastoid muscle results in tilting of the head toward the affected muscle and rotation of the chin toward the opposite side. Birth trauma, intrauterine malposition, muscle fibrosis, and venous abnormality within the muscle have all been implicated, but no single cause has been identified. Davids and associates[23] demonstrated that the sternocleidomastoid muscle is contained within a separate fascial compartment. They thought that a stretch or tear of the sternocleidomastoid muscle that caused bleeding could result in a compartment syndrome, leading to significant muscle damage and contracture. A palpable mass is sometimes present within the affected muscle during the first few weeks of life. Flattening of the head and slight facial asymmetry or plagiocephaly are usually present. If the deformity is not corrected, contractures of the soft tissues on the side of the affected muscle occur, and pronounced plagiocephaly may develop. The disorder, occasionally associated with a case of developmental dysplasia of the hip (DDH) severe enough to require treatment, varies between 3.7% and 10% of patients, depending on the study.[73,107,111] It is also seen in association with metatarsus adductus.[49] Both these conditions are often the consequence of in utero positioning.

Torticollis may also be the result of congenital cervicovertebral anomalies (Fig. 54-1). Ballock and colleagues[5] reported that Klippel-Feil syndrome and congenital scoliosis were diagnosed in 5% of all torticollis patients referred to a large tertiary children's hospital. The severity of the curvature and associated head deformity depend on the nature of the vertebral defect. Cervical hemivertebrae are sometimes less deforming than unsegmented, unilateral cervical bars. As in all cases of congenital spinal curvature, a careful search for other systemic anomalies, such as those involving the cardiac and genitourinary systems, must be made.

The cause of torticollis should be established before treatment is initiated. Careful radiographic examination of the cervical spine is recommended. Anteroposterior and lateral views of the neck should be obtained initially; computed tomography may be necessary in some cases. Particular attention should be given to the upper cervical spine, especially the occipitoatlantal (occiput-C1) and the atlantoaxial (C1-C2) regions. If no underlying skeletal abnormalities are identified, a program of stretching exercises is indicated to lengthen the contracted sternocleidomastoid muscle. The head is first tilted toward the opposite shoulder, and the chin is then rotated toward the affected side. Exercises should be performed gently, and the corrected position should be maintained for 5 to 10 seconds on each repetition. A program of 10 to 15 repetitions performed four times daily is sufficient in most cases. Stretching should begin early. This procedure seldom fails if begun during the first 3 months of life, but seldom succeeds if begun after 18 months of age.[24] Positioning the infant's crib with the normal side of the neck toward the wall sometimes stimulates an infant who lies prone to turn his head and stretch the sternocleidomastoid muscle. However, it is not a reliable method of treatment.

The surgical release of sternocleidomastoid contracture is indicated if there is significant deformity after 6 months of vigorous therapy or for older children with untreated torticollis.[16] Early surgery provides the best outcome, although children can benefit from surgery up to 10 years of age.[17] Delay results in significant plagiocephaly that will not be completely corrected after the release of contracture. Recurring contracture is a problem in older children.

The treatment of torticollis resulting from congenital cervical scoliosis is difficult because the primary cause of torticollis in these patients is skeletal, and soft tissue stretching cannot provide lasting correction. Surgical fusion of the affected area may be necessary to halt progression. It may be impossible to reverse the facial asymmetry that has developed because of head tilting.

Fractures

See also Chapter 28.

Neonatal fractures usually involve the upper extremity, particularly the shoulder region, and are the result of a difficult delivery. Fractures of the lower extremity are less common and may be indicative of an underlying neuromuscular disorder, especially those that limit joint mobility, such as arthrogryposis multiplex congenita. Fractures may also result from a bone disorder, such as osteogenesis imperfecta.

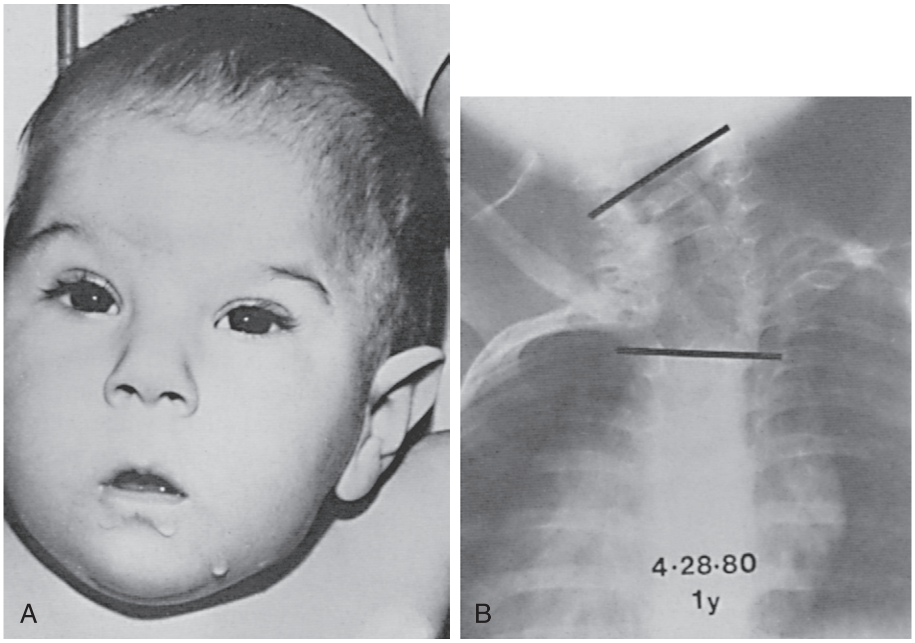

Figure 54–1. Congenital scoliosis may be manifested as torticollis. **A**, Clinical photograph of a 1-year-old child with congenital cervical scoliosis. The chin is tilted toward the right and the occiput toward the left. **B**, Radiographic views of the cervical spine in this patient show multiple hemivertebrae formation and an unsegmented congenital bar on the left side of the lower cervical spine. By convention, scoliosis films are viewed as if the examiner is facing the patient's back.

CLAVICLE

Fractures of the clavicle are the most common type of fracture in neonates. The incidence of clavicular fractures ranges from 2 to 7 cases per 1000 live births. McBride and coworkers[68] reported 9106 newborns prospectively screened for clavicular fracture. In this study, the risk factors included high birthweight, shoulder dystocia, and mechanically assisted delivery. Breech positioning was a factor in previous decades but not in this study. The liberal use of cesarean delivery appears protective. Of the 9106 babies reviewed, 1789 were delivered by cesarean section for various indications, including breech positioning. There were no clavicular fractures in these patients, although other authors have reported clavicular fractures after cesarean delivery.[48]

Fractures may be complete or incomplete (i.e., greenstick fracture). Complete fractures are more likely to be accompanied by classic symptoms and signs. Irritability and pseudoparalysis (i.e., decreased motion due to pain) of the involved limb are common. Discoloration, tenderness, and crepitation at the fracture site are common physical findings. Brachial plexus palsy, neonatal sepsis, traumatic separation of the proximal humeral epiphysis, humeral shaft fracture, and shoulder dislocation must be considered in the differential diagnosis.

The treatment of clavicular fracture is simple; asymptomatic patients with incomplete fractures need no immobilization. Symptomatic infants, usually those with complete fractures, should be treated. The treatment can include applying a figure-of-8 harness of gauze and tape or securing the affected arm to the chest with a bandage for 7 to 10 days. Pinning the sleeve of the infant's shirt to the front is often sufficient. An elastic bandage loosely applied around the chest and involved extremity after a cotton pad has been placed in the axilla can be considered for larger infants.

LONG-BONE FRACTURES

Fractures of other long bones are occasionally seen after a difficult delivery. Fractures or separations of the proximal humeral epiphysis may occur with the same force that produces clavicular fracture and brachial plexus injury. Symptoms and signs may be similar; pseudoparalysis, swelling, pain on passive motion, and crepitation with shoulder joint motion are usually present. The diagnosis of clavicular fracture can be made radiographically; however, because the proximal humeral epiphysis is not ossified at birth, routine radiography cannot demonstrate fracture or epiphyseal separation (Fig. 54-2). Ultrasonography can be used to establish the diagnosis in some cases, but most often the diagnosis is not confirmed until callus formation is seen radiographically 7 to 14 days later. Arthrography and magnetic resonance imaging can also be used to establish the diagnosis. When the diagnosis is confirmed soon after injury, the affected limb should be immobilized in a Velpeau bandage. Treatment is unnecessary if the diagnosis is delayed until callus formation has occurred. Scaglietti[90] pointed out that late contractures of the shoulder in patients with fractures or separations resulting from a severely displaced proximal humerus may be difficult to distinguish from contractures caused by brachial plexus injury.

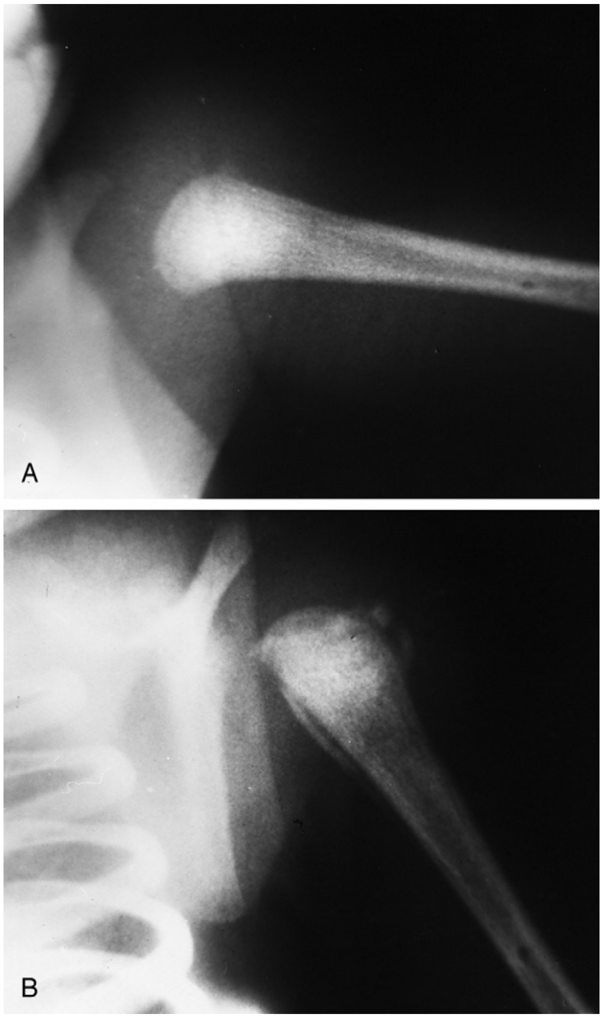

Figure 54–2. A, Normal-appearing radiograph of the humerus in a female newborn who had pseudoparalysis and appeared to have pain with passive motion of the left shoulder. **B**, Repeated radiograph 1 week later demonstrates subperiosteal new bone formation, indicating that there had been a traumatic separation of the proximal humeral epiphysis at delivery. The arm is now asymptomatic, and voluntary shoulder motion has returned.

Fractures of the humeral and femoral shafts occasionally occur during delivery or with the routine management of a premature infant or an infant with a severe metabolic or neurologic disorder. Such injuries are the result of an underlying weakness of the bone rather than traumatic handling, and accompanying soft tissue injury is rarely severe. Such fractures can usually be treated successfully with the application of a simple plaster splint until radiographic callus formation occurs. A spica cast may be necessary for fractures of the proximal femur. A Pavlik harness is occasionally used for treating quite proximal femoral fractures.[99] The remodeling potential of the neonatal skeletal system is extraordinary, and long-term sequelae from long-bone fractures are not common.

PART 2

Bone and Joint Infections

Daniel R. Cooperman and George H. Thompson

Bacterial infections of the neonatal skeletal system are potentially disabling because of damage to the articular cartilage and epiphysis. Prompt diagnosis and treatment are imperative to prevent sequelae.[9,80] Unfortunately, neonates with skeletal infections do not usually have the classic symptoms or laboratory findings of sepsis because of their immature immune systems. Diagnosis requires a high index of suspicion and appropriate evaluation. When infections involve the bone, the disease process is called *osteomyelitis*. When the synovium (the membrane lining of the joint) is the primary site of infection, the process is called *septic arthritis* (see also Chapter 39).[39]

OSTEOMYELITIS

Pathology and Etiology

Bone infection, or osteomyelitis, occurs by three mechanisms: bacteremia or hematogenous; direct inoculation from a puncture wound, such as a heel or femoral vein stick; and a contiguous spread from an adjacent focus of infection. In neonates, as in infants and children, most bone infections are hematogenous in origin. The most common site of osteomyelitis is the metaphysis, the region of the bone immediately beneath the physis, or growth plate. The anatomic arrangement of metaphyseal vessels and the dynamics of blood flow in this region permit bacteria to lodge and proliferate. The nutrient artery ascends to the metaphysis from a central location within the bone. When the arterioles reach the physis, they make 180-degree turns and empty into the venous sinusoids. This process creates an area of sluggish blood flow and an opportunity for bacteria to become trapped and proliferate. A separate set of vessels nourishes the epiphysis.

In childhood, there is no connection between the epiphyseal and metaphyseal blood supply. The physis creates a barrier that is seldom penetrated by the spread of infection from the metaphysis to the epiphysis or from the epiphysis to the metaphysis. However, during the first 12 to 18 months of life, this barrier to the spread of infection does not exist because there are vessels passing through the physis that connect the epiphyseal and metaphyseal circulations.[9,12,77] These vessels allow infections to cross the physis, which may account for the increased incidence of physeal damage seen in neonatal osteomyelitis when compared with childhood osteomyelitis.[9,39,80] Peters and associates[80] observed the late onset of growth disturbance after neonatal osteomyelitis and recommended that the affected neonates be followed to skeletal maturity to monitor for growth disturbances.

When bacteria lodge in the metaphyseal vessels and begin to proliferate, inflammation followed by abscess formation occurs. The pressure from the purulent material causes extrusion of the pus through the haversian canals to the cortex and subsequently into the subperiosteal space. The continued subperiosteal accumulation of purulent material strips the periosteum from the bone. Because the periosteum supplies blood to the cortex, this stripping process interrupts cortical blood flow. As a result, large areas of cortical bone may become devascularized. This dead bone, or sequestrum, can serve as a site for chronic infection, which is isolated from limited neonatal defense mechanisms and antibiotics.[77] The elevated periosteum produces new bone in an attempt to repair the injured bone. This process in turn produces the involucrum, which surrounds the sequestrum.

Draining cutaneous sinuses may arise when pus ruptures through the periosteum, adjacent soft tissues, and skin. Infection may occasionally spread into an adjacent joint space, causing secondary septic arthritis. The destruction of the epiphysis may occur through the direct spread of infection into it. This process can result in subsequent shortening, angular deformity, or both, of the involved extremity.[80] In neonates, complete physeal closure can occur, resulting in shortening.[9] Damage to the articular surface of the joint may result in the loss of motion and ultimately degenerative osteoarthritis.

The etiologic organisms responsible for neonatal osteomyelitis are variable. *Staphylococcus aureus* has traditionally been the most common causative organism.[9] Recently, methicillin-resistant *S. aureus* (MRSA) has been reported in neonates, which is especially destructive.[62] Streptococci and enteric aerobic bacilli account for much of the remaining responsible organisms. *Candida albicans* can also cause osteomyelitis in those neonates at high risk for infection.

Diagnosis

The clinical manifestations of osteomyelitis in children vary with age. In previously healthy neonates, it usually occurs during the first 2 weeks of life. Limitation of spontaneous movement with pseudoparalysis of the involved extremity is the most common sign. Localized tenderness, erythema, increased warmth, and swelling may occur. Associated septic arthritis with accompanying joint effusion and increased warmth occurs in many cases. Term neonates usually appear less ill than would be expected because of the persistence of maternal antibodies. They have less fever, leukocytosis, and elevation of the erythrocyte sedimentation rate[9] than older children with similar infections. Less commonly, neonatal osteomyelitis presents as septicemia. The presentation and course of osteomyelitis are strongly correlated with the health of the infant before presentation. Infants with multiple sites of infection are usually ill before its onset and have an increased incidence of placement of umbilical catheters or other lines. They are also more ill than those neonates presenting with only one site of infection.[9]

Some neonates are at increased risk for osteomyelitis; they also have a more severe course of the disease. Bergdahl and colleagues[9] identified the following risk factors in a study of 40 neonates with osteomyelitis: a birthweight of less than 2500 g or gestational age of less than 37 weeks, emergency cesarean delivery, a congenital malformation requiring neonatal surgery, respiratory distress syndrome, hyperbilirubinemia, large vessel (usually umbilical) catheterization, perinatal asphyxia, scalp laceration after vacuum extraction, and renal vein thrombosis. Twenty-one neonates were found to have risk factors, but 19 did not. Of the 21, most had multiple sites of infection; 13 of the 21 (62%) neonates with risk factors had serious skeletal sequelae. In the remaining 19 neonates, multiple sites of infection were uncommon, and serious skeletal sequelae occurred in less than 20%.

The early diagnosis of osteomyelitis is based on obtaining purulent material, blood, or both for cultures and antibiotic sensitivities. Early in the course of the disease, radiographs and bone scans may be normal.[4,12,25] Bone aspiration is usually positive. The cultures of subperiosteal metaphyseal pus yield a pathogen in about 70% of cases. The point of maximal swelling, bone tenderness, and fluctuation on physical examination is the most appropriate location for needle aspiration. The skin overlying the affected region should be prepared with an antiseptic solution and draped with sterile towels. After infiltration of the area with local anesthetic, an 18-gauge spinal needle, with the stylet in place, is passed through the skin to the bone. The subperiosteal space is aspirated first. If the tap is dry, the needle with the stylet should be gently twisted through the bone cortex into the metaphysis, which is then aspirated. The aspirated fluid or blood should be immediately Gram stained and cultured. The organism may also be recovered from other sources. Blood cultures are positive in 60% of the children with osteomyelitis. When osteomyelitis complicates meningitis, the organism may be recovered from cultures of the cerebrospinal fluid.

Imaging

See also Chapter 37.

A diagnosis cannot be easily made by bone aspiration during the inflammatory phase before abscess formation. At this point, imaging can be helpful. Plain radiographs of the suspected bone are often a valuable procedure. Within a few days of the onset of infection, deep edema, joint effusion, and sometimes bone destruction can be detected.[9] The edema is visible sooner in neonates than in children because the neonate has very porous bones and a loosely attached periosteum (Fig. 54-3), which permits the earlier collection of subperiosteal abscesses in neonates than in children. This fact also accounts for the relatively favorable results of diagnostic aspiration in neonates.

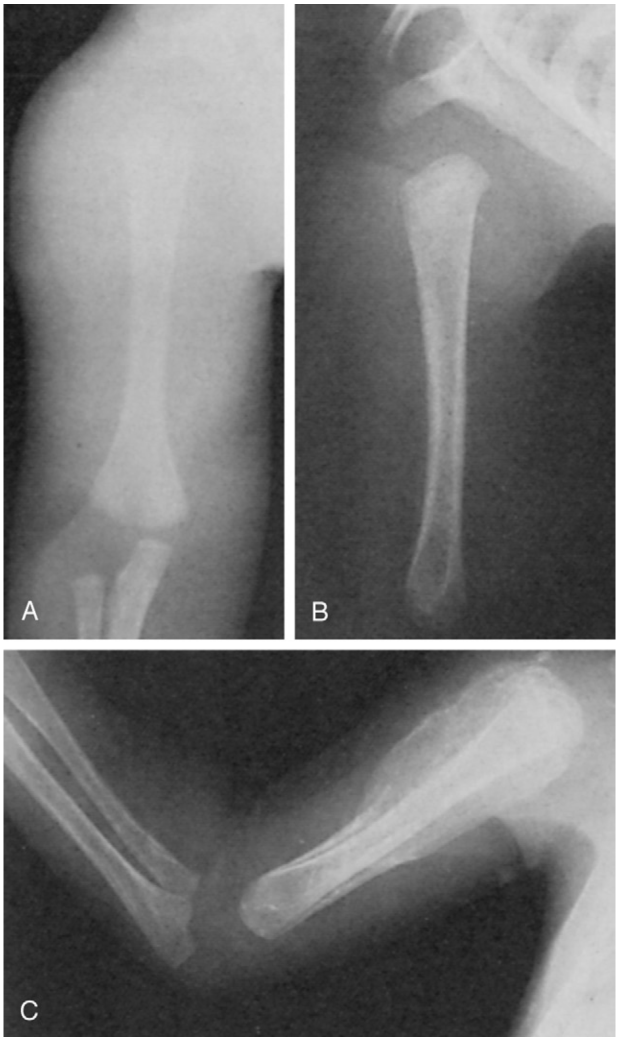

Figure 54–3. Radiologic changes in neonatal osteomyelitis. **A**, Early proximal humeral osteomyelitis. Soft tissue has become swollen around the affected bone. **B**, Periosteal elevation is manifested by subperiosteal bone formation. **C**, Massive subperiosteal new bone formation. The humeral shaft has become surrounded by new bone.

If radiographs are unproductive, ultrasound can be useful in localizing the areas of deep edema and joint effusion, as can magnetic resonance imaging. Technetium bone scanning is also recommended.[44] There is some controversy over the merits of bone scanning in neonates because of their decreased inflammatory response and the large amount of isotope uptake from the very active adjacent epiphysis. In 1980, Ash and Gilday[4] concluded that it was very unreliable. However, Bressler and coworkers[12] and others[25] have suggested that technetium bone scans can be helpful. Bressler's group scanned 33 infants suspected of having osteomyelitis. Each of the 25 sites of proven osteomyelitis in 15 infants was demonstrated on bone scanning. Another 10 sites that were radiographically negative were also demonstrated to be positive on bone scanning. The bone scan, if negative, does not exclude osteomyelitis.

The results of indium and gallium scans for acute osteomyelitis in neonates have not been reported. A concern about gallium scans is related to the pathology of osteomyelitis. If there is extensive septic embolization of metaphyseal vessels, labeled blood cannot penetrate the metaphysis. If the periosteum is stripped off the cortex, devascularizing the cortical bone, there can be no blood flow in the cortex. Under these circumstances, the uptake by bone may be difficult to predict. However, Demopulos and associates[25] recommended an indium scan if the technetium bone scan in the neonate is not highly suggestive of osteomyelitis.

Another concern in the assessment of osteomyelitis is the determination of whether metaphyseal aspiration can produce a positive bone scan. Canale and colleagues[14] assessed the effects of bone and joint aspiration on the bone scan results in healthy dogs. They used multiple aspiration techniques on the bones and joints of 15 dogs and scanned them between 5 hours and 10 days of aspiration. In no case did joint aspiration lead to a positive bone scan. Metaphyseal drilling and periosteal scraping with needles occasionally led to positive bone scans after a 2-day delay. Thus, bone aspiration does not initially affect a technetium bone scan.

Treatment

Treatment must not be delayed for neonates with suspected osteomyelitis. Antimicrobial therapy should be initiated, usually with a combination of agents, as soon as a presumptive diagnosis is made and appropriate material for cultures has been obtained. Treatment can later be appropriately altered according to culture results and antibiotic sensitivities. For neonates, optimal coverage is provided by a penicillinase-resistant penicillin coupled with an aminoglycoside. The new third-generation cephalosporins have been successfully used in the treatment of a form of osteomyelitis caused by enteric bacilli. However, these agents should not be used alone as the initial treatment because their activity against group B streptococci is inadequate. When these drugs are used as part of the initial therapeutic regimen, a penicillinase-resistant penicillin should be used concomitant with them. After an organism is isolated, focused antibiotic treatment is possible. The duration of treatment should be at least 3 weeks and probably not more than 6 weeks for acute hematogenous osteomyelitis. Nelson[75] suggests a clinical approach to antibiotic management. After local inflammation subsides and measures of inflammation such as erythrocyte sedimentation rate return to normal, he recommends 14 more days of antibiotics for group A streptococci and encapsulated bacteria such as pneumococci and 21 more days for staphylococcal infection.

Primary surgical treatment depends on the results of bone aspiration. If grossly purulent material is recovered from the subperiosteal space or the metaphysis, an abscess has formed. In these cases, surgical drainage is necessary to decompress the abscess. This procedure facilitates blood flow and the subsequent delivery of antibiotics. Surgical drainage also allows the removal of the bone sequestrum. When pus is not recovered at the time of initial aspiration, the patient's infection is in the cellulitic or inflammatory phase. The aspirated blood is used to obtain blood cultures, and antibiotic therapy is initiated. It is assumed that the bone blood flow is still adequate in the cellulitic phase to deliver antibiotics to the site of infection because there is no pus under pressure. The affected limb should be immobilized with splints. Neonates must be carefully followed during the early phases of treatment. Surgical intervention may become necessary if an adequate clinical response is not obtained within 48 hours of initial antimicrobial therapy.[64] An inadequate response implies that an abscess is forming. Reassessment, including repeated aspiration, is indicated. If an abscess is identified, surgical drainage will be necessary.

La Mont and coworkers[64] reviewed 69 children (15 neonates) retrospectively and 44 children (4 neonates) prospectively, all with acute hematogenous osteomyelitis. They concluded that surgery was seldom necessary because most of the prospective group improved clinically after 48 hours of appropriate intravenous antibiotics, and few of them had abscesses aspirated. In their study, surgery was infrequently used, and the results were excellent. It was their impression that the aspiration of pus from the bone was an indication for surgery but was seldom encountered. Drainage was also recommended for an extraosseous abscess.

It is believed that the surgical decompression of long bones such as the femur, tibia, humerus, radius, and ulna is necessary if pus is aspirated from bone or the subperiosteal space.[9] Decompression consists of drilling a hole in the metaphysis or removing a small cortical window. The wound is then left open to drain. It is closed later or allowed to close spontaneously, and dressings are changed two or three times a day. Surgical decompression is also necessary if there is not a good clinical response to antibiotics within 48 to 72 hours, even if no pus is aspirated from the bone.

If osteomyelitis is localized to flat bones, such as the pelvis or vertebrae, the administration of antibiotics without surgical decompression is usually sufficient treatment. However, caution is necessary because Bergdahl and associates[9] reported one death and one case of tetraparesis resulting from neonatal vertebral osteomyelitis.

SEPTIC ARTHRITIS

Pathology and Etiology

The mechanisms responsible for joint or synovial infections in neonates and children parallel those for osteomyelitis: septicemia, contiguous spread from an adjacent focus of infection, and traumatic penetration of the joint space. The risk factors include prematurity, umbilical catheterization, perinatal asphyxia, and a difficult birth.[51] Regardless of the source, the ensuing inflammatory response results in synovial hypertrophy and altered capillary permeability. Purulent material accumulates within the joint, and fibrinous clots may coat the joint surfaces. The diffusion of nutrients across the articular cartilage of the joint is interrupted, and the normal lubrication processes are altered. Lysosomal enzymes, which are released in neutrophil degeneration, attack the mucopolysaccharide components of articular cartilage. Hypertrophic granulation tissue forms a pannus that can erode articular cartilage and may allow the extension of infection to subchondral bone. Fibrous ankylosis of the joint may develop, with a permanent loss of motion.[86] Increased intra-articular pressure may occlude the vessels that supply the epiphyses and the physis, resulting in epiphyseal death or avascular necrosis. This process is especially applicable to the hip. The rupture of pus through the synovial membrane and into the surrounding tissues produces soft tissue abscesses that may later develop into draining sinuses.

Neonatal septic arthritis often results from osseous infection, and the bacterial agents responsible for the joint infections are similar to those previously described for neonatal osteomyelitis: *S. aureus*, streptococci, and enteric bacilli. Septic arthritis occurs less frequently as a primary entity; the Enterobacteriaceae family, the species of *Pseudomonas*, and *Neisseria gonorrhoeae* may be isolated in these cases. Fink and Nelson[33] reported septic arthritis from *Haemophilus influenzae* in neonates as young as 3 days of age. About 25% of the neonates with *H. influenzae* septic arthritis also have meningitis.

Diagnosis

The clinical presentation of neonatal septic arthritis is similar to that described for neonatal osteomyelitis. Joint effusion, increased warmth, and limited motion are often observed on physical examination.

The definitive diagnosis of septic arthritis requires aspiration of the affected joint. The causative agent can be recovered in about 60% of cases. The procedure should be performed under sterile conditions by an experienced physician because repeated attempts to penetrate the joint may further damage the joint surface and the underlying bone. After culture and Gram staining of the fluid, determinations of the cellular count as well as glucose and protein concentrations should be obtained. Infected synovial fluid typically contains more than 50,000 white blood cells per cubic millimeter (primarily polymorphonuclear leukocytes); a glucose concentration of less than 40 mg/dL, or less than 30% of the serum concentration; and an elevated protein concentration. Blood cultures should also be obtained.

Imaging

Neonatal septic arthritis has the same recommendations as those for osteomyelitis (Fig. 54-4). Of special interest are the findings of Canale and colleagues[14] that joint aspiration in dogs is never associated with a positive technetium bone scan. Consequently, the aspiration of joints should never be discouraged on the basis of a belief that it may affect a later bone scan.

Treatment

Neonatal septic arthritis, like osteomyelitis, requires prompt treatment. Irreversible joint damage may occur unless intra-articular pus is evacuated and effective antimicrobial therapy initiated.[76,100] Neonates should be managed jointly by pediatricians and orthopedic surgeons.

Combinations of antibiotics are selected to cover the most likely pathogens. A penicillinase-resistant penicillin and an aminoglycoside or cephalosporin usually provide adequate coverage pending the results of the cultures and antibiotic sensitivities (see Chapter 39).

Joint decompression is an essential component of successful therapy for pyogenic arthritis. However, opinions vary on the most effective method, specifically surgical drainage compared with repeated aspiration. Primary decompression is usually accomplished at the time of initial joint aspiration and may be sufficient in peripheral joints such as the knee, ankle, and elbow, which are easily aspirated and in which blood flow to intra-articular epiphyses is not at risk. Needle aspiration is not sufficient for decompression of the hip because increased intra-articular pressure may occlude blood flow to the femoral head, resulting in avascular necrosis. Immediate surgical drainage is mandatory for septic arthritis of the hip.

The repeated aspiration of joints other than that of the hip may be appropriate. The morbidity for careful aspirations is less than that for arthrotomy, but persistent infection after repeated aspiration is probably more harmful than the risk for primary arthrotomy. Poorly executed needle aspiration may damage the articular surfaces and inoculate underlying bone with purulent fluid.

Like the therapy for osteomyelitis, effective antimicrobial therapy for pyogenic arthritis is a function of the agent, route, and duration of drug administration. After the pathogen has been isolated and antibiotic sensitivities are known, a single agent may be used. Intra-articular antibiotic instillation is unnecessary because adequate drug concentrations are achieved in synovial fluid by the intravenous and parenteral routes.

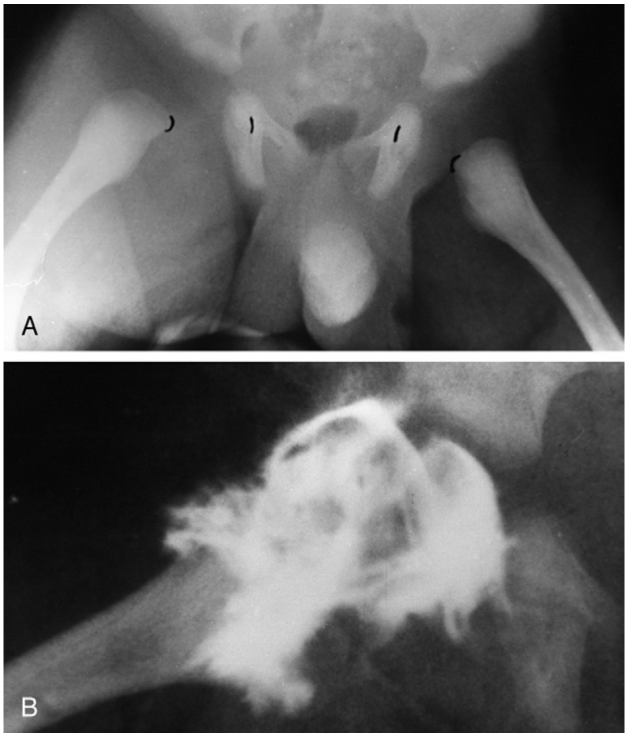

Figure 54–4. **A**, Anteroposterior pelvic radiograph of a 2-week-old boy who had been irritable during diaper changes for 1 week. There were no systemic symptoms, such as fever, although the child had been quite irritable and not feeding normally. The femoral heads are not visible because they do not begin to ossify until 4 to 6 months of age. Observe the widening between the acetabulum and the ossified medial corner of the proximal femoral metaphysis, which indicates lateral displacement or subluxation of the femoral head. **B**, Arthrocentesis revealed only a small amount of purulent material. An attempted arthrogram revealed gross distortion of the hip joint due to inspissated purulent material. At the time of hip arthrotomy, clotted, purulent material was removed. This child subsequently developed avascular necrosis as a consequence of septic arthritis with subluxation. Fortunately, he made a satisfactory recovery and regained essentially normal hip function.

Joint infections caused by *H. influenzae* require 2 to 3 weeks of therapy, whereas infections caused by other agents or those complicated by osteomyelitis may require up to 6 weeks of therapy. The treatment of neonatal gonococcal arthritis differs significantly from that of arthritis caused by other pathogens. Penicillin G, ampicillin, amoxicillin, tetracycline, and erythromycin have all been used successfully in therapy for gonococcal arthritis in 7- to 10-day courses. Other than diagnostic arthrocentesis, no surgical intervention is necessary for this disease.

PART 3

Congenital Abnormalities of the Upper and Lower Extremities and Spine

Daniel R. Cooperman and George H. Thompson

UPPER EXTREMITIES

Congenital anomalies of the upper extremities are those that occur during the embryonic period. Developmental deformities are those that occur primarily in the fetal or neonatal period. Because a developmental deformity may have a prenatal association, such as in utero positioning, it could be misinterpreted as a congenital deformity. Congenital and developmental disorders of the upper extremities are less common than those affecting the lower extremities.

Shoulder

The failure of the scapula and the upper extremities to descend to their normal locations is called *Sprengel deformity*, which can vary from mild to severe. The scapula is typically located abnormally elevated with respect to the child's neck and thorax, producing webbing of the skin at the base of the neck and a low posterior hairline. In the severe form, an accessory bone, the omovertebral bone, may connect the scapula to the spinous processes of the cervical spine and allow virtually no scapulothoracic motion. The severe forms are more likely than the mild forms to be diagnosed in the neonate. Associated muscle contractures that further limit the strength and stability of the shoulder girdle may also be present. In the mild form, the scapula is slightly elevated with less than normal motion. There may be an association with congenital cervicovertebral anomalies, particularly Klippel-Feil syndrome, and this association suggests the possibility of other congenital abnormalities, such as those in the cardiovascular and genitourinary systems. When Sprengel deformity is diagnosed, abnormalities in these other systems must be assessed.

Treatment is usually delayed until middle childhood and depends on the function of the child's shoulder and extremity. For a severe form, surgical repositioning and occasionally partial resection of the scapula may be necessary.

Elbow

Congenital radioulnar synostosis is an uncommon disorder that represents a failure of separation or congenital fusion between the proximal radius and ulna. It occurs from the fifth to the eighth week of gestation, when there is separation of the humerus, radius, and ulna from a common block of cartilage in the limb bud. This disorder is bilateral in about 50% of all patients and limits forearm pronation and supination. It is rarely recognized during the neonatal period because there is no obvious deformity, only a loss of forearm rotation. In most cases, the forearm is in a physiologic position of 45 to 60 degrees of pronation. Only if there is extreme supination may the disorder be recognized. The diagnosis of this disorder, which is confirmed radiographically, should be suspected in any neonate with restricted forearm pronation or supination.

Treatment is rarely indicated unless there is an abnormal position of the forearm that interferes with the function of the hand. The method of treatment, a rotational osteotomy through the synostosis, is usually delayed until middle childhood so that an adequate assessment of function can be determined. Attempts at restoring forearm pronation and supination by excising the synostosis have been unsuccessful.

Forearm and Wrist

RADIAL HYPOPLASIA AND CLUBHAND

Hypoplasia of the radius is a commonly discussed and infrequently encountered entity, occurring in 1 of 100,000 live births. It is bilateral in 50% of cases. The deformity can vary from mild shortening of the radius to its complete absence (i.e., radial clubhand). As the radius shortens, the deformity becomes more apparent. In complete absence of the radius, the hand is radially angulated 90 degrees to the long axis of the forearm. The ulna is markedly bowed, and the ulna and humerus can be half the length of the opposite normal side by maturity. As the deformity becomes profound, so does thumb involvement (i.e., an absent first ray, thumb hypoplasia) (Fig. 54-5).

The entire extremity may be involved, including the scapula and clavicle. The radially based muscles of the forearm are also hypoplastic or absent. There is hypoplasia or the absence of the radial artery, leaving the ulnar artery as the main blood

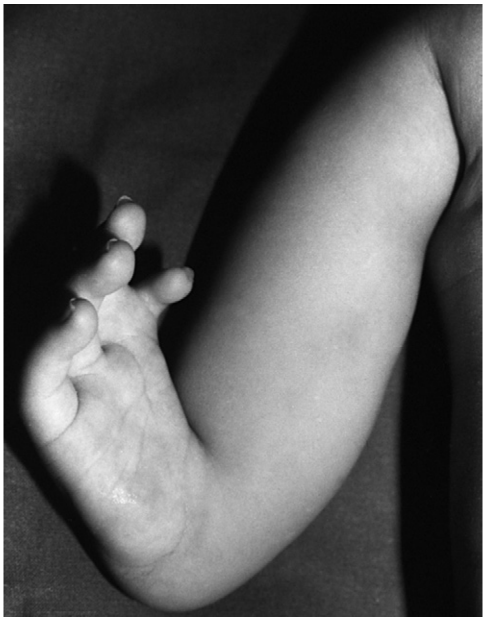

Figure 54–5. Clinical photograph of a 1-year-old boy with a right radial clubhand and hypoplastic index finger.

supply to the hand. There is no radial nerve innervation to the skin distal to the elbow, leaving the median and ulnar nerve to anastomose to provide dorsal sensation. Radial clubhand is not simply a bony defect.

The most frequently associated anomalies are blood dyscrasia and heart defects. Fanconi syndrome is a pancytopenia seen in some children with radial clubhand (see also Chapter 50). TAR syndrome (i.e., thrombocytopenia with an absent radius) is also seen. Holt-Oram syndrome, in which the primary manifestation is an absent thumb with atrioseptal defects, has a well recognized association with radial clubhand.

Radial hypoplasia alone is inherited sporadically. There is no definitely identifiable inheritance pattern; the careful scrutiny of relatives seldom yields another affected individual. Radial hypoplasia as part of a syndrome frequently has a defined inheritance pattern. Holt-Oram syndrome is inherited in a dominant fashion, and Fanconi pancytopenia is inherited as a recessive pattern.

Treatment comprises both operative and nonoperative options and is recommended for cosmetic and functional reasons. The treatment begins with stretching. During the first 6 months of life, casts and splints are used to stretch the radially deviated hand to conform to a more neutral alignment. If the deformity is corrected, the patient wears a splint all the time for the first 6 years of life and then after that only at night. If the deformity is not corrected, the hand is centralized onto the ulna. At surgery, the carpus is impaled onto the ulna after an osteotomy to straighten the ulna. If the patient has a useless thumb, the index finger occasionally undergoes pollicization—in essence it is turned into a thumb. The surgery is frequently performed when the patient is between 6 months and 1 year of age. After surgery, bracing is maintained 24 hours each day for the first 6 years of life. In bilateral cases, the hands are staged, with one operated on at 6 months and the other at about 3 years of age.

The contraindications to surgery are serious blood dyscrasia, heart problems, and profound muscle imbalance. If the elbow flexors are overpowered by the elbow extensors such that a child cannot touch the hand to the face even after physical therapy, surgery is not likely to provide a useful hand in a functional sense.

CONSTRICTION BANDS

Congenital constriction band syndrome, also known as *Streeter dysplasia* or *annular bands*, features defects of the skin resulting in ringlike strictures around the limbs and occasionally the trunk (Fig. 54-6).[35] It is seen in 1 of 15,000 live births, and multiple extremities are usually involved. The upper extremities, especially the hands, are involved more frequently than the lower extremities. The cause appears to be early amniotic rupture followed by temporary oligohydramnios with resulting intrauterine compression and the subsequent constriction of the fetal appendages by cords or bands of torn amnion (see also Chapter 22).[108]

Patterson[79] developed diagnostic criteria for congenital constriction ring syndrome. These criteria include simple ring constrictions, ring constrictions accompanied by deformity of the distal part with or without lymphedema, ring constrictions accompanied by fusions of distal parts ranging from fenestrated or terminal syndactyly (i.e., acrosyndactyly) to exogenous syndactyly, and intrauterine amputations. Other congenital anomalies frequently occur, such as clubfoot (30%), pseudarthrosis, peripheral hand palsy, and lower extremity length discrepancies.[35]

Rigid clubfoot distal to deep constriction bands may be difficult to correct.[1] Treatment involves the surgical release of the bands if the distal aspect is swollen and has lymphedema. The surgery is usually performed in two stages, although Greene[40] demonstrated that a complete one-stage release can be performed safely.

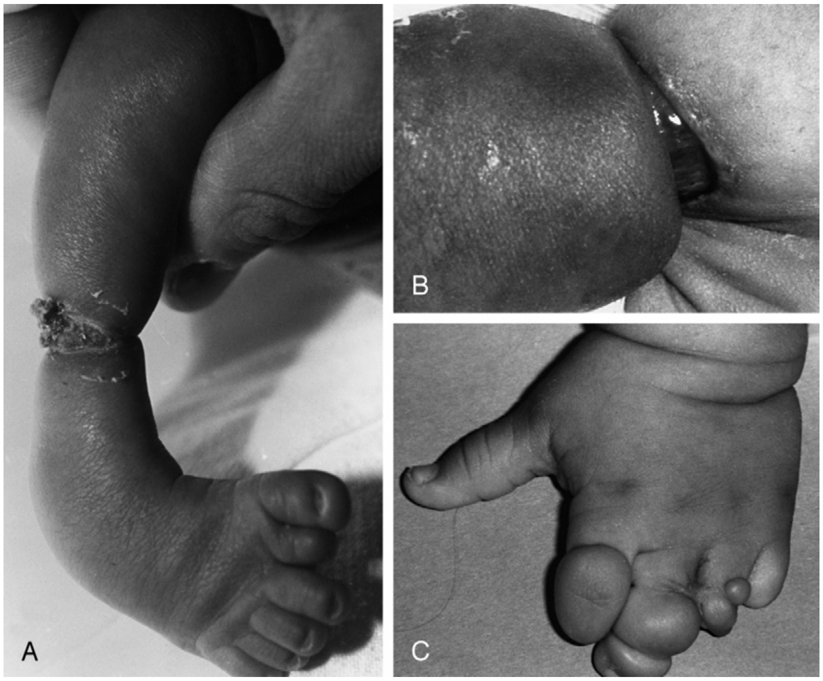

Figure 54–6. Clinical photographs of a newborn girl with multiple annular bands. **A**, The right lower extremity demonstrates a band with complete transection of the skin and subcutaneous tissue. The associated talipes equinovarus (clubfoot) deformity has a duplication of the great toe. **B**, A similar lesion is present in the right upper extremity, with a significant amount of distal edema from lymphatic and venous obstruction. **C**, The left hand shows multiple bands with segmented edema and partial amputations.

Fingers and Thumb of the Hand

CONGENITAL AMPUTATIONS

Congenital amputation is the best example of a failure of formation. In general, the greater the loss of length, the rarer the lesion. For instance, a child with a congenital amputation at the forearm level is encountered in 1 of 20,000 live births, and one with a missing arm is encountered in 1 of 270,000 live births.

When treating patients with congenital amputations of the upper extremities, it is necessary to define a goal for the patient. The arm serves as a positioning device for the hand. Consequently, treatment revolves around providing the patient with some sort of terminal device at the end of the usable arm. In the early stages, as the child achieves sitting balance, a soft terminal device is fitted. This device allows "two-handed" activities and is used to help pin objects against the normal hand. As the child reaches 2 to 3 years of age, prehension by means of a terminal device becomes possible. Early training allows children to become quite comfortable with these devices.

SYNDACTYLY

Syndactyly is the most common form of congenital anomaly in the upper extremities and represents a failure of separation of two fingers (Fig. 54-7). This failure of separation occurs sometime between weeks 5 and 8 of gestational life and is seen in 1 of 2250 live births. The anomaly appears to be sporadic in 80% of cases; the other 20% are the result of genetic transmission. Because all forms of genetic transmission have been linked to syndactyly, genetic counseling is quite difficult. The classification of syndactyly is defined by the degree of interconnection between the fingers. In complete syndactyly, the webbing extends from the tip of the fingers to the hand; in incomplete syndactyly, it does not. Simple syndactyly involves only the skin, whereas complex syndactyly includes bony fusion. Abnormalities of the blood vessels, nerves, and tendons are also seen in this anomaly.

Treatment is aimed at separating the digits to improve function. The affected digits are usually separated early, when they are of unequal length. If the thumb and index finger are syndactylized, the longer digit becomes tethered and deformed by the shorter digit.[119] Surgery within the first year of life is suggested. When the digits are of nearly equal length, such as the long finger and the index finger, the surgery can wait until 2 or 3 years of age without difficulty.

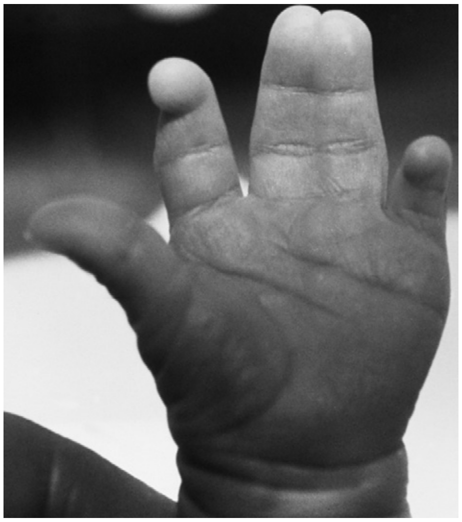

Figure 54–7. Clinical photograph of a 3-month-old boy with complete syndactyly between the third and fourth fingers. There is hypoplasia of the distal phalanges of the index and small fingers.

POLYDACTYLY

See also Chapter 29.

Polydactyly is a common duplication deformity of the hand (Fig. 54-8). This deformity is seen in 1 of 300 African-American and 1 of 3000 white live births in the United States. The incidence of thumb polydactyly is identical in African Americans and whites (0.8 of 1000 live births). Little-finger polydactyly is common in African Americans, with 1 of 300 affected. It is usually seen without associated abnormalities. In white infants, little-finger polydactyly is infrequent and often associated with other skeletal abnormalities, including syndactyly, coalescence of carpal bones, radioulnar synostosis, hypoplasia and aplasia of the tibia and fibula, hemivertebrae, and dwarfism. Other disorders also

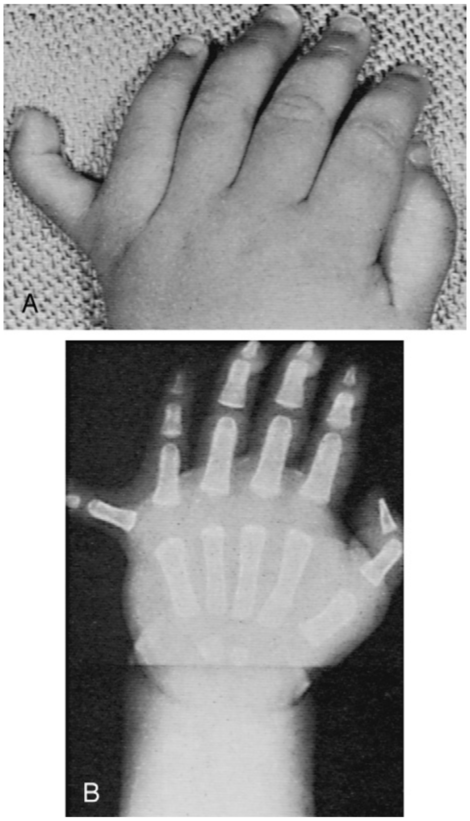

Figure 54–8. Clinical photograph (A) and radiograph (B) show congenital polydactyly, the most common digit duplication, with complete bones, tendons, and nerves. The recommended treatment is early ablation by amputation.

seen are hydrocephalus, cleft lip, hypogonadism, kidney abnormalities, and imperforate anus.

The surgical approach to polydactyly is based on the vascular and bony anatomy of the digits, and it is individualized. The surgery is usually performed sometime after 6 months but before 18 months of age to minimize the anesthetic risks.

MACRODACTYLY

Macrodactyly of the hand, also known as *idiopathic local gigantism*,[109] may involve one or more fingers and is bilateral in 5% of cases. All structures in the affected finger are enlarged, including the bone, blood vessels, nerves, and other soft tissues. True macrodactyly must be differentiated from other processes that create gigantism because the treatment is different. Local enlargement of the hand occurs in neurofibromatosis, lymphedema, hemangioma, lymphangioma, arterial vascular fistulas, fibrous dysplasia, aneurysmal bone cysts, and lipomas. The treatment for these disorders is individualized to the process. In typical macrodactyly, the child is followed carefully until the affected digit is about adult size, which usually happens between 7 and 8 years of age. At this point, growth arrests of all the bones in the affected digit are performed, and soft tissues are debulked. Occasionally, the growth is uncontrollable, and cosmesis is so poor that the parents and child prefer amputation. In contrast, ray resection with soft tissue reduction is the method of choice for managing macrodactyly of the foot, especially when it affects only the lesser toes.[15]

SPINE

Spinal disorders diagnosed during the neonatal period are uncommon.[78] Most are congenital in origin. Some, such as myelodysplasia and sacral agenesis, are obvious at birth, but others, such as congenital scoliosis and kyphosis, may not be recognized for months or years. Idiopathic spinal deformities can also occur but are rare.

Infantile Idiopathic Scoliosis

Scoliosis without a known causation is called *idiopathic*. Idiopathic spinal deformities are classified as infantile, with the onset between birth and 3 years of age; juvenile, with the onset between 4 and 10 years of age; and adolescent, with the onset at 11 years of age or older. The adolescent type is the most common form of scoliosis, and the infantile type is the least common. The infantile type is more common in the United Kingdom than in North America, the reason for which is unknown.

When a neonate or infant is found to have a spinal deformity, a very careful physical examination and radiographic assessment are necessary to determine an underlying reason. Physical examination includes evaluation of the spine for mobility and areas of tenderness. The skin should be inspected for cutaneous lesions that may indicate underlying spinal dysraphism. The lower extremities need to be carefully evaluated for symmetry and neurologic function.

Plain radiographs usually determine whether there is a spinal deformity. However, additional studies, such as magnetic resonance imaging (MRI), may be necessary to evaluate the spinal canal and spinal cord for possible lesions.

The treatment of infantile scoliosis is variable. Some curves may be observed and even improve with growth. However, others are progressive and require cast or orthotic management and possibly surgical intervention. It is important that all neonatal spinal abnormalities be referred to an orthopedic surgeon experienced in the management of pediatric spinal deformities.

CONGENITAL SPINAL DEFORMITIES

Abnormalities of vertebral formation can result in structural deformities of the spine that may be evident in the neonate or become more obvious during the first year of life. Deformities in the coronal plane produce congenital scoliosis, whereas those in the sagittal plane produce congenital kyphosis. The failure of formation, total or partial, of the sacrum is called *sacral agenesis*. If the lower lumbar spine is also absent, it is called *lumbosacral agenesis*.

CONGENITAL SCOLIOSIS

Congenital scoliosis is classified as a failure of formation (i.e., hemivertebrae), failure of segmentation (i.e., unsegmented bars), or mixed (Fig. 54-9). A failure of formation and segmentation can be partial or complete and may occur as a single abnormality or in combination with other bone, soft tissue, or neurologic abnormalities of the axial or appendicular skeleton.[28] Congenital genitourinary malformations occur in 20% of children with congenital scoliosis. Unilateral renal agenesis is the most common abnormality. Most genitourinary abnormalities do not require treatment, but about 6% of the affected patients have a silent obstructive uropathy.[37] Renal ultrasound should be performed on all neonates with congenital scoliosis to search for possible urinary tract abnormalities. Congenital heart disease (10% to 15%) and spinal dysraphism (20%) occur in neonates with congenital scoliosis. These abnormalities include a tethered spinal cord, an intradural lipoma, syringomyelia, and diastematomyelia (Fig. 54-10).[8,11,67,69,117] They are frequently associated with cutaneous lesions of the back, such as hairy patches, skin dimples, and hemangiomas, and with abnormalities of the feet and lower extremities, such as cavus feet, calf atrophy, asymmetric foot size, and neurologic changes. An ultrasound examination and MRI can be useful in the evaluation of spinal dysraphism in a neonate with congenital scoliosis. Congenital scoliosis may also occur in association with syndromes such as Klippel-Feil and VATER (vertebrae, anus, trachea, esophagus, and renal abnormalities) and with spinal dysraphic disorders such as myelodysplasia.[118]

The risk for the progression of congenital scoliosis depends on the growth potential of the malformed vertebrae.[116] Defects such as block vertebrae have little growth potential, whereas unilateral unsegmented bars invariably produce progressive deformities.[70] About 75% of children with congenital scoliosis demonstrate some progression that typically continues until skeletal growth stops. About 50% require treatment.[71] Rapid progression can be expected during periods of rapid growth, such as those between birth and 2 years of age and after 10 years of age. Orthotic management is usually contraindicated because the disorder is a growth abnormality. When progression occurs, surgery is necessary. It usually consists of a combined anterior and posterior convex hemi-epiphysiodesis to halt progression and allow for some correction from growth on the concavity of the curvature.

CONGENITAL KYPHOSIS

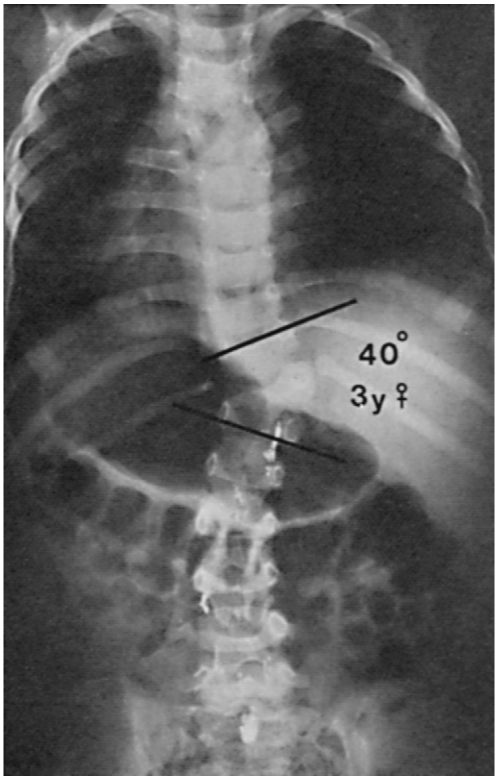

Figure 54–9. Radiograph of congenital scoliosis in a 3-year-old girl. A hemivertebra at T12 produces a 40-degree curve over a short segment of the spine. The mixed formation and segmentation defects in the upper thoracic spine are balanced and have not produced a significant curve.

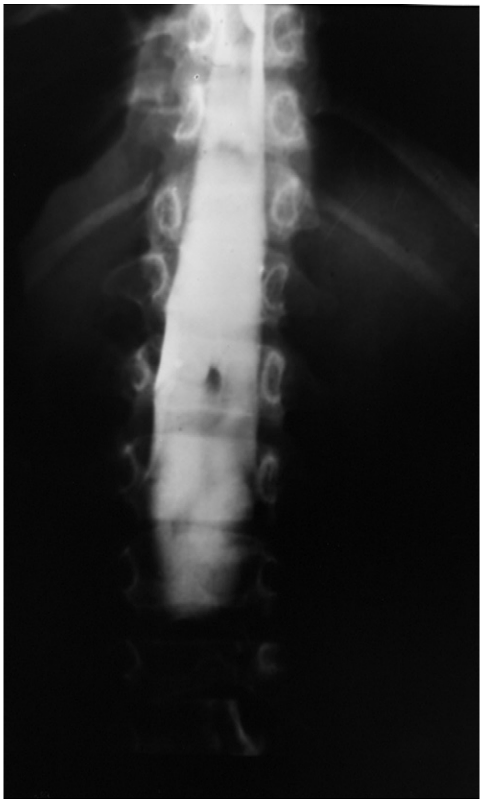

Figure 54–10. Metrizamide myelogram demonstrates cartilaginous diastematomyelia at L2 in a 3-year-old boy. Observe the midline filling defect and the increased widening or interpedicular distance in the middle lumbar region.

Congenital kyphosis includes congenital failure of the formation of all or part of the vertebral body but preservation of the posterior elements and failure of the anterior segmentation of the spine (i.e., anterior unsegmented bar). The more severe deformities are usually recognized in the neonate, and they rapidly progress. The less obvious deformities may not appear until several years later. After progression begins, it does not cease until the end of growth. The most important factor regarding congenital kyphosis is the possibility that a progressive deformity in the thoracic spine can result in paraplegia.[72] This potential outcome is usually associated with failure of the formation of the vertebral body. When necessary, the treatment of congenital kyphosis is operative.[57]

SACRAL AGENESIS

Sacral agenesis comprises a group of disorders with partial or complete absence of the sacrum. If the lower lumbar spine is also involved, it is called *lumbosacral agenesis*.[3,6,81] Motor function is typically lacking below the level of the remaining spine; however, sensation tends to present at a much more caudal level. The disorder can be classified by the amount of sacrum remaining and the articulation between the spine and pelvis. It is a rare disorder, occurring in about 1 of 25,000 live births, and the exact cause is unknown. The incidence is increased among the children of diabetic mothers (see also Chapter 16 and Chapter 49, Part 1).[42,88]

The presentations of neonates with sacral agenesis can vary considerably. In the severe forms, there is a small pelvis, with pterygia anteriorly at the hip and posteriorly at the knees, and bilateral foot deformities, typically clubfoot. There may be spinopelvic instability. The neurologic examination tends to show no motor function below the last existing vertebra or sacral segment. However, sensation can be more variable. Children with sacral agenesis also have other visceral anomalies similar to those seen in congenital scoliosis.

The treatment of sacral agenesis is variable. Patients with only partial agenesis and a stable spinopelvic articulation can be observed. Those who are unstable may require a spinopelvic fusion in childhood for stabilization. This operation can enhance sitting balance and improve the function of the upper extremities. The problems associated with the lower extremities also require orthopedic intervention. If a child has the potential for ambulation, these problems need to be corrected to allow the child to assume an upright posture. Orthotics is usually necessary to support the extremities after they have been corrected.

LOWER EXTREMITIES

Most common neonatal congenital and developmental abnormalities of the lower extremities include torsional and angular deformities; developmental dysplasia of the hip (DDH); proximal femoral focal deficiency (PFFD); congenital hyperextension, subluxation, and dislocation of the knee; clubfoot; metatarsus adductus; vertical talus; the calcaneovalgus foot; and less serious toe deformities, such as syndactyly and polydactyly of the toes.

Torsional and Angular Deformities

PHYSIOLOGIC BOWLEG

The lower extremities of neonates commonly have mild to moderate bowing (i.e., genu varum) and internal rotation of the lower leg because of in utero positioning. The bowed appearance is actually a torsional combination of the external rotation of the hip (i.e., tight posterior capsule) and internal tibial torsion from in utero positioning. With the onset of standing and independent walking, the bowing and torsion are spontaneously corrected over a 6- to 12-month period. Significant improvement does not occur during the neonatal period or the first year of life. The typical neonate has 15 degrees of genu varum, which decreases to about 10 degrees by 1 year of age. By 2 years of age, most children have straight or neutrally aligned lower extremities. Treatment is indicated for children older than 2 to 3 years of age who have had no documented improvement with growth.

TIBIAL TORSION

Torsional changes of the tibia may be internal or external, depending on in utero positioning. The degree of tibial torsion may be measured by the thigh-foot angle. With the child in the prone position, the knee is flexed to 90 degrees to neutralize the normal tibiofemoral rotation. The foot is placed in a neutral or simulated weight-bearing position. The long axis of the foot is compared with the long axis of the thigh. An inwardly rotated foot is assigned a negative value and represents internal tibial torsion. An outwardly rotated foot represents external tibial torsion and is given a positive value. It is important that the measurements be recorded on each visit to document the improvement. Radiographic evaluation is of no value in the assessment of tibial torsion.

Internal Tibial Torsion

Internal tibial torsion is the most common cause of pigeon-toed children from birth to 2 years of age. It is the major component of physiologic bowleg, or genu varum. Because this condition is physiologic, spontaneous resolution can be anticipated with normal growth and development. The persistence of internal tibial torsion in the older child or adolescent is uncommon.

External Tibial Torsion

External tibial torsion is a common deformity and is always associated with a calcaneovalgus foot. It is caused by a variation in the normal in utero position. The sole of the foot lies pressed against the wall of the uterus, forcing the limb into a hyperdorsiflexed, everted position. This physiologic configuration produces the calcaneovalgus foot and secondarily the external tibial torsion. When these two conditions are combined with a normally externally rotated hip from a tight posterior hip capsule, they produce a very externally rotated or out-toed position. Because they are also physiologic in origin, both undergo spontaneous resolution and follow a clinical course similar to that of internal tibial torsion.

CONGENITAL ANGULAR DEFORMITIES OF THE TIBIA AND FIBULA

Congenital angular deformities of the tibia and fibula are uncommon neonatal problems. They are classified according to the direction of angulation—posteromedial or anterolateral. Posteromedial angulation is the least common but is characterized by spontaneous resolution with growth and development. Anterolateral angulation is more common and is typically associated with other underlying congenital abnormalities, such as the congenital absence of the fibula (i.e., fibular hemimelia), the congenital absence of the tibia (i.e., tibial hemimelia), and congenital pseudarthrosis of the tibia (i.e., neurofibromatosis).

Posteromedial Angulation

Posteromedial angulation has three associated clinical problems: angular deformity, the calcaneovalgus foot, and length discrepancy of the lower extremities. The angular deformity occurs at the junction of the middle and distal thirds of the shafts. The deformity is usually unilateral (Fig. 54-11). The neonates are normal and healthy, and there is no increased incidence of other congenital anomalies. The degree of angulation varies between 25 and 65 degrees and is equal in both directions. The foot is hyperdorsiflexed and has a marked calcaneovalgus posture. Radiographs are necessary to confirm the diagnosis. The cause of congenital posteromedial angulation in the tibia and fibula is unknown.

Posteromedial angulation resolves with growth, especially during the first 3 years of life. The posterior bowing tends to resolve more quickly than the medial bowing, which may not resolve until 5 years of age. However, the associated shortening of the tibia and fibula persists and progresses during growth. The fibula tends to be slightly shorter than the tibia. The appearance of the foot also improves, although a pes planovalgus appearance may persist.

Nonoperative treatment is indicated in the neonatal period.[104] If the bowing does not resolve by 3 or 4 years of age, a tibial or fibular osteotomy may be necessary. The most common sequela of posteromedial angulation is a discrepancy in leg length. Most of these children have enough discrepancy to require equalization. An appropriately planned epiphysiodesis (physeal closure) is the most common procedure. Lengthening may sometimes need to be considered.

Anterolateral Angulation

When anterolateral bowing is encountered, it is usually associated with a significant underlying pathologic disorder, such as congenital pseudarthrosis of the tibia or congenital longitudinal deficiencies of the tibia or fibula. Careful clinical and radiographic evaluation is necessary to establish the correct diagnosis. Congenital pseudarthrosis of the tibia is typically associated with neurofibromatosis.

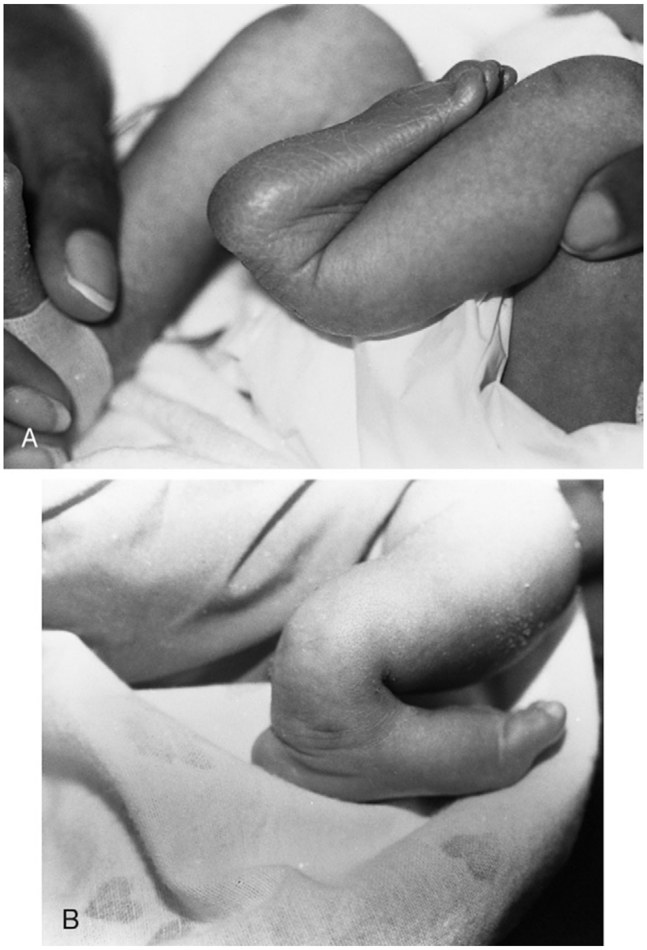

Figure 54–11. **A**, One-month-old boy with posteromedial angulation of the left tibia. This condition resembles a calcaneovalgus foot because the dorsum of the foot comes in contact with the lower leg. However, there is posterior angulation of the tibia in this case. **B**, The medial angulation is visible when viewed from the front.

Hip

The most common neonatal hip disorders include DDH and septic arthritis and osteomyelitis. Septic arthritis and osteomyelitis were discussed in Part 2, “Bone and Joint Infections”. Another congenital abnormality, although uncommon, is proximal femoral focal deficiency (PFFD).

DEVELOPMENTAL DYSPLASIA OF THE HIP

DDH is the most common neonatal hip disorder.[91,113] It was initially thought to be congenital in origin but is now recognized as developmental, hence the change in terminology to DDH. At birth, an involved hip is rarely dislocated; instead, it is dislocatable. Whether the hip stabilizes, subluxates, or ultimately dislocates depends on postnatal factors. Most developmental dislocations are postnatal in origin; however, the exact time of their occurrence is controversial.

Neonatal hip dislocations are classified into two major groups: the typical, which is found in a neurologically normal infant, and the teratologic, which is found in an infant with an underlying neuromuscular disorder, such as myelodysplasia, arthrogryposis multiplex congenita, or a complex of syndromes. Teratologic dislocations occur in utero and are therefore truly congenital in origin. This section concentrates on typical DDH because it is the most common form.

Pathology and Etiology

The pathogenesis and causes of typical DDH are multifactorial; genetic, physiologic, and mechanical factors are involved. The genetic factors include a positive family history (20%) and generalized ligamentous laxity, an inherited trait. The physiologic factors include female predominance (9:1) and maternal estrogen and other hormones associated with pelvic relaxation during labor and delivery. The mechanical factors include primigravida, breech presentation, and postnatal positioning. Positioning has a significant effect in determining which hip stabilizes and which may progress to dislocation.

The genetic and physiologic aspects are related etiologic factors. Most neonates with DDH have generalized ligamentous laxity, which can be a predisposition to hip instability. The maternal estrogen and other hormones associated with pelvic relaxation at delivery cross the placenta and result in further, albeit temporary, relaxation of the newborn hip joint.

About 60% of children with typical DDH are first born, and 30% to 50% develop it as a result of the breech position. In this position, there is extreme hip flexion and a limitation of hip motion that results in the stretching of an already lax hip capsule and ligamentum teres and in the posterior uncovering of the femoral head. Decreased hip motion results in the lack of normal stimulation for the growth and development of the cartilaginous acetabulum.

Congenital muscular torticollis and metatarsus adductus are associated with DDH. The presence of either of these two conditions necessitates a careful examination of the hips.

Postnatal factors are important determinants in ultimate hip stability. Positioning an unstable hip in adduction and extension may lead to dislocation. These positions put the unstable hip under abnormal pressure as a result of the normal hip flexion and abduction contracture. Consequently, an unstable femoral head can be displaced from the acetabulum over several days or weeks.

Because the hips are not dislocated at birth, the components of the hip joints, excluding the hip capsule and ligamentum teres, are usually relatively normal. There may be some variation in the shape of the cartilaginous acetabulum. If a subluxation or dislocation is not recognized, it will lead to progressive acetabular dysplasia and maldirection, excessive femoral anteversion (i.e., torsion), and hip muscle contracture. It is critical that an early diagnosis be made and appropriate treatment instituted. The longer a dislocation continues, the more complex the treatment becomes.

Diagnosis

The physical findings in neonates with DDH include a positive Barlow test (i.e., dislocatable hip), a positive Ortolani test (i.e., dislocated hip), asymmetric thigh skin folds, uneven knee levels (i.e., Allis or Galeazzi sign), and the absence of normal knee flexion contractures.

The Barlow and Ortolani tests are the most sensitive for neonatal hip instability (Fig. 54-12). The Barlow[7] test is a provocative means of diagnosing an unstable hip and is the most important maneuver in examining the neonatal hip. With the infant supine, this test is performed by stabilizing the pelvis with one hand, flexing and adducting each hip separately, and applying a posterior force with the other hand (Fig. 54-13). If a hip is dislocatable, it is usually felt as a "clunk." After release of the posterior pressure, the hip usually spontaneously relocates. It has been estimated that about 1 in 100 newborns has a clinically unstable hip (i.e., subluxatable or dislocatable) and that 1 in 800 to 1000 infants eventually develops a true dislocation.

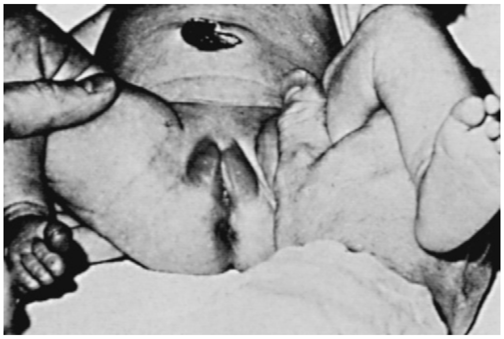

Figure 54–12. Positioning of the hip in the newborn to perform two diagnostic tests. The Ortolani sign, or click of reduction, is elicited when abducting the hip in this manner. The reverse Ortolani, or Barlow, maneuver is performed by bringing the femur into adduction with flexion, causing a click of exit or dislocation.

The Ortolani test is a procedure to reduce a recently dislocated hip (Fig. 54-14). It is most likely to be positive in infants who are 1 to 2 months of age because adequate time must have passed for true dislocation to occur. This test is performed concomitant with the Barlow test. With the hip flexed, the thigh is abducted and the femoral head lifted anteriorly into the acetabulum. If a reduction occurs, it is felt as a clunk. Clunks should not be confused with hip "clicks," which are common in neonates. A variety of normal factors produce a clicking sensation during examination of the hip, including the breaking of surface tension across the hip joint, the snapping of gluteal tendons, patellofemoral motion, and femorotibial (knee) rotation. These normal characteristics are commonly misinterpreted as a sign of instability. After 2 months of age, the Ortolani test usually becomes negative. It is no longer possible to relocate a dislocated hip because of the development of soft tissue contractures.

When the hip is dislocated, its abduction is limited by soft tissue contractures (Fig. 54-15). There is also an increased number of thigh skinfolds on the involved side because of redundant soft tissues, the appearance of a shortened extremity, and a positive Allis or Galeazzi sign. The latter sign is demonstrated by placing the feet of the supine neonate together on the examining table and assessing the relative heights of the knees. An apparent shortening is observed on the involved side. With a proximal displacement of the femoral head, the quadriceps and hamstrings become relaxed. This effect can be demonstrated best by the so-called "ham-

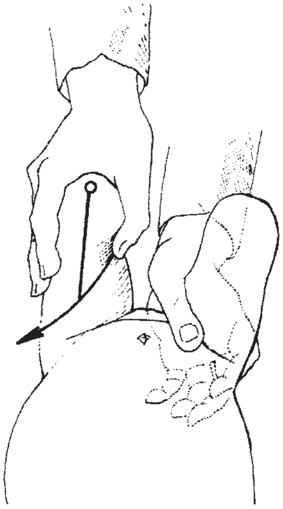

Figure 54–13. The Barlow test permits the early diagnosis of hip instability. It is a provocation test for dislocatability. The pelvis is steadied with one hand while the leg to be tested is grasped with the other. The thumb of the examiner's hand should lie over the lesser trochanter and the tip of the middle finger over the greater trochanter. With the hip and knee in flexion, gentle pressure is exerted with the thumb over the lesser trochanter. Dislocatability is manifested by a sudden shift of the proximal femur. Dislocation may be reduced with the Ortolani test.

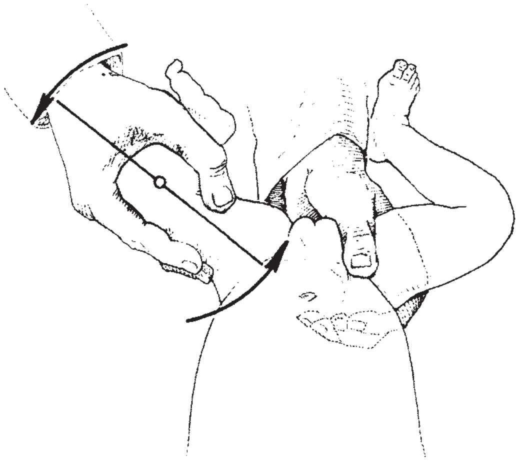

Figure 54–14. In the Ortolani test, the pelvis is held steady with one hand while the limb to be examined is grasped with the other. The hip and knee are flexed. While gently pulling the femur forward, the examiner abducts the limb under examination, using the greater trochanter as a fulcrum. Reduction of dislocation is manifested by a sudden shift in the position of the proximal femur, often accompanied by a palpable or audible click. There must be sufficient ligamentous laxity to permit relocation of the proximal femur into the acetabulum; therefore, the test is useful primarily in the neonatal period.

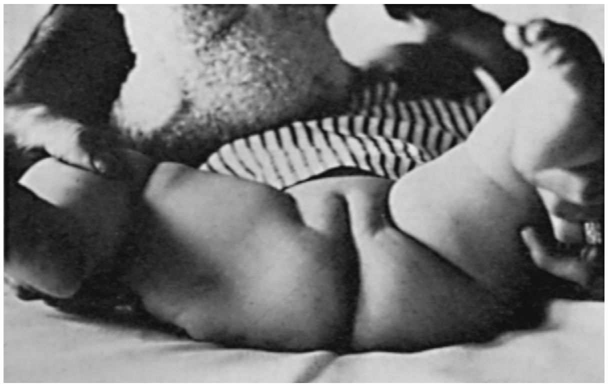

Figure 54–15. Clinical photograph showing the limitation of abduction of the thighs when the hips are flexed at 90 degrees.

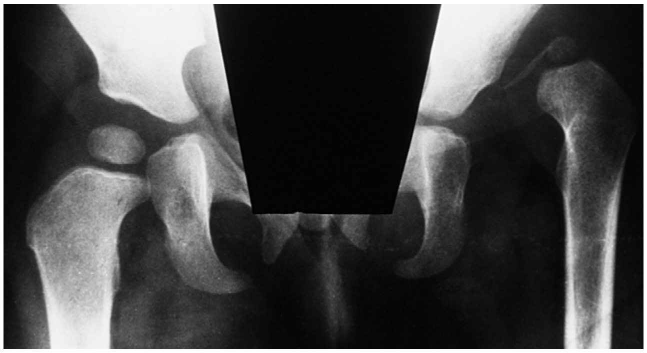

Figure 54–16. Anteroposterior pelvic radiograph of a 9-month-old girl with a complete dislocation of the left hip. Observe the hypoplasia of the proximal femur and ossific nucleus of the femoral head. The right hip is normal.

string" test. Both hips are flexed and abducted with the knees flexed. Attempts to extend the knee are resisted on the normal side because of increased tightness in the hamstrings. If a dislocated hip is present, the knee can come into full extension because of the lack of proximal stability, which produces a fixed fulcrum for the hamstring muscles.

Imaging

The imaging of neonatal DDH is best accomplished with ultrasonography and plain radiographs. Ultrasonography[43] is becoming an increasingly popular method for the evaluation and assessment of the neonatal hip because the femoral head does not ossify until 4 to 7 months of age. Hip stability and acetabular and femoral head development can be accurately assessed by an experienced ultrasonographer. Ultrasonography allows avoidance of the effects of ionizing radiation but is very user dependent and expensive. It is so sensitive that false-positive results are common. In large screening programs in which all births are screened, it is common to identify 7.5% of neonates with abnormal results.[18] This percentage decreases to a more appropriate level of 0.4% by 6 weeks, but the expense, anxiety, and administrative stress of retesting can be considerable. At present, there is no agreement about the efficacy of routine screening for all infants. Some large centers suggest it,[66] whereas others claim that selective ultrasonography is as effective as universal screening when it is accompanied by a good clinical screening program.[29] Additionally, a stable, normal ultrasound does not ensure normal hips after 6 months of age. Jones has reported on seven developmental dislocations in five babies (age 6 to 22 months) in whom ultrasound demonstrated stable and reduced hips. The Pediatric Orthopedic Society of North America warns that late-onset dislocation can be expected in 1 in 5000 infants who are clinically stable in the newborn period.[91] Anteroposterior and frog lateral radiographs of the pelvis may also be obtained. The limitation of plain radiographs is due to the lack of ossification of the femoral head, which may be further delayed in DDH (Fig. 54-16). Line measurements are drawn to determine the development of the acetabulum and the relationship between the femoral head and acetabulum (see also Chapter 27 and Chapter 37).

Treatment

The treatment of neonatal DDH is simple and effective. The most important factor in the treatment of this disorder is an accurate and early diagnosis. When an unstable or dislocatable hip is recognized at birth, maintenance of the hip in the position of flexion and abduction, or the "human position," for 1 to 2 months is usually sufficient. This position maintains a reduction of the femoral head in the acetabulum and allows the progressive tightening of the ligamentous structures as the child grows. It also stimulates the normal growth and development of the acetabulum. The methods that can be used to maintain the hip in this position include double or triple diapers, the Pavlik harness, the Frejka pillow splint, and a variety of abduction orthoses. Double or triple diapers, although controversial, are commonly used in early infancy because the harness, pillow splint, and abduction orthoses usually do not fit satisfactorily. Treatment is continued until there is clinical stability of the hip and the ultrasonographic or radiographic results are normal, both of which usually take place within 3 to 4 months. There may be a true dislocation during the neonatal period. As a consequence, treatment is directed toward the reduction of the femoral head in the true acetabulum.[30,38,45]

The Pavlik harness is the major mode of treatment in this age group (Fig. 54-17). The harness places the hips in the human position by flexing them more than 90 degrees (preferably 100 to 110 degrees) and maintaining relatively full but gentle abduction (50 to 70 degrees). This position redirects the femoral head toward the acetabulum. A spontaneous relocation usually occurs within 3 to 4 weeks. The Pavlik harness is about 95% successful for dysplastic or subluxated hips and 80% successful for true dislocations. If true dislocations are initially irreducible, treatment with the Pavlik harness may not be effective. Lerman and coworkers[65] reported on 93 DDH patients treated with a Pavlik harness. There were 82% who were successfully treated. Six patients had initially irreducible hips and less than 20% ultrasound coverage; all six failed treatment with the Pavlik harness. If the reduction of a dislocated hip is achieved, treatment is continued until ultrasonography or the radiographic parameters have returned to normal. If a spontaneous reduction does not occur, closed reduction by surgery will be necessary. This approach

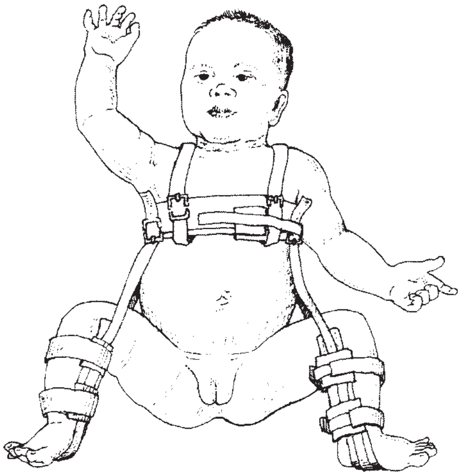

Figure 54–17. The Pavlik harness is a safe, reliable means of treating hip instability and dislocation in the neonate.

consists of preliminary skin traction for 1 to 3 weeks to stretch the existing soft tissue contractures followed by an examination under anesthesia, percutaneous adductor tenotomy, closed reduction, an arthrogram to assess the concentricity of the reduction, and the application of a hip spica cast in the human position. Treatment is continued until the radiographic parameters are within normal limits. The indications for an open reduction in the neonate and up to the first 6 months of life are limited.[45] Follow-up for at least 1 year is necessary because dysplastic hips that improve with treatment can deteriorate after it is withdrawn.[30] If this deterioration occurs, more treatment is indicated.

The complications attending the treatment of neonatal DDH include reduction failure and redislocation.[38] Avascular necrosis of the capital femoral epiphysis, which is the most devastating complication of this disorder, develops in about 5% of infants no matter how careful the initial management has been.

PROXIMAL FEMORAL FOCAL DEFICIENCY

PFFD is a congenital abnormality affecting the development of the proximal end of the femur and possibly the acetabulum. There is considerable variation, ranging from a mildly shortened femur to severe shortening with an absence of the femoral head and acetabulum. It may be bilateral or unilateral; bilateral cases tend to have more severe involvement. The cause of PFFD is unknown, but it results from an embryologically abnormal formation of the hip that occurs during limb bud formation.

The clinical examination is usually diagnostic. The thigh is shortened and the hip held in flexion, abduction, and external rotation (Fig. 54-18). There are usually hip- and knee-flexion contractures. Because of the proximity of the lower leg to the trunk, the entire extremity appears similar to a funnel. There may also be abnormalities of the lower leg. About 50% to 70% of affected neonates also have fibular hemimelia with or without the absence of the lateral portion of the foot.

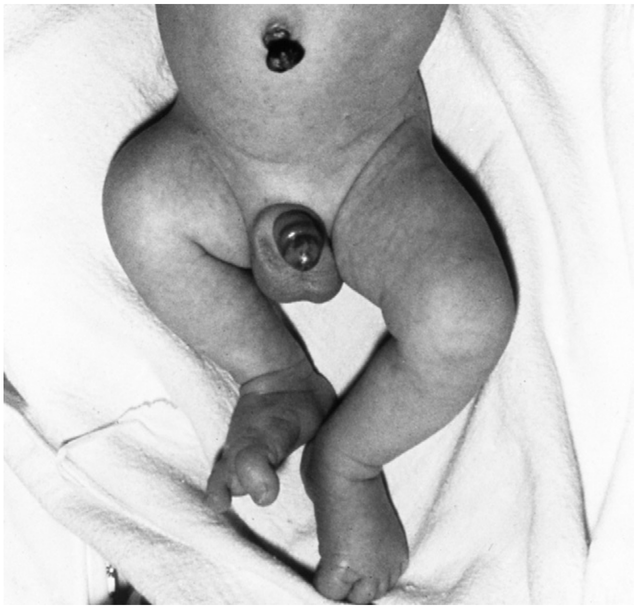

Figure 54–18. Clinical photograph of a newborn boy with significant shortening of the right thigh caused by proximal femoral focal deficiency.

Radiographs are necessary in the assessment of children with PFFD. However, the components may not be fully visualized owing to the lack of ossification. If an acetabulum is present, there will usually be a femoral head. MRI scans can be helpful in difficult cases to determine the shape of the proximal femur and acetabulum.

The most important therapeutic component of the treatment of neonatal PFFD is observation. It is important that a careful evaluation be performed to search for other associated congenital abnormalities. The ultimate treatment depends on the length of the extremity, the stability of the hip, the presence or absence of a functional foot, and a determination of whether the disorder is unilateral or bilateral. Possible treatment options include prosthetic fitting; knee fusion, Syme amputation, and prosthesis; surgical reconstruction; and lengthening of the femur. The lengthening of the femur is considered only if the hip and knee are relatively normal and the degree of predicted shortening is less than 15 to 20 cm at skeletal maturity.

Knee

HYPEREXTENSION, SUBLUXATION, AND DISLOCATION OF THE KNEE

The congenital disorder comprising hyperextension, subluxation, and dislocation of the knee is uncommon. The tibia is displaced anterior to the femur, and the knee is hyperextended. The cause is multifactorial, with mechanical and genetic elements. Most cases are sporadic, with no particular predisposition; however, patients with inherited Larsen disease frequently demonstrate congenital subluxation and dislocation of the knee. Breech positioning is more frequently seen in children with congenital subluxation and dislocation of the knee, suggesting that mechanical factors are also important.

The pathologic picture is complex, and associated anomalies are common. Curtis and Fisher[22] reported on 11 patients, and in every case they noted congenital hip deformities. Seven patients had clubfoot, and seven were thought to have arthrogryposis multiplex congenita. Fibrosis of the quadriceps muscle was found in all surgical cases. The quadriceps muscle in effect runs from the anteroinferior iliac spine to the tibial tubercle. Progressive fibrosis would provide pressure for anterior subluxation of the tibia and for hip deformity as well as a tendency to hyperextend the knee.

The diagnosis is made on physical examination. Recurvatum at the knee sometimes approaches 90 degrees (Fig. 54-19). A lateral radiograph can demonstrate that the tibia is anterior to the femur. A line is drawn down the long axis of the tibia and the long axis of the femur; it does not meet at the normal axis of the knee joint.

In benign hyperextension of the knee, recurvatum of 15 to 30 degrees is common. Flexion is frequently limited to a few degrees. In this “packing deformity,” the radiographs demonstrate that the tibia is not anterior to the femur and that the center of rotation of the knee joint is normal, unlike congenital dislocation and subluxation of the knee. It is important to obtain the radiographs of knees that hyperextend considerably to determine whether an epiphyseal fracture is responsible for hyperextension of the knee. The results of treatment are very different when benign hyperextension of the knee is compared with congenital dislocation of the knee. In benign hyperextension of the knee and, to a certain extent, congenital subluxation of the knee, manipulation and serial casting provide an adequate result. Early manipulation and casting are often successful in uncomplicated congenital knee dislocation if treatment is begun during the first few weeks of life. The prognosis is much worse when the knee dislocation is associated with Larsen disease or arthrogryposis multiplex congenita.[60] Children with congenital dislocation of the knee who fail casting may benefit from traction delivered through skeletal pins in the tibia and femur. The goal of treatment is to achieve at least 100 to 110 degrees of knee flexion and full, stable knee extension before the child reaches walking age. If these objectives cannot be attained with casting, splinting, or traction, surgery before the child reaches walking age is recommended.

Foot and Toes

The most common foot and toe disorders include metatarsus adductus, the calcaneovalgus foot, talipes equinovarus (clubfoot), congenital vertical talus, and syndactyly and polydactyly of the toes.

METATARSUS ADDUCTUS

Metatarsus adductus, or forefoot adduction, is probably the most common neonatal foot problem. It results from in utero positioning, occurring equally in boys and girls,[31] and is bilateral in about 50% of neonates. The disorder has hereditary tendencies and is more common in the first-born than subsequent children because of an increased molding effect from the primigravid uterus and abdominal wall. It is also associated with hip dysplasia. About 10% of children with metatarsus adductus have DDH, and careful examination of the hips is necessary in any neonate with metatarsus adductus.[63]

Diagnosis

Clinically, the forefoot is adducted and occasionally supinated. The hindfoot and midfoot are normal. The lateral border of the foot is convex, and the base of the fifth metatarsal appears to be prominent (Fig. 54-20). The medial border of the foot is concave. There is usually an increased interval between the first and second toes, with the great toe being held in a greater varus position. Ankle dorsiflexion and plantar flexion are normal. These characteristics distinguish metatarsus adductus from a congenital clubfoot. Forefoot flexibility is variable. This flexibility can be passively assessed by stabilizing the hindfoot in a neutral position with one hand and applying pressure over the first metatarsal head with the other. Active flexibility is assessed by gently stroking the lateral border of the involved foot. This approach induces reflex activity in the peroneal

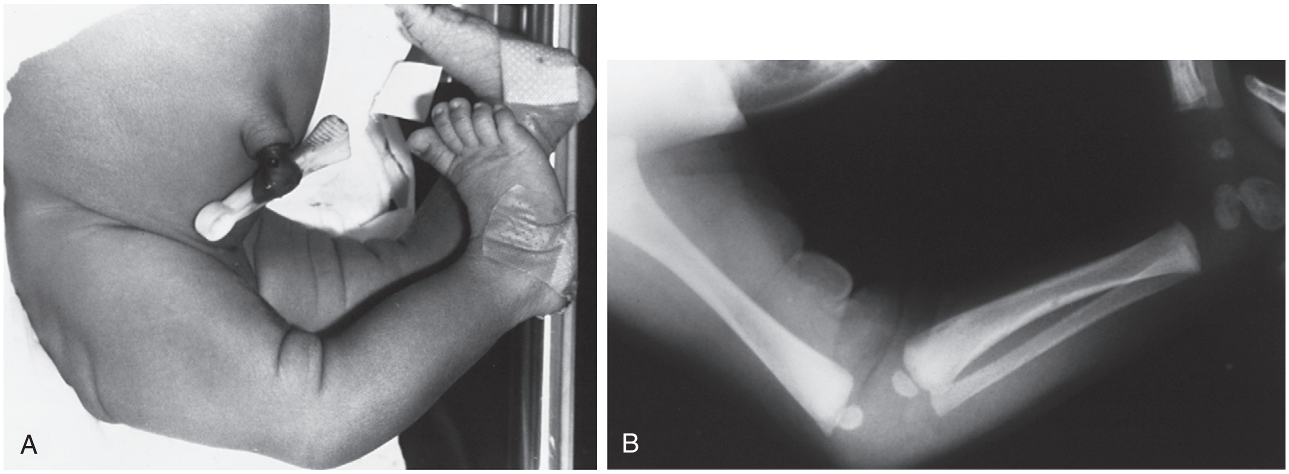

Figure 54–19. **A**, Clinical photograph of a newborn boy with bilateral congenital or developmental subluxation of the knees. The knees are hyperextended and have limited flexion. **B**, Lateral radiograph demonstrating the hyperextension or subluxation of the right knee.

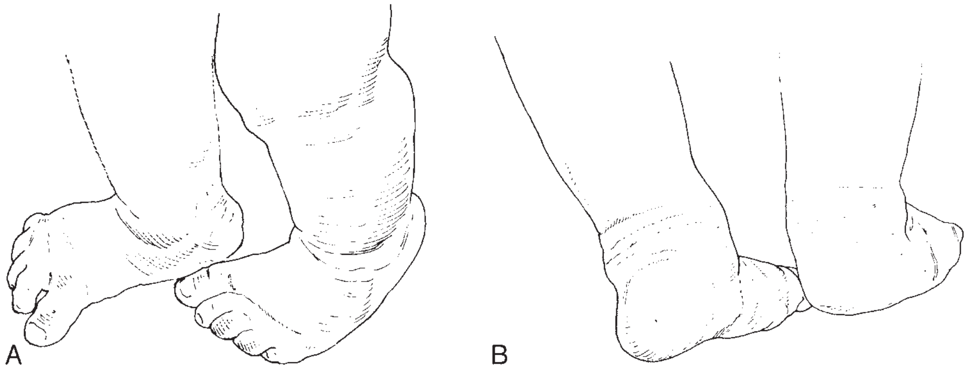

Figure 54–20. Bilateral metatarsus adductus. **A**, Dorsomedial and dorsolateral views. The medial border of the foot is concave; the lateral border is convex. The medial arch may be accentuated. **B**, Posterior view. A slightly valgus hindfoot may be present in the standing position.

muscles along the lateral aspect of the calf. The forefoot is typically classified as flexible, moderately flexible, or rigid.[21] In flexible metatarsus adductus, the forefoot achieves the overcorrected position actively and passively. In moderately flexible metatarsus adductus, the forefoot can be brought to the neutral position; in the rigid deformity, the forefoot cannot be corrected to achieve the neutral position.

Imaging

Routine radiographs are unnecessary in the evaluation of metatarsus adductus. Radiographs do not demonstrate forefoot mobility; however, anteroposterior and lateral simulated weight-bearing radiographs of the foot are necessary to assist in the diagnosis of rigid deformities and those in which a diagnosis by other means is uncertain.

Treatment

About 85% of the neonatal metatarsus adductus deformities resolve spontaneously by 3 years of age,[31,83,87] and 95% resolve by 16 years of age.[115] Treatment is seldom recommended for metatarsus adductus because most patients develop normal foot position and mobility without treatment, and even those with some residual deformity generally have normal function.[31]

CALCANEOVALGUS FOOT

The calcaneovalgus foot is a common physiologic variant.[103] It results from in utero positioning. This condition is manifested by a hyperdorsiflexed foot, with an abducted forefoot and increasingly valgus hindfoot. It is usually associated with external tibial torsion and typically occurs unilaterally but occasionally bilaterally. In utero, the plantar surface of the foot was against the wall of the uterus, forcing it into a hyperdorsiflexed, abducted, and externally rotated position (Fig. 54-21). This position produces the calcaneovalgus foot and external tibial torsion. When these two conditions are combined with the normal, increased external rotation of the hip (i.e., tight posterior capsule) in the neonate, the result is a lower extremity that appears excessively externally rotated.

Diagnosis

The neonate typically presents with external rotation of the involved extremity and a calcaneovalgus foot. The forefoot is abducted, and the heel is everted or in the valgus position. The foot can be hyperdorsiflexed to bring its dorsal surface in contact with the anterior aspect of the lower leg. This condition should not be confused with the neonatal maturity classification of Dubowitz. External tibial torsion of 20 to 50 degrees is common. Ankle motion usually shows normal to nearly normal plantar flexion.

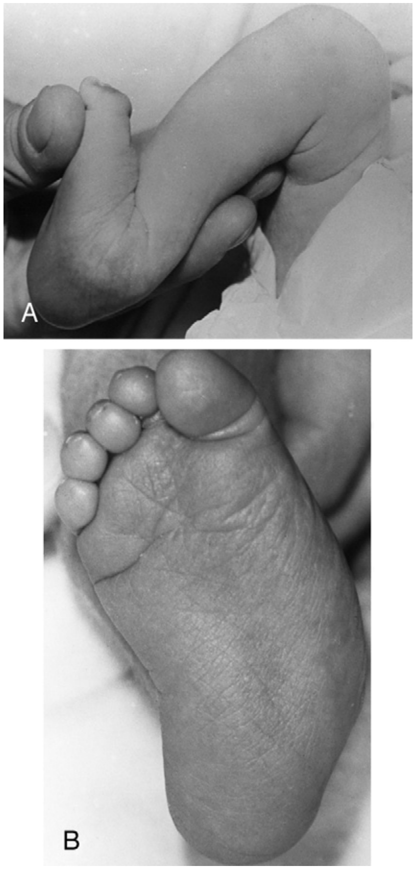

Figure 54–21. **A**, A 3-month-old boy with a calcaneovalgus foot. The foot can be dorsiflexed to allow the dorsum to come in contact with the anterior aspect of the lower leg. **B**, There is abduction of the forefoot and increased valgus alignment of the hindfoot. This condition is always associated with external tibial torsion.

Three conditions must be distinguished from the benign calcaneovalgus foot: congenital vertical talus; posteromedial bowing of the tibia; and neuromuscular abnormalities, with paralysis of the gastrocnemius muscles.[103] This differentiation can usually be established by clinical examination.

Imaging

Routine imaging of a benign calcaneovalgus foot is unnecessary; it is predominantly a clinical diagnosis. However, in severe deformities or in those with limited mobility, anteroposterior and lateral simulated weight-bearing radiographs of the foot and possibly the lower leg are necessary. These radiographs allow the recognition of a congenital vertical talus or posteromedial bowing of the tibia.

Treatment

The benign calcaneovalgus foot does not require treatment. This deformity usually resolves during the first 6 months of life. However, external tibial torsion follows the same natural history as that of internal tibial torsion. Spontaneous improvement does not take place until the child begins to pull to stand and walk independently. It takes 6 to 12 months thereafter to achieve complete correction. Most neonates presenting with a benign calcaneovalgus foot and external tibial torsion have a normally aligned foot and lower extremity by 2 years of age.

TALIPES EQUINOVARUS (CLUBFOOT)

A congenital clubfoot is one of the most common pathologic deformities affecting the neonatal foot. It is a deformity of the foot and the entire lower leg. It is classified as congenital, teratologic, or positional. The congenital clubfoot is usually an isolated abnormality, whereas the teratologic form is associated with an underlying neuromuscular disorder, such as myelodysplasia or arthrogryposis multiplex congenita. Positional clubfoot refers to a normal foot that has been held in the equinovarus position in utero.

The cause of congenital clubfoot is unknown. There are hereditary factors, and they are considered multifactorial, with a major influence from a single autosomal dominant gene. It develops more commonly in boys (2:1) and is bilateral in 50% of cases. The probability of the deformity occurring randomly is 1 in 1000 live births, but within affected families, the probability is about 3% for subsequent siblings and 20% to 30% for the offspring of affected parents. Muscle biopsies of the extrinsic muscles, electromyographic studies of these muscles, and histologic analysis of the associated connective tissue have indicated a probable neuromuscular etiology.[32,50] There are disproportionate fiber types and increased neuromuscular junctions within these muscles. These findings contrast with previous etiologic theories in which the deformity of the talus was thought to be the primary abnormality. These findings also suggest why clubfoot is ubiquitous in syndromes and neuromuscular disorders, and any child with a clubfoot deformity requires a careful musculoskeletal and neurologic evaluation to search for other abnormalities.

Diagnosis

A congenital clubfoot is characterized by equinovarus deformity of the foot and ankle; variable rigidity of the deformity; mild calf atrophy; and mild hypoplasia of the tibia, fibula, and bones of the foot (Fig. 54-22).[84,101,106]

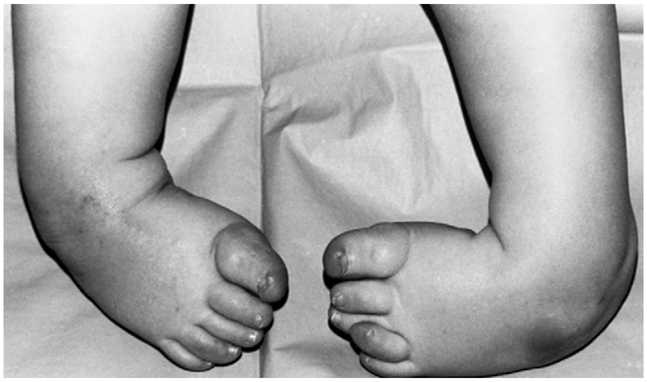

Figure 54–22. Clinical photograph of a 9-month-old boy with bilateral talipes equinovarus (clubfoot) deformity.

Imaging

Anteroposterior and lateral standing or simulated weight-bearing radiographs are used in the assessment of clubfoot.[106] Multiple different radiographic measurements can be made. The navicular bone, which is the primary site of the deformity, does not ossify until 3 years of age in girls and 4 years of age in boys. Line measurements are required to determine the position of the unossified navicular bone and the overall alignment of the foot.

Treatment

Both nonoperative and operative methods are used in the treatment of clubfoot deformities.[84] Nonoperative methods include taping, malleable splints, and serial plaster casts. Taping and malleable splints are particularly useful in premature infants until they attain an appropriate size for casting. Serial plaster casting is the major nonoperative method of treatment. For each cast change, the foot is gently manipulated toward the corrected position. Casts are changed at 1- to 2-week intervals to allow for progressive correction. Complete clinical and radiographic correction should be achieved by 3 months of age. If this expectation is realized, holding casts are used for an additional 3 to 6 months and followed by orthoses or corrective shoes until the child is walking well. The failure to achieve clinical and radiographic correction by 3 months of age is an indication for surgical treatment. Further attempts at casting may result in articular damage or a midfoot breech (i.e., rocker-bottom deformity). The rate of success for the nonoperative treatment of a congenital clubfoot is low. Previously, most children required a complete soft tissue release, which was usually performed between 6 and 12 months of age. Satisfactory long-term results were anticipated for 80% to 90% of cases.[106] However, the Ponseti method of casting[84] (augmented with percutaneous tendo Achilles tenotomy when necessary) has become widely accepted. The Ponseti casting technique and tendo Achillis tenotomy are followed by a prolonged period of bracing, which lasts from 2 to 4 years. Strict adherence to the bracing protocol is mandatory for a positive outcome.[26]

CONGENITAL VERTICAL TALUS

Congenital vertical talus is an uncommon neonatal foot deformity, but its etiology is similar to that of clubfoot.[19,27] It must be distinguished from the benign calcaneovalgus foot, which is a much more common deformity. Congenital vertical talus typically presents as a rigid rocker-bottom deformity. Most of these deformities are associated with an underlying disorder such as teratologic malformation, myelodysplasia, or arthrogryposis multiplex congenita or a syndrome such as trisomy 18.

Diagnosis

The clinical characteristic of congenital vertical talus is a rocker-bottom foot (Fig. 54-23). There is an equinus hindfoot, a valgus hindfoot, a convex plantar surface, forefoot abduction and dorsiflexion, and rigidity. A careful musculoskeletal and neurologic examination must be performed on all neonates to search for associated disorders or syndromes.

Imaging

The radiographic evaluation of congenital vertical talus is similar to that of clubfoot. Anteroposterior and lateral simulated weight-bearing radiographs of the feet are obtained (Fig. 54-24) and typically reveal a vertically oriented talus, dorsal displacement of the midfoot on the hindfoot, and a valgus hindfoot.

Treatment

As in clubfoot, nonoperative treatment is the initial method of management. Serial casting begins at birth. The forefoot is manipulated in the equinus position in an attempt to reduce the dorsally dislocated navicular bone onto the head of the talus. The rate of success for nonoperative treatment is low; most infants require an extensive soft tissue release.

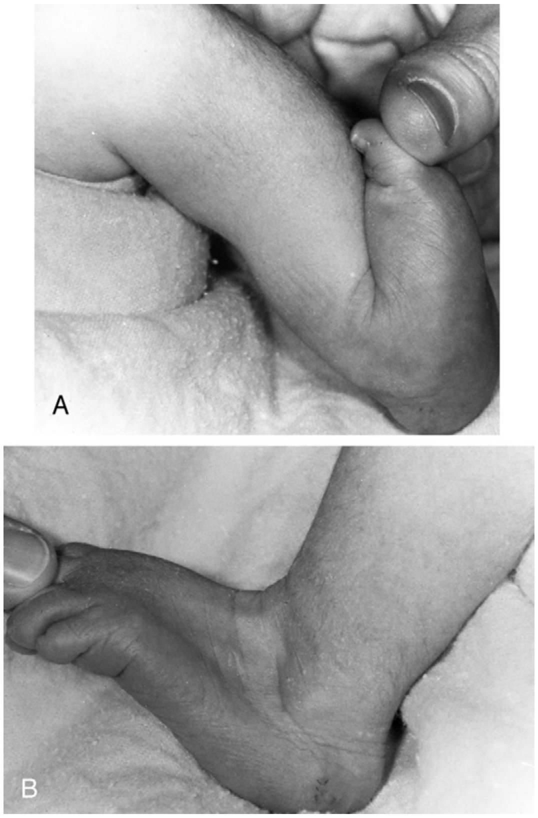

Figure 54–23. A, Newborn girl with congenital vertical talus. The dorsum of the foot also comes in contact with the anterior aspect of the lower leg. The foot has a rocker-bottom appearance. B, Attempted plantar flexion shows the tightness of the anterior musculature and a persistent rocker-bottom appearance of the midfoot and hindfoot.

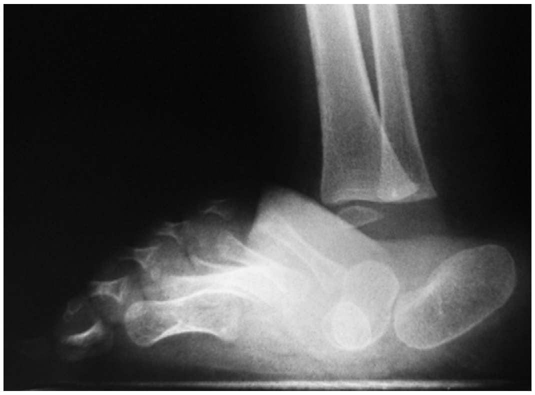

Figure 54–24. Radiograph of a 9-month-old infant showing the vertical alignment of the talus, equinus hindfoot, and dorsal angulation of the midfoot and forefoot.

The goals for the treatment of congenital vertical talus are modest and include the achievement of a plantigrade, painless foot on which a shoe can be worn. Orthotic management is frequently necessary postoperatively to maintain alignment and minimize the risk for recurrent deformity.

SYNDACTYLY AND POLYDACTYLY OF THE TOES

Syndactyly and polydactyly are common disorders of the toes.[34,105] Syndactyly of the toes is almost always asymptomatic and rarely requires treatment but may be associated with a positive family history. Syndactyly may be classified as *zygodactyly*, a complete or incomplete webbing usually involving the second and third toes, and *polysyndactyly*, with polydactyly of the fifth toe and syndactyly between the duplicated toes.[105] Zygodactyly does not interfere with wearing shoes or normal function and does not require treatment; polysyndactyly usually requires treatment.

Polydactyly of the toes can be preaxial (i.e., great toe), central, or postaxial (i.e., fifth toe).[105] It occurs in about 2 of 1000 live births and is more common among African Americans than whites. Postaxial deformities are the most common (80%) and can be subdivided into type A (articulated) and type B (rudimentary). About 30% of the neonates with polydactyly have a positive family history. It is usually an isolated disorder with autosomal dominant inheritance. Polydactyly of the hands and associated metatarsal deformities are common.

The goal of treatment is to restore a relatively normal contour to the forefoot to allow the appropriate fitting of shoes. The rudimentary digits are ligated at birth, whereas the articulated ones are removed at 9 to 12 months of age.[105] The most central of the involved digits are usually preserved and the more peripheral ones amputated.
SYNDROMES
See also Chapter 29.

Skeletal Dysplasias

Skeletal dysplasias constitute a group of disorders that produce short stature. Diagnoses are typically made antenatally. Many of these disorders are recognizable at birth, whereas others are manifested during growth and development. The defects can occur in the epiphyses of the physeal or growth plates or as abnormalities of bone remodeling that may affect the metaphysis or diaphysis.

The most common skeletal dysplasia is achondroplasia, which produces short-limb dwarfism that is caused by a defect in a gene that encodes one of the fibroblast growth factor receptors. Diagnostic and prenatal testing is available. It is inherited as an autosomal dominant trait, but about 80% of cases are new mutations. It is caused by abnormal endochondral ossification in the physes. Achondroplasia produces a rhizomelic pattern of shortening, with the proximal segments (i.e., humerus and femur) more involved than the lower segments (i.e., radius and ulna or tibia and fibula). Periosteal and intramembranous ossification is normal.

The diagnosis of achondroplasia is confirmed by characteristic features of the head, face, and short extremities. The head is typically enlarged; there are disproportionately short limbs and a normal trunk. Facial features include frontal bossing, flattening of the nasal bridge, midfacial hypoplasia, and prominence of the mandible. The trunk appears relatively normal, but the abdomen is usually protuberant. The hands characteristically have a space between the long and ring fingers, producing a trident hand. The thoracolumbar spine may show a gibbous or kyphotic deformity before the onset of walking. The lower extremities are usually bowed, and the musculature appears enlarged. It is important to make an early diagnosis so that genetic counseling can be performed.

Treatment is usually not indicated in the neonatal period or during the first year. The one possible exception is the presence of a gibbous deformity of the thoracolumbar spine, which may benefit from orthotic management.

Osteogenesis Imperfecta

Osteogenesis imperfecta is an inherited disorder of connective tissues. It is caused by mutations in the *COL1A1* and *COL1A2* genes, which code for type I procollagen.[61] More than 150 separate mutations have been identified. Because type I collagen is the primary matrix protein for bone, dentin, sclerae, and ligaments, there is a heterogeneous mix of phenotypes. All children with osteogenesis imperfecta have increased bone fragility and susceptibility to fracture. Some children also present with blue sclerae, defective dentinogenesis, growth restriction, presenile hearing loss, scoliosis and kyphosis, and multiple angular deformities of bone (Fig. 54-25). Osteogenesis imperfecta is uncommon, occurring in fewer than 1 of 20,000 children. In its mildest form, children have a few fractures, normal teeth, sclerae with a slightly blue tinge, minimal hearing loss, and somewhat short stature. In its most severe form, perinatal death is the rule. These children have blue sclerae, and their bones crumble in utero.

Sillence and Danks[95] and Sillence[94] suggested a comprehensive classification scheme based on genetic inheritance and clinical manifestation. In osteogenesis imperfecta type I, patients have increased bone fragility, distinct blue sclerae, and presenile hearing loss. Some of these patients have defective dentinogenesis, whereas others do not. The inheritance pattern is autosomal dominant. In type II, the children are severely affected. Most die perinatally, and their bones crumble in utero. The inheritance pattern is autosomal recessive. At present, efforts to establish a relationship between genotype and phenotype are ongoing, but complex. Recently, Bodian and associates analyzed 63 subjects with type II osteogenesis imperfecta.[10] They found 61 distinct heterozygous mutations in type I collagen, of which 43 had not been previously seen. To say that osteogenesis imperfecta is heterogeneous would be an understatement.[10] In type III, the bone fragility is quite marked but compatible with survival. The children are born with multiple fractures and have progressive bowing of bones throughout life. Early on, their sclerae are quite blue but become less blue as they mature, and by adolescence, the sclerae are essentially normal in appearance. The inheritance pattern is autosomal recessive. In type IV, the bone fragility is modest. These patients usually have white sclerae; some have defective dentinogenesis, whereas others do not. They have modest bowing of bones. Some of these children may be difficult to differentiate from the normal population early in life.

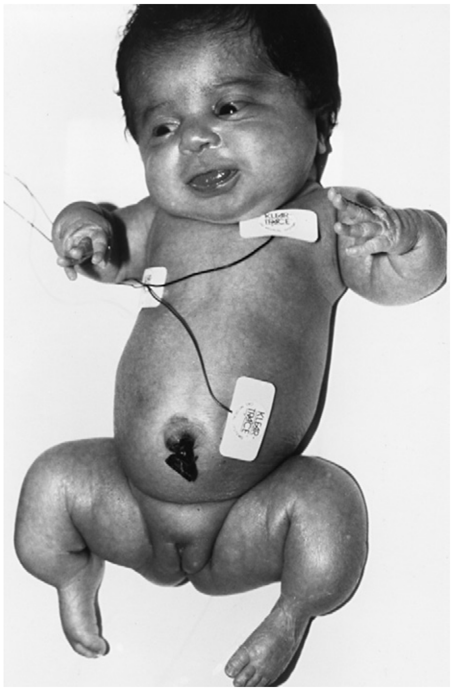

Figure 54–25. Clinical photograph of a newborn girl with severe congenital osteogenesis imperfecta. The child had multiple fractures at birth. Observe the severe shortening of the extremities. Darkened (blue) sclera were present.

The goal of orthopedic treatment in osteogenesis imperfecta is to maximize comfort and function. In modestly affected children, this approach frequently focuses on the closed treatment of fractures. The management of fractures in modestly affected children is not dissimilar from that in the average population. Children with increased bone fragility frequently benefit from orthotics, which is used to protect their bones as they are mobilized. Intravenous pamidronate has shown promise for increasing bone density in children with moderate to severe osteogenesis imperfecta. Investigators also report reduced bone pain, a decreased incidence of fracture, and improved ambulation.[82,85,120] Children occasionally develop severe angular deformities from the poorly developed union of fractures or the insidious collapse of bones. As the deformities increase in magnitude, stress is concentrated at the angular deformities, and children become increasing susceptible to fracture. Osteotomies to straighten bones and intramedullary rods to maintain alignment may be helpful in assisting these children with their mobility. The rod provides internal support for the bone, and the elimination of angular deformities decreases stress within the bones.

Children with osteogenesis imperfecta may be quite bright. Every effort should be made to maximize their ability to attend school and interact with their peers.

Neurofibromatosis

Neurofibromatosis is a relatively common disorder that may or may not be diagnosable in the neonatal period. The presence of multiple café au lait spots or anterolateral bowing of the tibia suggests neurofibromatosis (Fig. 54-26). The café au lait spots frequently do not appear until the child is at least 2 years of age. The criteria for diagnosis have been outlined by Crawford[20] and include at least two of the following: multiple café au lait spots; a positive family history; a definitive biopsy; and characteristic bony lesions such as pseudarthrosis of the tibia, hemihypertrophy, or short and angulated spinal curvature. The café au lait spots are typically smooth; the presence of at least five spots larger than 0.5 cm in diameter is considered diagnostic.

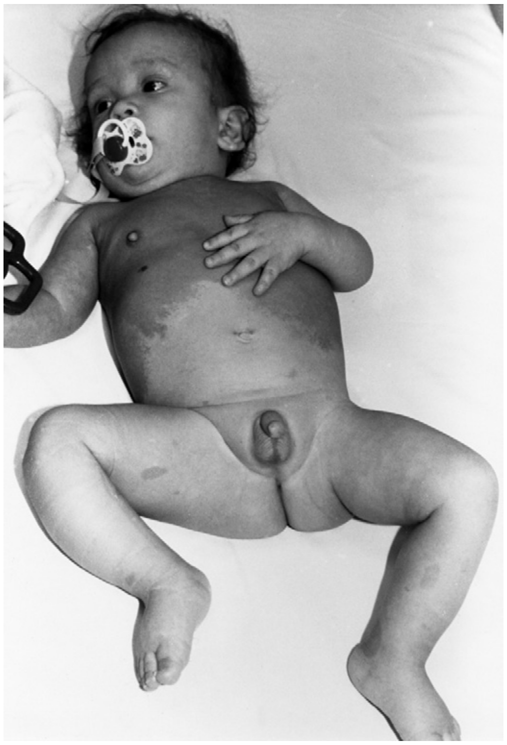

Figure 54–26. Clinical photograph of a 6-month-old boy with multiple café-au-lait spots due to neurofibromatosis.

Arthrogryposis Multiplex Congenita

Arthrogryposis multiplex congenita refers to a symptom complex (syndrome) characterized by multiple joint contractures that are present at birth. The involved muscles are replaced partially or completely by fat and fibrous tissue. However, it is not a single disease because there are about 150 different syndromes that are associated with multiple congenital contractures. The major form of arthrogryposis multiplex congenita is known as *amyoplasia*,[89,92] which refers to the classic syndrome in which the upper and lower extremities are involved. It accounts for about 40% of all children with multiple congenital contractures. Its cause is unknown. Children with this disorder have a decreased number of anterior horn cells in their spinal cords, suggesting a neuropathic origin. The distribution of joint contractures is variable; the classic presentation is involvement of the upper and lower extremities. The clinical features include adduction, internal rotation, and contractures of the shoulders; fixed flexion and extension contractures of the elbow; rigid volar flexion and ulnar deviation or dorsiflexion and radial deviation contractures of the wrist; thumb and palm deformities; rigid interphalangeal joints of the thumb and fingers; flexion, abduction, external rotation, and hip contractures, with dislocation of one or both hips; fixed extension or flexion contractures of the knees; and severe, rigid, bilateral clubfoot (Fig. 54-27). Radiographs of all involved joints are obtained to assess their development; specialized studies are ordered as necessary.

Treatment modalities during the neonatal period consist of physical therapy and serial casting. Occasionally, orthotics and surgical intervention may be necessary; however, surgery is usually delayed until early childhood.[96]

FIBRODYSPLASIA OSSIFICANS PROGRESSIVA

With acknowledgement to Joseph A. Kitterman
and Frederick S. Kaplan

Fibrodysplasia ossificans progressiva (FOP) is a rare genetic disease (incidence about 1 in 1.6 million) characterized by skeletal malformations and episodic heterotopic bone formation leading to progressive loss of mobility. Although FOP was first described in the 17th century, most individuals with FOP are initially misdiagnosed, and many suffer permanent disability from inappropriate diagnostic or therapeutic interventions. Two likely causes for these harmful diagnostic errors are the lack of teaching exposure to FOP in most medical schools and the lack of coverage of FOP in most medical textbooks.

The mode of inheritance of FOP is autosomal dominant with complete penetrance, but almost all cases result from a spontaneous activating mutation in the gene encoding activin receptor IA/activin like kinase-2 (ACVR1/ALK2), a bone morphogenetic protein type I receptor. Only seven small multigenerational families are known worldwide.[52-56,59,93]

The two classic findings in FOP are distinctive malformations of the great toes and episodic “flare-ups” characterized by soft tissue tumor-like swellings that often result in heterotopic ossification at the lesional site. The invariant malformations of the great toes are due to hypoplasia or agenesis of the proximal phalanges that result in short great toes with a valgus deformity (Fig. 54-28A). The toe malformations are present at birth and may be the only congenital sign of FOP.

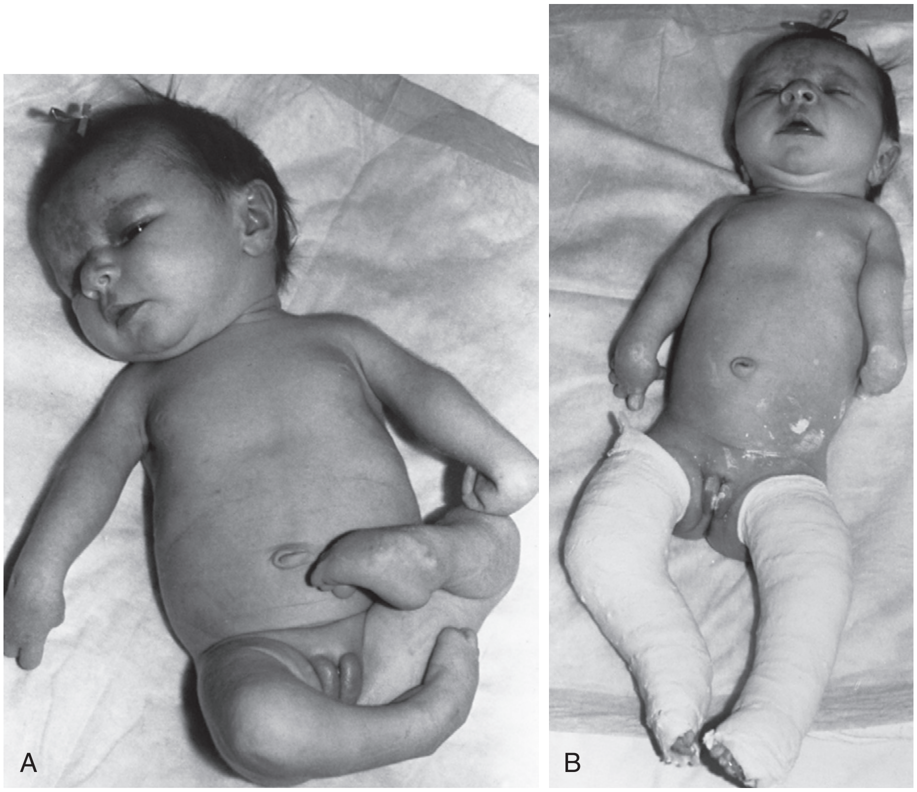

Figure 54–27. A, A 1-month-old girl with arthrogryposis multiplex congenita involving the upper and lower extremities. The elbows are stiff in extension, whereas the wrist, fingers, and thumb are flexed. The hips are flexed and externally rotated. There are knee flexion contractures and bilateral talipes equinovarus clubfoot deformities. B, Serial casting is initiated at birth to improve the alignment of the lower extremities. Occupational therapy and splinting are used at a later time on the upper extremities.

Flare-ups, especially in the occipital region, may commence in the neonatal period, and are often mistaken for cephalohematomas. However, flare-ups are usually recognized later in the first decade and typically appear on the head, neck, back, or shoulders (see Fig. 54-28B). The onset of a tender soft tissue swelling often appears overnight, triggered by soft tissue trauma or viral illnesses or may occur spontaneously. The soft tissue swellings may resolve completely but most often result in heterotopic bone formation.

Microscopically, perivascular lymphocytic, mast cell, and macrophage infiltration occurs in striated muscle, followed by widespread death of muscle cells. Subsequently, an angiogenic fibroproliferative lesion forms, evolving through a cartilage stage and finally into mature heterotopic bone through a characteristic endochondral mechanism. This process involves striated muscles, ligaments, tendons, and aponeuroses, but spares the diaphragm, tongue, extraocular muscles, and cardiac and smooth muscle.

Additional common findings may include short thumbs, short broad femoral necks, proximal medial tibial osteochondromas, tall narrow cervical vertebra, and ankylosis of facet joints of the cervical spine. Findings later in life include hearing loss and a typical facies, which usually develops in the second decade of life and is due to mandibular hypoplasia.[53]

FOP can be diagnosed clinically and with great accuracy when the clinician recognizes the pathognomonic combination of great toe malformations with the presence of rapidly

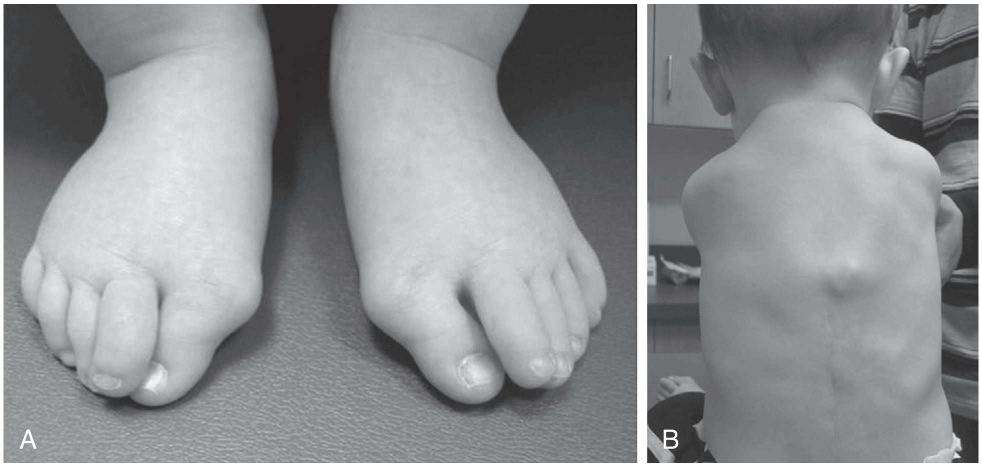

Figure 54–28. A, See color insert. Photograph of the feet of an infant with fibrodysplasia ossificans progressiva (FOP) showing the characteristic findings of short great toes and hallux valgus. B, Photograph of the back of a very young child with a tumor-like swelling on his back that represents an early FOP flare-up. Note the surgical scar from an unnecessary biopsy that exacerbated the disease process.

appearing soft tissue tumors in characteristic anatomic locations (see Fig. 54-28C). In most cases, the swellings are misdiagnosed, most commonly as cancer or aggressive fibromatosis, often because the physician is unfamiliar with FOP. In newborns, FOP should be suspected when the typical malformations of the great toes are present. For suspected cases, diagnostic genetic testing is readily available from a simple blood test.[55]

There is no effective treatment for FOP. The process of heterotopic ossification is often accelerated by trauma, including traumatic medical interventions. These include biopsies, intramuscular injections (including neonatal vitamin K), immunizations, and surgical procedures, all of which should be avoided. For flare-ups involving major joints or the airway, a brief (3 to 4 days) course of high-dose corticosteroids will reduce soft tissue swelling and may prevent ossification.

OUTCOME

Episodic heterotopic bone formation in FOP leads to progressive immobilization of the joints and restrictive disease of the chest wall.[56] Malnutrition is common if there is ossification of the jaw muscles leading to restricted mouth opening and swallowing. Average life expectancy is 40 years (range, 3 to 77 years). Identification of the responsible gene provides hope for future effective treatment of FOP.

APPENDIX A

Therapeutic Agents

Thomas E. Young

Agent	Dosage	Comments
Anti-infective Agents		
Antibacterials		
For drugs marked by *, exact dose and dosing interval are dependent on postmenstrual and postnatal age.		
Amikacin*	15-18 mg/kg/dose every 24-48 hr	Monitor serum concentrations if treating >48 hr
Ampicillin*	Meningitis: 100 mg/kg/dose IV, IM every 6-12 hr Non-CNS infections: 25-50 mg/kg/dose IV, IM every 6-12 hr	
Azithromycin	Pertussis infections: 10 mg/kg/dose PO every 24 hr	IV administration has not been evaluated in pediatric patients
Aztreonam*	30 mg/kg/dose IV, IM every 6-12 hr	Adequate glucose must be provided to prevent hypoglycemia
Cefazolin*	25 mg/kg/dose IV, IM every 6-12 hr	First-generation cephalosporin; use is limited to perioperative prophylaxis and treatment of urinary tract and soft tissue infections
Cefepime	30-50 mg/kg/dose IV, IM every 12 hr	Fourth-generation cephalosporin; reserved for treatment of infections caused by multidrug-resistant organisms
Cefotaxime*	50 mg/kg/dose IV, IM every 6-12 hr Gonococcal ophthalmia: 100 mg/kg IV, IM single dose	Broad spectrum third-generation cephalosporin; may use to treat gram-negative meningitis
Cefoxitin*	25-33 mg/kg/dose IV every 6-12 hr	Do not use to treat meningitis
Ceftazidime*	30 mg/kg/dose IV, IM every 8-12 hr	Only cephalosporin effective against *Pseudomonas* species
Ceftriaxone*	50-100 mg/kg/dose IV, IM every 24 hr Gonococcal ophthalmia: 50 mg/kg (maximum 125 mg) IV, IM single dose	Not recommended for infants with hyperbilirubinemia; do not administer concurrently with calcium-containing solutions
Chloramphenicol	Loading dose: 20 mg/kg IV over 30 min Maintenance dose (begin 12 hr after loading dose) Premature <1 month old: 2.5 mg/kg IV every 6 hr Full term <1 week old, premature >1 month old: 5 mg/kg IV every 6 hr Full term >1 week old: 12.5 mg/kg IV every 6 hr	Monitor serum concentrations; concentrations >50 μg/mL associated with gray baby syndrome; can cause bone marrow suppression, aplastic anemia

Continued

Agent	Dosage	Comments
Clindamycin*	5-7.5 mg/kg/dose IV, PO every 6-12 hr	Do not use to treat meningitis; may cause pseudomembranous colitis
Erythromycin	10-12.5 mg/kg/dose PO every 6 hr	Higher dose used to treat pertussis and chlamydial pneumonitis and conjunctivitis
Gentamicin*	4-5 mg/kg/dose every 24-48 hr IV	Monitor serum concentrations if treating >48 hr
Imipenem	20 to 25 mg/dose IV every 12 hr	Seizures may occur if treating meningitis
Linezolid	10 mg/kg/dose IV every 8 hr (premature infants <7 days of age: dose every 12 hr)	Do not use to treat meningitis; do not use for empirical therapy if suspecting gram-negative infection
Meropenem*	Sepsis: 20 mg/kg/dose IV every 8-12 hr Meningitis and pseudomonal infections: 40 mg/kg/dose every 8 hr	Reserve for infections caused by multidrug-resistant organisms
Metronidazole*	Loading dose: 15 mg/kg IV, PO Maintenance dose: 7.5 mg/kg/dose IV, PO every 8-48 hr	Measure CSF concentrations when treating meningitis
Nafcillin*	25-50 mg/kg/dose IV every 6-12 hr	Greatest CSF penetration of antistaphylococcal penicillins; predominantly biliary excretion; irritating to veins
Oxacillin*	25-50 mg/kg/dose IV every 6-12 hr	
Penicillin G*	25,000-100,000 IU/kg/dose IV, IM every 6-12 hr	Higher doses are suggested for severe group B streptococcal infections
Piperacillin/ tazobactam*	50-100 mg/kg/dose IV every 8-12 hr	For non-CNS infections caused by susceptible β-lactamase–producing bacteria
Quinopristin, dalfopristin	7.5 mg/kg/dose IV every 12 hr	Reserve for multidrug-resistant gram-positive infections
Rifampin	PO: 10-20 mg/kg every 24 hr IV: 5-10 mg/kg/dose every 12 hr Prophylaxis against meningococcal disease: 5 mg/kg/dose PO every 12 hr for 2 days Prophylaxis against *Haemophilus influenzae* type B disease: 10 mg/kg/dose PO every 24 hr for 4 days	Used in combination with vancomycin or aminoglycosides for treatment of persistent staphylococcal infections
Ticarcillin, clavulanate*	75-100 mg/kg/dose IV every 6-12 hr	For non-CNS infections caused by susceptible β-lactamase–producing bacteria
Tobramycin*	4-5 mg/kg/dose every 24-48 hr	Serum concentrations should be monitored and doses adjusted to achieve peak concentrations of 8-10 μg/mL and trough concentrations of <2 μg/mL
Vancomycin*	10-15 mg/kg/dose IV every 6-18 hr	Trough concentrations 5-10 μg/mL for most infections, 15-20 μg/mL when treating endocarditis, pneumonia, bone and joint infections; may not be effective against organisms with MIC >2 μg/mL
Antifungals		
Amphotericin B	1-1.5 mg/kg/day IV infusion over 2-6 hr	Serum potassium and creatinine clearance values should be monitored closely; alternate-day therapy may permit better control of electrolyte status
Amphotericin B liposome (AmBisome)	5-7 mg/kg/dose every 24 hr	Less nephrotoxic than amphotericin B, but also not indicated for treating renal candidiasis

Agent	Dosage	Comments
Amphotericin B lipid complex (ABELCET)	5 mg/kg/dose every 24 hr	Less nephrotoxic than amphotericin B, but also not indicated for treating renal candidiasis
Caspofungin	25 mg/m^2/dose (about 2 mg/kg/dose) IV every 24 hr	Limited data in neonates—reserve for treatment of refractory candidemia or patients intolerant of amphotericin
Fluconazole*	Loading dose: 12-25 mg/kg Systemic infections: 6 to 12 mg/kg IV or PO every 24-72 hr Prophylaxis: 3 mg/kg/dose IV twice weekly Thrush: 6 mg/kg PO on day 1, then 3 mg/kg/dose PO every 24 hr	Reversible elevations of transaminases have occurred in 12% of children. Interferes with metabolism of barbiturates and phenytoin; may also interfere with metabolism of aminophylline, caffeine, theophylline, and midazolam
Flucytosine	12.5-37.5 mg/kg/dose PO every 6 hr	Use only in conjunction with amphotericin B to treat fungal CNS infections
Micafungin	7-10 mg/kg IV every 24 hr	Limited data in neonates—reserve for treatment of refractory candidemia or patients intolerant of amphotericin
Nystatin	Topical: apply to affected area every 6 hr, continue treatment for 3 days after symptoms subside Thrush: 1 mL (premature) to 2 mL (full term) of 100,000 units/mL suspension, swab inside mouth every 6 hr	
Antivirals		
Acyclovir	20 mg/kg/dose IV every 8 hr for 14-21 days Chronic suppression: 75 mg/kg/dose PO every 12 hr	Neutropenia, phlebitis may occur; use slow infusion rates to avoid transient renal dysfunction
Ganciclovir	6 mg/kg/dose IV every 12 hr Chronic suppression: 30-40 mg/kg/dose PO every 8 hr	Significant neutropenia occurs in most patients
Lamivudine	2 mg/kg/dose PO every 12 hr	Refer to the Perinatal Guidelines at http://www.aidsinfo.nih.gov/ for the latest treatment information
Nevirapine	2 mg/kg PO single dose	Refer to the Perinatal Guidelines at http://www.aidsinfo.nih.gov/ for the latest treatment information
Valganciclovir	16 mg/kg/dose PO every 12 hr	Neutropenia occurs frequently
Zidovudine*	IV: 1.5 mg/kg/dose every 6-12 hr PO: 2 mg/kg/dose every 6-12 hr	Initiate treatment within 12 hr of birth; anemia and neutropenia may occur
Cardiovascular Drugs		
Antiarrhythmics		
Adenosine	Give 50 μg/kg as a rapid IV bolus followed by a flush; if there is no response in 1-2 min, double the dose and continue to double it every 1-2 min until a response is obtained (usual maximum dose of 250 μg/kg)	Resolution of SVT is usually short lived, so it must be followed by the use of a more long-acting agent such as digoxin
Amiodarone	Loading dose: 5 mg/kg IV over 30-60 min IV infusion: Start at 7 μg/kg/min, may increase to 15 μg/kg/min PO: 5-10 mg/kg/dose every 12 hr	For treatment of refractory supraventricular arrhythmia; long elimination half-life; may cause hypothyroidism and corneal microdeposits; may increase plasma concentrations of digoxin and phenytoin

Continued

Agent	Dosage	Comments
Digoxin	Preterm, loading dose: IV: 15-20 μg/kg divided into 3 doses over 24 hr PO: 20-25 μg/kg divided into 3 doses over 24 h Maintenance dose: IV: 4-5 μg/kg daily PO: 5-6 μg/kg daily	Be aware of drug interactions; obtain periodic ECGs to assess for both desired effects and signs of toxicity
	Full term, loading dose: IV: 30-40 μg/kg divided into 3 doses over 24 hr; PO: 40-50 μg/kg divided into 3 doses over 24 hr Maintenance dose: IV: 4-5 μg/kg every 12 hr PO: 5-6 μg/kg every 12 hr	
Digoxin immune Fab (Digibind)	Dose (# of vials) = [(serum digoxin concentration) × (weight in kg)]/100	Each vial contains 38 mg and will bind 0.5 mg digoxin; once administered, digoxin serum concentrations can no longer be determined accurately
Flecainide	Begin at 2 mg/kg/dose PO every 12 hr; adjust dose based on response and serum concentrations to a maximum of 4 mg/kg/dose PO every 12 hr	Used for treatment of SVT not responsive to conventional therapies; can cause new or worsened arrhythmias
Lidocaine	0.5-1 mg/kg/dose by slow IV push; may be repeated every 10 min as needed; maintenance IV infusion: 10-50 μg/kg/min	Contraindicated in infants with cardiac failure and heart block; adverse effects include hypotension, seizures, respiratory arrest, and asystole
Procainamide	Initial IV loading dose: 7-10 mg/kg/dose Maintenance IV infusion: 20-80 μg/kg/min	Treatment of SVT refractory to vagal maneuvers and adenosine
Propranolol	Starting oral dose: 0.25 mg/kg/dose PO every 6 hr Maximum: 3.5 mg/kg/dose PO every 6 hr Starting IV dose: 0.01 mg/kg/dose IV every 6 hr Maximum: 0.15 mg/kg/dose IV every 6 hr	Preferred therapy for SVT if associated with Wolff-Parkinson-White syndrome; adverse effects related to β-receptor blockade
Sotalol	1 mg/kg PO every 12 hr, may increase to 4 mg/kg every 12 hr	For tetralogy spells; indicated for ventricular arrhythmias; has properties that prolong both β-blockade and action potentials
Vasodilators/Vasoconstrictors		
Alprostadil	Initial dose: 0.05-0.1 mcg/kg/min IV Maintenance doses may be as low as 0.01 mcg/kg/min	Apnea is most common adverse effect and occurs more frequently in premature infants
Captopril	0.01-0.05 mg/kg/dose PO every 8 hr	Angiotensin-converting enzyme inhibitor; may be effective in high renin hypertension and severe CHF; must monitor renal function; contraindicated in infants with bilateral renovascular disease
Dobutamine	2-20 μg/kg/min IV	Titrate dose to target effect; in young infants, increased heart rate may occur; tolerance may develop with prolonged use (>3 days)
Dopamine	2-20 μg/kg/min IV	Doses in the lowest part of the range cause an increase in glomerular filtration rate, renal blood flow, and Na^+ excretion; as dose is increased, cardiotonic effects predominate at first, followed by increased systemic vascular resistance; effects vary depending on gestational and postnatal age and disease process

Agent	Dosage	Comments
Epinephrine	Resuscitation: 0.1-0.3 mL/kg/dose of 1:10,000 concentration IV push, or IC (equal to 0.01-0.03 mg/kg [10-30 μg/kg]) Continuous infusion: 0.1-1 μg/kg/min IV	Higher doses, up to 0.1 mg/kg (100 μg/kg), may be given intratracheally immediately followed by 1 mL NS Monitor for hyperglycemia, tachycardia, and lactic acidemia
Hydralazine	IV: begin with 0.1-0.5 mg/kg/dose every 6 to 8 hr Gradually increase as needed to a maximum of 2 mg/kg/dose every 6 hr PO: 0.25-1 mg/kg/dose	Use with a β-blocker to enhance antihypertensive effect and decrease the magnitude of reflex tachycardia Administer with food to enhance absorption
Ibuprofen	First dose: 10 mg/kg IV Second and third doses: 5 mg/kg IV Administer at 24-hr intervals	Less renal effects than indomethacin
Indomethacin	Initial dose: 0.2 mg/kg IV Subsequent doses: If <2 days, 0.1 mg/kg/dose every 12-24 hr for 2 doses If 2-7 days, 0.2 mg/kg/dose every 12-24 hr for 2 doses If >7 days, 0.25 mg/kg/dose every 12-24 hr for 2 doses	Prostaglandin synthase inhibitor used for PDA closure; monitor renal function; avoid concomitant steroid therapy to decrease risk for GI perforation
Isoproterenol	0.05-2 μg/kg/min IV	Continuous ECG and blood pressure monitoring essential to prevent hypotension and tachycardia
Milrinone	Loading dose: 50-75 μg/kg IV over 60 min Begin infusion at 0.5 μg/kg/min May titrate to 0.75 μg/kg/min	Has both inotropic and vasodilatory properties; hypotension more likely with bolus doses
Nitric oxide	Begin at 20 ppm, wean over several days	Monitor for methemoglobinemia; use in premature infants for indications other than pulmonary hypertension is controversial
Phentolamine	Inject a 0.5-mg/mL solution SC into the periphery of the affected area	Prevention of dermal necrosis caused by extravasation of vasoconstrictive agents
Sodium nitroprusside	Start at 0.25-0.5 μg/kg/min continuous IV infusion, increase dose every 20 min as needed Maintenance dose is usually <2 μg/kg/min For hypertensive crisis, can use doses as high as 10 μg/kg/min for ≤10 min	Must have continuous intra-arterial blood pressure monitoring; may produce profound hypotension, metabolic acidosis, thrombocytopenia, and/or CNS symptoms; cyanide toxicity can occur
Central Nervous System Drugs		
Analgesics and Narcotics		
Acetaminophen*	PO: 20-25 mg/kg loading dose, then 12-15 mg/kg every 6-12 hr Rectal: 30 mg/kg loading dose, then 12-18 mg/kg every 6-12 hr	Dosing intervals dependent on postmenstrual age
Fentanyl	1-4 μg/kg IV, may be repeated as needed Continuous IV infusion: 1-5 μg/kg/hr	Synthetic opioid; may cause chest wall rigidity at the higher doses or with rapid infusion Continuous infusions are associated with development of tolerance
Methadone	0.05-0.2 mg/kg/dose every 12-24 hr PO	Reduce dose based on signs and symptoms of withdrawal

Continued

Agent	Dosage	Comments
Morphine	IV: 0.05-0.2 mg/kg/dose every 3-4 hr Neonatal narcotic abstinence: begin at 0.03 to 0.1 mg/kg/dose PO repeated every 3-4 hr as needed Adjust dose based on abstinence scoring	May exacerbate hypotension; repetitive or continuous infusion dosing associated with ileus and urinary retention Paregoric not recommended because it contains alcohol and benzoic acid
Anticonvulsants		
Fosphenytoin	Loading dose: 15-20 PE/kg IV, IM Maintenance dose: 4-8 PE/kg IV, IM every 24 hr	Fosphenytoin 1 mg PE = phenytoin 1 mg; monitor trough serum phenytoin concentrations; term infants >1 week of age may require more frequent dosing; use with caution in neonates with hyperbilirubinemia
Levetiracetam	10 mg/kg/dose IV, PO every 24 hr Increase dosage every 1-2 wk as needed to attain seizure control, to a maximum of 30 mg/kg/dose every 12 hr	Very limited data in neonates
Lidocaine	Loading dose: 2 mg/kg IV over 10 minutes, followed immediately by a Maintenance infusion: 6 mg/kg/hr for 6 hr, then 4 mg/kg/hr for 12 hr, then 2 mg/kg/hr for 12 hr	Preterm newborns and term newborns undergoing hypothermia treatment are at risk for drug accumulation due to slower drug clearance; precise dosing in these infants is uncertain
Phenobarbital	Loading dose: 20 mg/kg slow IV push, additional 5 mg/kg doses may be given up to a total of 40 mg/kg Maintenance dose: 3-4 mg/kg IV, IM, or PO as a single daily dose	Serum concentrations should be monitored and doses adjusted to maintain concentrations at 15-40 μg/mL; the long half-life of the drug suggests that single daily doses will be sufficient; little information is available on oral absorption in the first month of life
Phenytoin	Loading dose: 15-20 mg/kg IV over 30 min Maintenance dose: 4-8 mg/kg daily IV slow push or PO	Unstable in solution and may precipitate in central lines
Neuromuscular Blockers		
These agents must be used in conjunction with an effective sedative/hypnotic agent. They do not provide any analgesia or amnesia.		
Pancuronium	0.04-0.15 mg/kg/dose IV, repeat as needed	Prolonged use may be associated with delayed recovery of muscle tone; may cause an increase in heart rate
Rocuronium	0.3-0.6 mg/kg/dose IV, repeat as needed	Shortest duration of action in this group
Vecuronium	0.03-0.15 mg/kg IV, repeat as needed	Minimum cardiovascular side effects; prolonged use may result in delayed recovery of muscle strength
Sedatives/Tranquilizers		
Chloral hydrate	25-75 mg/kg/dose PO, PR	No analgesic properties; for short-term use only
Lorazepam	0.05-0.1 mg/kg/dose IV	May cause respiratory depression; may be used acutely to stop seizures
Midazolam	0.05-0.15 mg/kg/dose IV, IM: every 2-4 hr Continuous IV infusion: 0.01-0.06 mg/kg/hr	Dosage requirements are decreased by concurrent use of narcotics; monitor for respiratory depression and hypotension; may cause myoclonic seizure-like activity
Pentobarbital	2-6 mg/kg IV	Short-acting barbiturate for short-term use

Agent	Dosage	Comments
Diuretics		
Bumetanide	0.005-0.1 mg/kg per dose IV, IM, or PO every 24 hr in preterm infants <34 weeks' gestation in the first 2 mo of life and more mature infants in the first month, then every 12 hr thereafter	Water and electrolyte imbalances occur frequently, especially hyponatremia, hypokalemia, and hypochloremic alkalosis; potentially ototoxic, but less so than furosemide; may displace bilirubin from albumin binding sites when given in high doses or for prolonged periods; may be used at the same dose PO and IV because of excellent bioavailability
Chlorothiazide	10-20 mg/kg/dose PO every 12 hr	May cause hypokalemia, alkalosis, and hyperglycemia; effective in the treatment of nephrocalcinosis secondary to loop diuretics
Furosemide	IV: 1-2 mg/kg/dose PO: 2-6 mg/kg/dose Premature infants: every 24 hr Term infants in the first month of life: every 12 hr Afterward: every 6-8 hr	Potentially ototoxic; may cause hypokalemia, alkalosis, and dehydration; consider alternate-day therapy for long-term use
Spironolactone	1-3 mg/kg/dose PO every 24 hr	May require several days of therapy before effect is seen; monitor serum potassium
Endocrine Agents		
Dexamethasone	0.075 mg/kg/dose IV or PO, every 12 hr for 3 days, then wean over 7 days (DART [Dexamethasone: a randomized trial] protocol)	Treat only those infants at highest risk for chronic lung disease; adverse effects include growth failure and increased risk for cerebral palsy; do not use concurrently with indomethacin due to risk for GI perforation
Hydrocortisone	Physiologic dose: 6-10 mg/m^2/day divided into 2 or 3 doses Stress dose: 20-50 mg/m^2/day (3 mg/kg/day) divided into 2 or 3 doses	Doses for physiologic replacement and stress remain controversial; adverse effects include hyperglycemia, hypertension, water and salt retention; there is an increased risk for GI perforations when treating concurrently with indomethacin
Insulin	0.01-0.1 U/kg/hr continuous IV infusion	For hyperglycemia; titrate rate of infusion to achieve desired serum glucose concentration; may be used to treat hyperkalemia
Levothyroxine	Start with 10-14 μg/kg/dose PO or 5-8 μg/kg/dose IV daily, adjust dose to desired TSH level	Oral doses changed in 12.5-μg increments; assess thyroid function 2 weeks after a dosing change
Octreotide	Treatment of hyperinsulinemic hypoglycemia: starting dose: 1 μg/kg/dose IV or SC every 6 hr; titrate to desired effect, maximum dose is 10 μg/kg Treatment of chylothorax: 1-7 μg/kg/hr continuous infusion	Decreases chyle production
Gastrointestinal Agents		
Cimetidine	2.5-5 mg/kg/dose PO, IV every 6-12 hr	May increase risk for NEC
Erythromycin	10-12 mg/kg/dose PO every 6 hr	Treatment of feeding intolerance due to GI dysmotility; may also lessen parenteral nutrition-associated cholestasis

Continued

Agent	Dosage	Comments
Famotidine	IV: 0.25-0.5 mg/kg/dose every 24hr PO: 0.5-1 mg/kg/dose every 24 hr	May increase risk for NEC due to alterations in GI flora; continuous infusion of the daily dose in adults provides better gastric acid suppression than intermittent dosing
Lansoprazole	0.73 to 1.66 mg/kg/dose PO every 24 hr	
Metoclopramide	0.1-0.3 mg/kg/day IV, PO divided every 8 hr	May reduce gastric aspirates and reflux; may improve feeding tolerance; observe for dystonic reactions
Nizatidine	2 to 5 mg/kg/dose PO every 12 hr	
Omeprazole	0.5 to 1.5 mg/kg/dose PO every 24 hr	
Ranitidine	PO: 2 mg/kg/dose every 8 hr IV preterm: 0.5 mg/kg/dose every 12 hr IV full term: 1.5 mg/kg/dose every 8 hr IV infusion: 0.0625 mg/kg/hr	May increase risk for NEC due to alterations in GI flora; continuous infusion of the daily dose in adults provides better gastric acid suppression than intermittent dosing
Ursodiol	10-15 mg/kg/dose PO every 12 hr	
Hematologic Agents		
Alteplase (t-PA)	Dissolution of intravascular thrombi: 200 μg/kg/hr for 6 to 48 hr Restoration of patency for central venous catheter: instill a 1-mg/mL solution into the catheter	Dose is an average of that used in case reports—range 20 to 500 μg/kg/hr
Enoxaparin	Term: 1.7 mg/kg/dose SC every 12 hr Preterm: 2 mg/kg/dose SC every 12 hr	Adjust dosage to maintain anti–factor Xa level between 0.5 and 1 U/mL
Epoetin alfa	300 units/kg/dose SC daily for 10 days	May also be given IV over at least 4 hr in a protein-containing solution; patient should be on supplemental iron therapy
Heparin	0.5-1 U/mL of IV fluid	
IVIG	500 to 750 mg/kg/dose IV over 2-6 hr	Usually given as a single dose; if subsequent doses are used, administer at 24-hr intervals
Minerals/Vitamins		
Calcium gluconate 10%	Acute treatment: 1-2 mL/kg/dose IV (100-200 mg/kg CaCl salt, 10-20 mg/kg elemental calcium) Maintenance treatment: 2-8 mL/kg/day by continuous IV infusion (200-800 mg/kg CaCl salt, 20-80 mg/kg elemental calcium)	May also be given orally at the same daily dosage
Ferrous sulfate (15 mg/mL Fe)	2-6 mg/kg/day elemental iron divided into 2-3 doses PO	Higher dose for infants on epoetin therapy
Iron dextran	0.4-1 mg/kg/day continuous IV infusion in hyperalimentation solution	For infants unable to tolerate oral iron therapy
Potassium chloride	Acute treatment of symptomatic hypokalemia: begin with 0.5-1 mEq/kg IV over 1 hr, then reassess Initial oral replacement: 0.5-1 mEq/kg/day PO divided and administered with feedings	Maximum concentrations: 40 mEq/L for peripheral, 80 mEq/L for central venous infusions Small, more frequent aliquots preferred; adjust dosage based on serum potassium concentrations
Pyridoxine (vitamin B_6)	Initial diagnostic dose: 50-100 mg IV push, or IM Maintenance dose: 50-100 mg PO every 24 hr	Risk for profound sedation; ventilator support may be necessary

Agent	Dosage	Comments
Sodium bicarbonate	1-2 mEq/kg/dose IV over at least 30 min Maximum concentration used is 0.5 mEq/mL	Treatment of normal anion gap metabolic acidosis caused by renal or GI losses; sodium bicarbonate is not a recommended therapy in neonatal resuscitation; administration during brief CPR may be detrimental
THAM acetate	1-2 mmol/kg (3.3-6.6 mL/kg) per dose IV in a large vein over at least 30 min	Do not use in patients who are anuric or uremic
Vitamin A	5000 IU IM 3 times/wk for 4 weeks	Administer using 29-g needle and insulin syringe. DO NOT ADMINISTER IV.
Vitamin D	Supplementation: 400 U/day PO Treatment of deficiency: 1000 U/day PO	Vitamin D_3 (cholecalciferol; fish derived) has been shown to be more effective in raising 25(OH)-D levels when compared with vitamin D_2 (ergocalciferol; plant derived)
Vitamin E	5 to 25 U/day PO	Dilute with feedings; impairs iron absorption if administered simultaneously
Vitamin K_1	Prophylaxis: term and late preterm: 0.5-1 mg IM at birth Preterm <32 weeks' gestational age: >1000 g birthweight: 0.5 mg IM <1000 g birthweight: 0.3 mg/kg IM Treatment of HDN: 1-10 mg IV slow push	
Ophthalmic Agents		
Cyclopentolate	1-2 drops in the eye 10-30 min before funduscopy	Use solutions with concentrations of 0.5% or less in neonates; anticholinergic effects if absorbed systemically; apply pressure to lacrimal sac during and for 2 min after instillation
Phenylephrine	1 drop in the eye 10-30 min before funduscopy	Use only the 2.5% solution in neonates
Tropicamide	1 drop in the eye 10-30 min before funduscopy	Use only the 0.5% solution in neonates; anticholinergic effects if absorbed systemically; apply pressure to lacrimal sac during and for 2 min after instillation
Pulmonary Agents		
Beractant (Survanta)	4 mL/kg/dose intratracheally in 2 aliquots; may administer 3 subsequent doses at 6-hr intervals	
Calfactant (Infasurf)	3 mL/kg/dose intratracheally in 2 aliquots; may administer 3 subsequent doses at 12-hr intervals	
Poractant alfa (Curosurf)	2.5 mL/kg intratracheally in 2 aliquots; may administer 2 subsequent doses of 1.25 mL/kg/dose at 12-hr intervals	
Albuterol	0.1-0.5 mg/kg/dose every 2-6 hr through nebulization	Selective β_2-agonist; may be used every 2 hr for treatment of hyperkalemia
Aminophylline (IV)	Loading dose: 20-25 mg/kg IV or PO (10-12.5 mg/kg caffeine base)	If changing from IV to PO aminophylline—increase dose by 20%
Theophylline (PO)	Maintenance dose: 1.5-3 mg/kg/dose every 8-12 hr IV or PO	If changing from IV aminophylline to PO theophylline—no change in dose

Continued

Agent	Dosage	Comments
Caffeine citrate	Loading dose: 20-25 mg/kg IV or PO (10-12.5 mg/kg caffeine base) Maintenance dose: 5-10 mg/kg/dose every 24 h IV or PO (2.5-5 mg/kg/dose caffeine base)	Therapeutic serum caffeine levels are in the range of 5-20 μg/mL
Dornase alpha	1.25 mL-2.5 mL via nebulizer, or 0.2 mL/kg instilled directly into the endotracheal tube Administer once or twice per day	Desaturation and/or airway obstruction may occur due to rapid mobilization of secretions
Ipratropium bromide	2 puffs (34 μg)-4 puffs (68 μg) via MDI with spacer device placed in the inspiratory limb of the ventilator circuit	Precise dosing is uncertain, although therapeutic margin is wide

CHF, congestive heart failure; CNS, central nervous system; CPR, cardiopulmonary resuscitation; CSF, cerebrospinal fluid; ECG, electrocardiogram; GI, gastrointestinal; HDN, hemolytic disease of the newborn; IC, intracardiac; IV, intravenous; IVIG, intravenous immunoglobulin; IM, intramuscular; MDI, metered-dose inhaler; MIC, minimum inhibitory concentration; NEC, necrotizing enterocolitis; NS, normal saline; PDA, patent ductus arteriosus; PE, phenytoin equivalent; PO, per oral route; SC, subcutaneous; SVT, supraventricular tachycardia; TSH, thyroid-stimulating hormone.

APPENDIX B

Tables of Normal Values

Mary L. Nock

PHYSIOLOGIC PARAMETERS

Blood Pressure

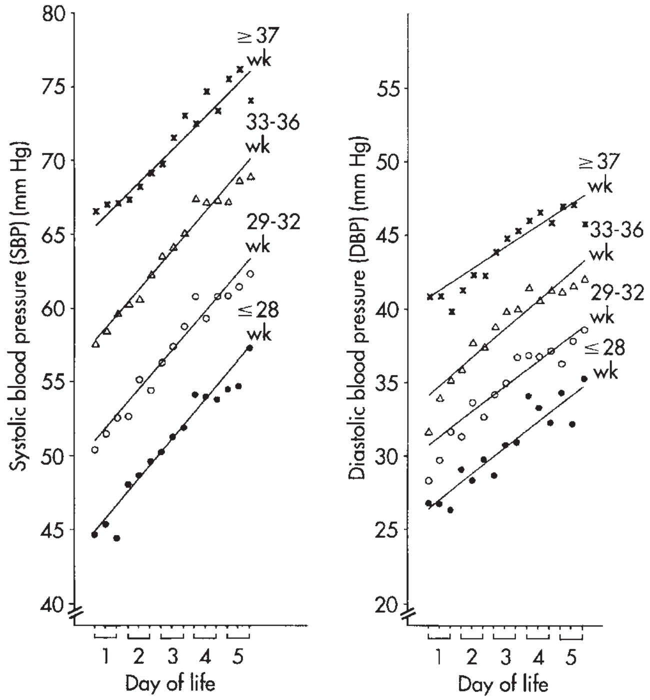

Figure B–1. Systolic and diastolic blood pressures plotted for the first 5 days of life, with each day subdivided into 8-hour periods. Infants are categorized by gestational age into 4 groups: ≤28 weeks (n = 33), 29 to 32 weeks (n = 73), 33 to 36 weeks (n = 100), and ≥37 weeks (n = 110). *(From Zubrow AB et al: Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. Philadelphia Neonatal Blood Pressure Study Group,* J Perinatol *15:470, 1995.)*

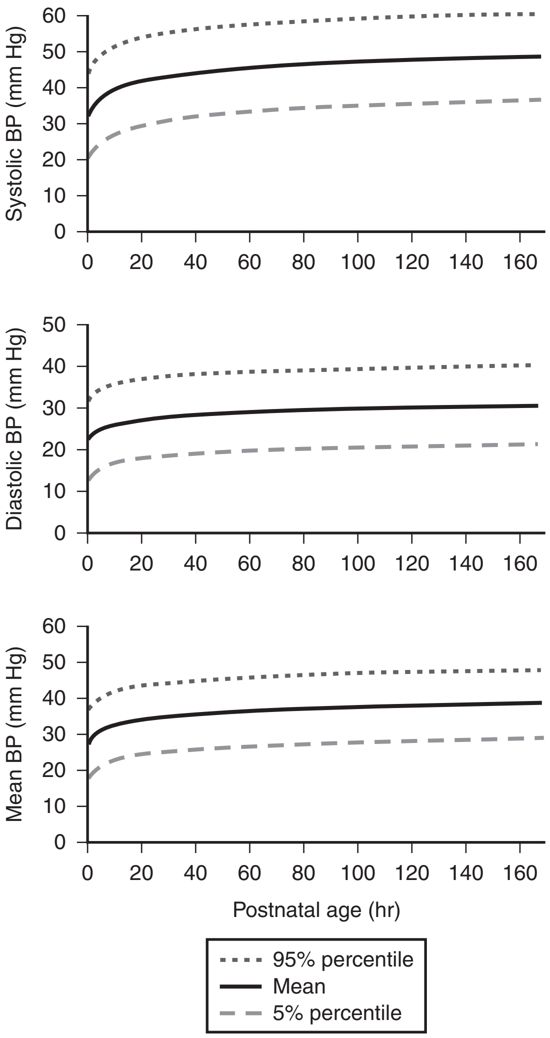

Figure B–2. Systolic, diastolic, and mean blood pressure during the first postnatal week in 86 infants of gestational ages 23 to <26 weeks who did not receive blood pressure support. *(From Batton B et al: Blood pressure during the first 7 days in premature infants born at postmenstrual age 23 to 25 weeks,* Am J Perinatol *24:109, 2007.)*

Time of First Void and Stool

TABLE B–6 Serum Calcium (mg/100 dL) and Phosphate (mg/dL) Levels in Infants with Very Low Birthweight Receiving Parenteral and Enteral Nutrition*

	Calcium Levels		Phosphate Levels	
Age (days)	**500-1000 g**	**1001-1500 g**	**500-1000 g**	**1001-1500 g**
1	8.39 ± 1.21	8.48 ± 0.65	6.16 ± 1.33	5.73 ± 0.90
2	8.50 ± 0.91	8.68 ± 1.07	5.96 ± 1.55	6.14 ± 1.13
3	9.36 ± 0.96	9.28 ± 0.98	5.21 ± 1.53	6.15 ± 1.22
4	9.28 ± 1.59	9.56 ± 0.56	4.84 ± 1.60	5.86 ± 1.07
5	9.50 ± 1.42	10.06 ± 0.74	4.41 ± 1.69	5.66 ± 1.39
12	9.52 ± 1.77	10.05 ± 0.55	5.13 ± 1.23	6.79 ± 1.16
19	9.70 ± 0.58	10.05 ± 0.86	5.97 ± 1.17	7.35 ± 0.91
26	9.46 ± 2.03	10.07 ± .055	5.98 ± 1.12	6.79 ± 0.71
33	9.71 ± 0.47	9.96 ± 0.69	5.37 ± 1.21	6.58 ± 0.60

* Included are 24 neonates of birthweight 500-1000 g, 28 neonates of birthweight 1001-1500 g. All* values are mean ± standard deviation.

Modified from El Hassan et al: Premature infants: analysis of serum phosphate during the first 4 weeks of life, *Am J Perinatol* 24:327, 2007.

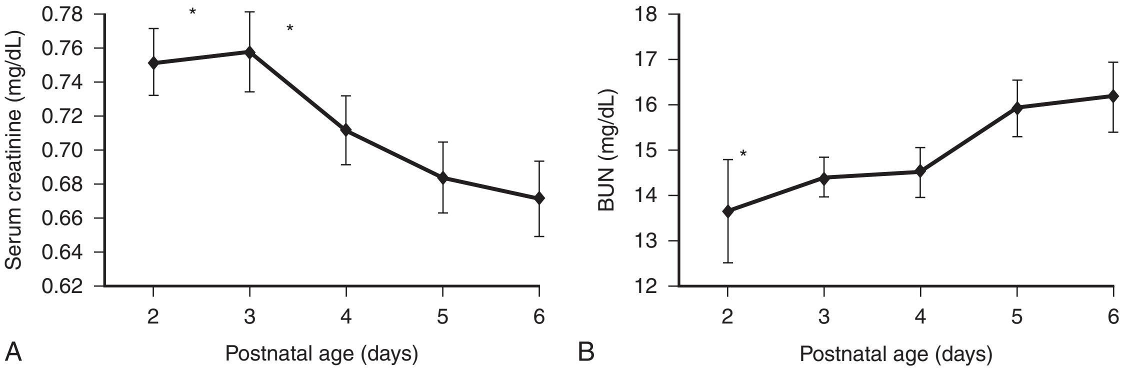

Figure B–5. Serum creatinine (**A**) and serum blood urea nitrogen (**B**) values in infants with very low birthweight (≤1500 g) during their first days of life. Data are presented as mean ± standard error of the mean, *n* = 138. Asterisk (*) indicates a statistically significant difference with day 6 of life. BUN, blood urea nitrogen. *(From Auron A et al: Serum creatinine in very low birth weight infants during their first days of life,* J Perinatol *26:756, 2006.)*

TABLE B–7 Plasma Creatinine (mg/dL) in Premature Babies <28 Weeks' Gestational Age During the First 8 Weeks of Life*

Age	22-24 wk (*n* = 33)	25-26 wk (*n* = 55)	27-28 wk (*n* = 73)
Birth	0.9 (0.67, 1.15)	0.87 (0.68, 1.18)	0.87 (0.69, 1.1)
12 hr	1.08 (0.8, 1.3)	1.03 (0.8, 1.27)	1 (0.77, 1.29)
24 hr	1.2 (1.02, 1.4)	1.18 (0.94, 1.41)	1.12 (0.9, 1.36)
36 hr	1.3 (1.11, 1.58)	1.25 (0.96, 1.41)	1.15 (0.9, 1.43)
48 hr	1.34 (1.12, 1.58)	1.27 (0.94, 1.6)	1.13 (0.93, 1.38)
3 days	1.32 (1.1, 1.64)	1.28 (0.89, 1.58)	1.12 (0.9, 1.43)
4 days	1.33 (1.09, 1.63)	1.26 (0.95, 1.64)	1.08 (0.84, 1.39)
7 days	1.28 (0.95, 1.71)	1.16 (0.71, 1.5)	1 (0.78, 1.22)
2 week	1.24 (0.78, 1.96)	0.95 (0.59, 1.3)	0.84 (0.64, 1.06)
3 week	1.04 (0.69, 1.49)	0.84 (0.55, 1.07)	0.71 (0.57, 0.87)
4 week	0.8 (0.6, 1.02)	0.76 (0.51, 0.94)	0.63 (0.5, 0.79)
5 week	0.79 (0.54, 1.1)	0.64 (0.46, 0.81)	0.59 (0.49, 0.67)
6 week	0.62 (0.5, 0.79)	0.59 (0.41, 0.7)	0.54 (0.44, 0.64)
7 week	0.6 (0.46, 0.78)	0.54 (0.41, 0.68)	0.51 (0.43, 0.6)
8 week	0.58 (0.44, 0.81)	0.52 (0.35, 0.62)	0.5 (0.41, 0.59)
Peak creatinine	1.5 (1.2, 1.83)	1.43 (1.01, 1.71)	1.24 (0.98, 1.52)

*Values are mean (10th, 90th percentile).

Modified from Thayyil S et al: A gestation- and postnatal age-based reference chart for assessing renal function in extremely premature infants, *J Perinatol* 28:227, 2008.

TABLE B–8 Capillary Blood Gas Reference Values in Healthy Term Neonates

Variable	No. of Patients	Mean ± SD	2.5 Percentile	97.5 Percentile
pH	119	7.395 ± 0.037	7.312	7.473
P_{CO_2} (mm Hg)	119	38.7 ± 5.1	28.5	48.7
P_{O_2} (mm Hg)	119	45.3 ± 7.5	32.8	61.2
Lactate (mmol/L)	114	2.6 ± 0.7	1.4	4.1
Hemoglobin (g/dL)	122	20.4 ± 11.6	14.5	23.9
Glucose (mg/dL)	122	69 ± 14	38	96
iCa (mmol/L)	118	1.21 ± 0.07	1.06	1.34

Samples collected at 48 ± 12 hours of life.

Modified from Cousineau J et al: Neonate capillary blood gas reference values, *Clin Biochem* 38:906, 2005.

TABLE B–9 Reference Serum Amino Acid Concentrations That Have Been Proposed as Standards for Neonates

Amino Acids	Term Infant Fed Human Milk (mmol/L)	Cord Blood (mmol/L)
Isoleucine	26-93	21-76
Leucine	53-169	47-120
Lysine	80-231	181-456
Methionine	22-50	8-42
Phenylalanine	22-71	24-87
Threonine	34-168	108-327
Tryptophan	18-101	19-98
Valine	88-222	98-276
Alanine	125-647	186-494
Arginine	42-148	28-162
Aspartic acid	5-51	18 ± 17
Glutamic acid	24-243	92 ± 57
Glycine	77-376	123-312
Histidine	34-119	42-136
Proline	82-319	72-278
Serine	0-326	57-174
Taurine	1-167	41-461
Tyrosine	38-119	34-83
Cysteine	35-132	4-37

Modified from Hanning RM et al: Amino acid and protein needs of the neonate: effects of excess and deficiency, *Semin Perinatol* 13:131, 1989.

TABLE B–10 Plasma Ammonia Levels in Preterm Infants ≤32 Weeks' Gestational Age

	AMMONIA LEVEL*	
Age (days)	*μmol/L*	*μg/dL*
Birth	71 ± 26	121 ± 45[†]
1	69 ± 22	117 ± 37
3	60 ± 19	103 ± 33
7	42 ± 14	72 ± 24
14	42 ± 18	72 ± 30
21	43 ± 16	73 ± 28
28	42 ± 15	72 ± 25
Term infants at birth	45 ± 9	77 ± 16

*Values represent mean ± SD.

[†] Significant decline in plasma ammonia level from birth to 7 days of age ($P < .01$).

Modified from Usmani SS et al: Plasma ammonia levels in very low birth weight preterm infants, *J Pediatr* 123:798, 1993.

TABLE B–11 Tests of Liver Function

Test	Unit of Measurement	Age	Value
Albumin	g/L	0-5 days (<2.5 kg)	20-36
		0-5 days (>2.5 kg)	26-36
		1-30 days	26-43
		31-182 days	28-46
		183-365 days	28-48
PT	sec	1 days (30-36 wk of gestation)	10.6-16.2
		5 days (30-36 wk of gestation)	10.0-15.3
		30 days (30-36 wk of gestation)	10.0-13.6
		90 days (30-36 wk of gestation)	10.0-14.6
		180 days (30-36 wk of gestation)	10.0-15.0
	sec	1 day	11.6-14.4
		5 day	10.9-13.9
		30 day	10.6-13.1
		90 day	10.8-13.1
		180 day	11.5-13.1
PTT	sec	1 days (30-36 wk of gestation)	27.5-79.4
		5 days (30-36 wk of gestation)	26.9-74.1
		30 days (30-36 wk of gestation)	26.9-62.5
		90 days (30-36 wk of gestation)	28.3-50.7
		180 days (30-36 wk of gestation)	21.7-53.3
	sec	1 day	37.1-48.7
		5 day	34.0-51.2
		30 day	33.0-47.8
		90 day	30.6-43.6
		180 days	31.8-39.2
Ammonia	μmol/L	1-90 days	42-144
		3-11 mo	34-133
AST	U/L	0-5 days	35-140
		1-3 yr	20-60
ALT	U/L	0-5 days	6-50
		1-30 days	1-25
		31-365 days	3-35
ALP	U/L	0-5 days	110-300
		1-30 days	48-406
		31-365 days	82-383
γGT	U/L	0-5 days	34-263
		1-182 days	12-132
		183-365 days	1-39

For full-term infants unless otherwise noted.
ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; γ GT, γ-glutamyltransferase; PT, prothrombin time; PTT, partial thromboplastin time.
Adapted from Rosenthal P: Assessing liver function and hyperbilirubinemia in the newborn, National Academy of Clinical Biochemistry, *Clin Chem* 43:228, 1997.

TABLE B–12 Plasma Albumin and Total Protein in Preterm Infants from Birth to 8 Weeks

Gestation (wk)	26	27	28	29	30	31	32	33	34	35	36	37	38	39	40	41	42
Albumin (g/dL)																	
Reference range (95% confidence limits)	—	1.18–3.06	1.09–2.87	1.20–2.74	1.21–2.75	1.63–2.75	1.08–3.20	1.38–3.14	1.44–3.34	0.53–3.87	1.15–3.87	1.96–3.44	1.50–4.10	1.89–4.15	2.07–4.05	2.04–3.90	2.08–3.90
Corrected Age																	
26-28 wk		2.13	2.10	2.58	2.29	2.39				2.73

TABLE B–13 Cardiac Troponin T (cTnT) and Cardiac Troponin I (cTnI) Levels in 869 Healthy Term Newborns with Respect to Gender*

	cTnT (μg/L)		cTnI (μg/L)	
	Male	*Female*	*Male*	*Female*
Mean	0.017	0.012	0.011	0.007
Median	0.01	0	0	0
Minimum	0	0	0	0
Maximum	1.26	0.58	0.71	0.98
99th percentile†	0.093	0.101	0.206	0.094

*Cardiac troponin T measured with Roche Elecsys® 2010 3rd generation assay; cardiac troponin I measured on a DadeBehering Dimension RxL assay.

†Diagnostic cutoff value for adults with possible myocardial damage is at 99th percentile of apparently healthy reference population; the same cutoff has been proposed for neonates.

Modified from Baum H et al: Reference values for cardiac troponins T and I in healthy neonates, *Clin Biochem* 37:1080, 2004.

Hormone Levels

TABLE B–14 Serum Growth Hormone (GH) Levels in Control Infants and Infants with Intrauterine Growth Restriction (IUGR)

	GH (ng/mL) (Mean ± SD)		
	Cord Blood	*3 days*	*1 month*
Term	19 ± 9	29 ± 17	10 ± 8
Preterm	28 ± 16		
Term IUGR	46 ± 44	39 ± 31	12 ± 8
Preterm IUGR	55 ± 49	53 ± 34	20 ± 14

From Leger J et al: Growth factors and intrauterine growth retardation. II. Serum growth hormone, insulin-like growth factor, (IGF) I, and IGF-binding protein 3 levels in children with intrauterine growth retardation compared with normal control subjects: prospective study from birth to two years of age. Study Group of IUGR, *Pediatr Res* 40:101, 1996.

TABLE B–15 Range of Serum Testosterone Levels in Newborn Male and Female Infants

	SERUM TESTOSTERONE (ng/mL)		
	Cord Blood	*0-48 hr*	*48 hr to 1 wk*
Male	0.25-0.6	1-5	<1
Female	0.2-0.5	0.05-0.8	<0.25

From Forest MG et al: Pattern of plasma testosterone and delta 4-androstenedione in normal newborns: evidence for testicular activity at birth, *J Clin Endocrinol Metab* 41:977, 1975.

TABLE B–16 Pooled Luteinizing Hormone (LH) and Follicle-Stimulating Hormone (FSH) Values from Male and Female Newborns[*]

Age (days)	No. of Patients	LH	FSH
Male			
1-5	30	0.39 ± 0.48, median 0.20	0.96 ± 0.60, median 0.85
6-10	15	2.31 ± 2.29, median 1.50	2.91 ± 4.38, median 1.40
11-15	17	3.55 ± 2.84, median 2.90	3.71 ± 2.69, median 3.00
16-20	14	4.13 ± 2.76, median 3.65	2.63 ± 1.45, median 2.15
21-25	7	2.86 ± 1.51, median 2.70	2.50 ± 1.51, median 2.10
26-28	8	2.22 ± 2.37, median 1.40	2.25 ± 0.81, median 2.40
Female			
1-5	31	0.48 ± 0.66, median 0.20	2.00 ± 1.37, median 1.80
6-10	17	0.45 ± 0.33, median 0.30	2.44 ± 2.52, median 1.40
11-15	8	1.58 ± 1.28, median 1.60	8.16 ± 4.27, median 8.95
16-20	6	1.03 ± 1.39, median 0.35	1.62 ± 1.05, median 1.90
21-25	3	0.46 ± 0.25, median 0.50	7.07 ± 5.92, median 3.90
26-28	8	2.75 ± 2.39, median 2.80	9.74 ± 9.89, median 6.15

[*] All values are mIU/mL, mean ± standard deviation unless otherwise indicated.

From Schmidt H, Schwarz HP: Serum concentration of LH and FSH in the healthy newborn, *Eur J Endocrinol* 143:214, 2000.

TABLE B–17 Reference Ranges of Sex Steroids in Infants[*]

		FEMALE			MALE		
Steroid	*Age*[†]	*2.5th*	*50th*	*97.5th*	*2.5th*	*50th*	*97.5th*
Estradiol (pmol/L)	1-7 days	25	81	116	<20	55	229
	8-15 days	42	88	134	31	66	126
	16 days-3 yr	21	48	113	<20	37	65
Prolactin (mIU/L)	1-7 days	475	4102	8003	1028	3445	8658
	8-15 days	919	3074	7018	854	2650	5889
	16 days-3 yr	126	319	1343	208	477	1559
Progesterone (nmol/L)	1-7 days	0.8	2.2	9.6	1	3.2	12.5
	8-15 days	1	2.8	4.7	1	2.8	8.2
	16 days-3 yr	0.3	0.9	3.2	0.3	1.2	3.6
SHBG (nmol/L)	1-7 days	7.4	22.8	34.8	8.8	24.1	50.7
	8-15 days	10.1	22.8	51.2	13.7	27.4	68.7
	16 days-3 yr	12.9	34.9	96.6	19.8	55.4	114.4
DHEAS (μmol/L)	1-7 days	1.87	4.29	12.8	2.32	4.42	11.47
	8-15 days	0.91	3.11	9.49	0.82	2.15	4.77
	16 days-3 yr	<0.2	0.47	3.33	<0.2	3.3	2.69

[*] Reference range is between 2.5th and 97.5th percentiles.

[†] For infants 1-7 days, 28 were male, and 17 were female; for infants 8-15 days, 20 were male, 20 were female; for infants 16 days-3 year, 42 were male, 44 were female.

DHEAS, dehydroepiandrosterone sulfate; SHBG, sex hormone–binding globulin.

Adapted from Elmlinger MW et al: Reference ranges for serum concentrations of lutropin (LH), follitropin (FSH), estradiol (E2), prolactin, progesterone, sex-hormone binding globulin (SHBG), dehydroepiandrosterone sulfate (DHEAS), cortisol and ferritin in neonates, children and young adults, *Clin Chem Lab Med* 40:1154, 2002.

TABLE B–18 Reference Ranges for Serum Cortisol in Well Preterm Infants*

Gestational Age (wk)	Cortisol (nmol/L†)
24	110-744
25	100-671
26	90-605
27	81-545
28	73-491
29	66-443

*n = 37, 31 were exposed in prenatal steroids.

†See Table B-31 for conversion to μg/dL.

From Heckmann M et al: Reference range for serum cortisol in well preterm infants, *Arch Dis Child Fetal Neonatal Ed* 81:F172, 1999.

TABLE B–19 Cortisol Concentration Quartiles in Infants with Extremely Low Birthweight (<1000 g)

		CORTISOL CONCENTRATION (μg/dL)		
Age	n	*Lower Quartile*	*Median*	*Upper Quartile*
12-48 hr	332	8.9	16	31
5-7 days	153	8.7	13.1	18.1

Adapted from Aucott SW et al: Do cortisol concentrations predict short-term outcomes in extremely low birth weight infants? *Pediatrics* 122:777, 2008.

TABLE B–20 Plasma 17-Hydroxyprogesterone (17-OHP) in Healthy and Ill Term and Preterm Infants*

	Healthy Term	Ill Term	Healthy Preterm	Ill Preterm
Plasma 17-OHP (nmol/L)	4.4 ± 2.6	10.6 ± 7.5	13.6 ± 11.4	24.39 ± 27.5

*All values are mean ± standard deviation.

From Murphy JF et al: Plasma 17-hydroxyprogesterone concentrations in ill newborn infants, *Arch Dis Child* 58:533, 1983.

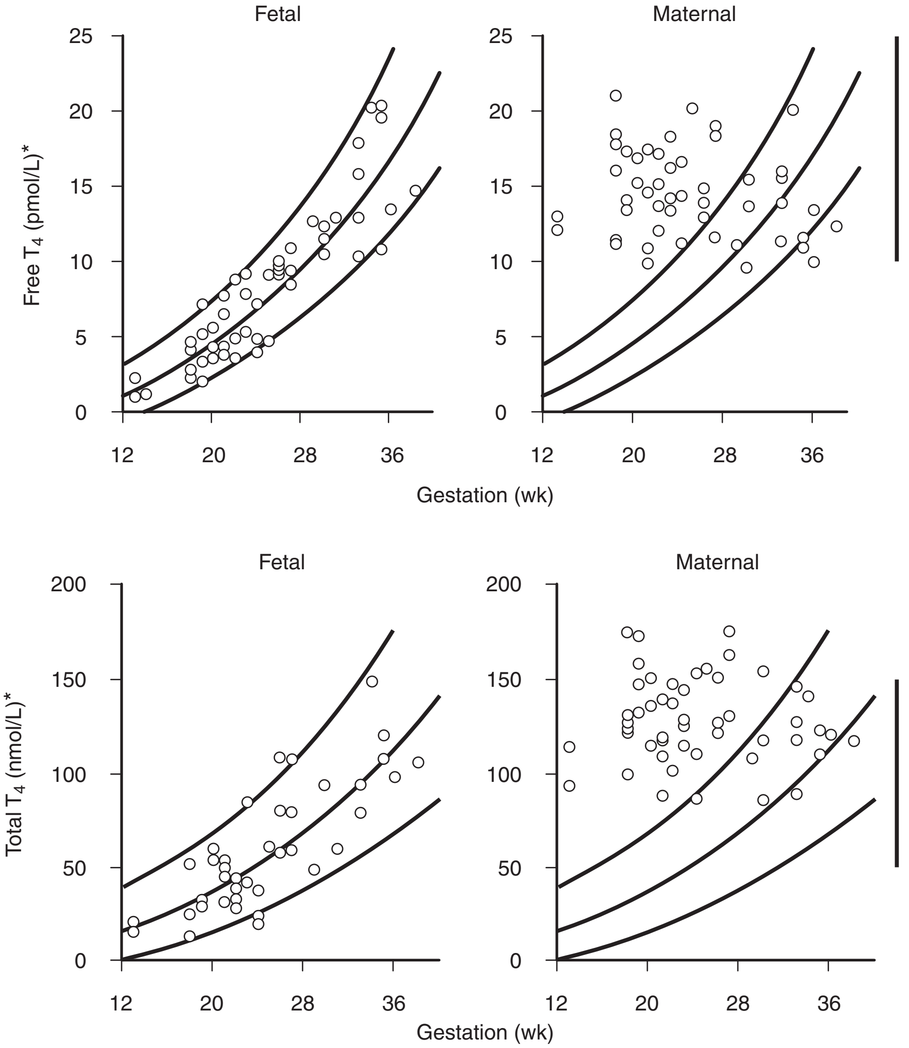

Figure B–6. Scatterplots showing individual fetal and maternal serum free and total thyroxine (T_4) concentrations during gestation. *Curved lines* represent the mean and the 5th and 95th percentile values. *Vertical lines* on the right indicate normal ranges in nonpregnant adults*. See Table B-31 for conversion from pmol/L to ng/dL and from nmol/L to µg/dL. *(From Thorpe-Beeston JG et al: Maturation of the secretion of thyroid hormone and thyroid-stimulating hormone in the fetus,* N Engl J Med *324:534, 1991.)*

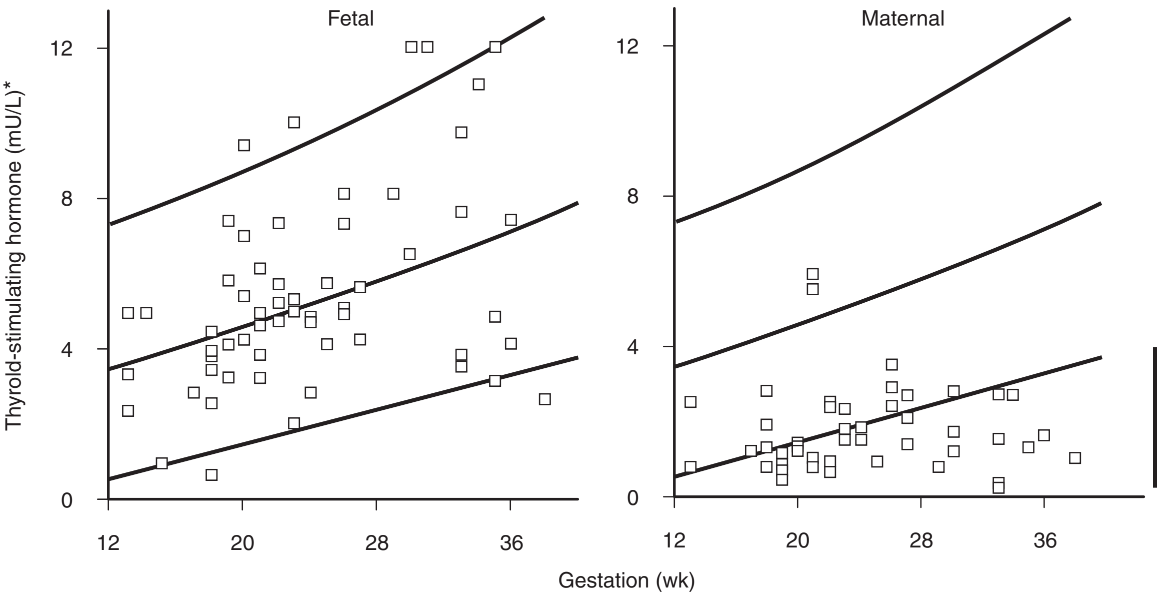

Figure B–7. Scatterplots showing individual fetal and maternal serum thyroid-stimulating hormone concentrations during gestation. *Sloping lines* are the mean and 5th and 95th percentile values. *Vertical line* on the right is the normal range in nonpregnant adults*. See Table B-31 for conversion of mU/L to μU/mL. (*From Thorpe-Beeston JG et al: Maturation of the secretion of thyroid hormone and thyroid-stimulating hormone in the fetus,* N Engl J Med *324:533, 1991.)*

TABLE B–21 Reference Intervals for Thyroid Hormones*

	Age[†]	2.5th	50th	97.5th
T_4 (nmol/L)	1-7 days	114.5	207.9	399
	8-15 days	178.5	319.2	534.1
	1 mo-3 yr	75.4	126.8	155.5
Free T_4 (nmol/L)	1-7 days	29.6	62.4	79.2
	8-15 days	18	42.3	63.6
	1 mo-3 yr	11.1	19.7	27.3
T_3 (nmol/L)	1-7 days	2.7	6	8
	8-15 days	2.4	4.7	5.1
	1 mo-3 yr	1.9	3	3.4
Free T_3 (nmol/L)	1-7 days	2.76	6.91	11.67
	8-15 days	2.84	5.53	11.86
	1 mo-3 yr	3.28	6.08	11.06
TSH (μIU/mL)	1-7 days	1.79	4.63	9.69
	8-15 days	1.8	3.71	7.97
	1 mo-3 yr	0.63	2.04	4.12
TBG (nmol/L)	1-7 days	116.6	196.1	399.6
	8-15 days	220	320.8	442.9
	1 mo-3 yr	235.1	450.5	571.7

*Reference range is range between the 2.5th and 97.5th percentiles.

[†] Sample included 45 infants aged 1-7 days, 40 aged 8 to 15 days, and 86 aged 1 month to 3 years.

TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone.

Adapted from Elmlinger MW et al: Reference intervals from birth to adulthood for serum thyroxine (T_4), triiodothyronine (T_3), free T_3, free T_4 thyroxine binding globulin (TBG), and thyrotropin (TSH), *Clin Chem Lab Med* 39:976, 2001.

Cerebrospinal Fluid

TABLE B–22 Cerebrospinal Fluid Values in Infants with Birthweight of ≤1000 Grams

	POSTNATAL AGE (DAYS)					
	0-7		8-28		29-84	
	Mean ± SD	*Range*	*Mean ± SD*	*Range*	*Mean ± SD*	*Range*
Birthweight (g)	822 ± 116	630-980	752 ± 112	550-970	750 ± 120	550-907
Gestational age at birth (wk)	26 ± 1.2	24-27	26 ± 1.5	24-28	26 ± 1.0	24-27

All		108	7.3 ± 13.9	6.6-8	4	0-130	11	64.2 ± 24.2	51.2 ± 12.9

*All neonates represented were suspected of having an infection, and no central nervous system infection was found.
Modified from Ahmed A et al: Cerebrospinal fluid values in the term neonate, *Pediatr Infect Dis J* 15:301, 1996.

Immunoglobulin Values

TABLE B–25 Plasma Immunoglobulin (Ig) Concentrations in Premature Infants at 25 to 28 Weeks' Gestation

Age (mo)	No. of Patients	IgG* (mg/dL)	IgM* (mg/dL)	IgA* (mg/dL)
0.25	18	251 (114-552)†	7.6 (1.3-43.3)	1.2 (0.07-20.8)
0.5	14	202 (91-446)	14.1 (3.5-56.1)	3.1 (0.09-10.7)
1.0	10	158 (57-437)	12.7 (3.0-53.3)	4.5 (0.65-30.9)
1.5	14	134 (59-307)	16.2 (4.4-59.2)	4.3 (0.9-20.9)
2.0	12	89 (58-136)	16 (5.3-48.9)	4.1 (1.5-11.1)
3	13	60 (23-156)	13.8 (5.3-36.1)	3 (0.6-15.6)
4	10	82 (32-210)	22.2 (11.2-43.9)	6.8 (1-47.8)
6	11	159 (56-455)	41.3 (8.3-205)	9.7 (3-31.2)
8-10	6	273 (94-794)	41.8 (31.1-56.1)	9.5 (0.9-98.6)

*Geometric mean.

†The normal ranges in parentheses were determined by taking the antilog of the mean logarithm ± 2 standard deviations of the logarithms.

From Ballow M et al: Development of the immune system in very low birth weight (less than 1500 g) premature infants: concentrations of plasma immunoglobulins and patterns of infections, *Pediatr Res* 20:899, 1986.

TABLE B–26 Plasma Immunoglobulin (Ig) Concentrations in Premature Infants 29 to 32 Weeks' Gestation

Age (mo)	IgG* (mg/dL)	IgM* (mg/dL)	IgA* (mg/dL)
0.25	368 (186-728)†	9.1 (2.1-39.4)	0.6 (0.04-1)
0.5	275 (119-637)	13.9 (4.7-41)	0.9 (0.01-7.5)
1	209 (97-452)	14.4 (6.3-33)	1.9 (0.3-12)
1.5	156 (69-352)	15.4 (5.5-43.2)	2.2 (0.7-6.5)
2	123 (64-237)	15.2 (4.9-46.7)	3 (1.1-8.3)
3	104 (41-268)	16.3 (7.1-37.2)	3.6 (0.8-15.4)
4	128 (39-425)	26.5 (7.7-91.2)	9.8 (2.5-39.3)
6	179 (51-634)	29.3 (10.5-81.5)	12.3 (2.7-57.1)
8-10	280 (140-561)	34.7 (17-70.8)	20.9 (8.3-53)

*Geometric mean.

†The normal ranges in parentheses were determined by taking the antilog of the mean logarithm ± 2 standard deviations of the logarithms.

From Ballow M et al: Development of the immune system in very low birth weight (less than 1500 g) premature infants: concentrations of plasma immunoglobulins and patterns of infections, *Pediatr Res* 20:899, 1986.

HEMATOLOGIC VALUES

TABLE B–27 Red Blood Cell Parameters of Infants with Very Low Birthweight During the First 6 Weeks of Life Derived from Arterial or Venous but Not Capillary Blood Samples

	PERCENTILES										
	Day of Life	*No. of Patients*	*3*	*5*	*10*	*25*	*Median*	*75*	*90*	*95*	*97*
Hemoglobin (g/dL)	3*	559	11.0	11.6	12.5	14.0	15.6	17.1	18.5	19.3	19.8

Serum iron (μmol/L)	3	181	0.8	1.0	1.6	3.5	7.5	13.8	18.6	22.4	26.7
Transferrin saturation (%)	3	179	2.6	2.7	4.2	9.6	22.7	39.4	54.9	62.1	79.8

*On day 3, all infants are included regardless of antenatal steroids and transfusions up to that time. Thereafter, infants who did not receive erythropoietin were studied regardless of the use of antibiotics and steroids.

From Obladen M et al: Venous and arterial hematologic profiles of very low birth weight infants. European Multicenter rhEPO Study Group, *Pediatrics* 106:710, 2000.

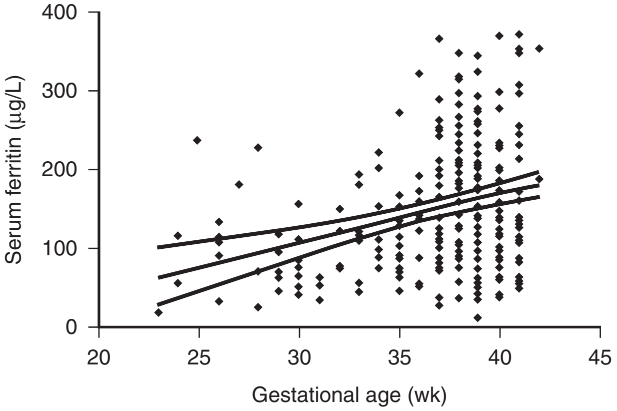

Figure B–8. Ferritin concentrations as a function of gestational age. Regression line and its 5th and 95th percentile confidence limits for the mean regression are shown. *(From Siddappa AM et al: The assessment of newborn iron stores at birth: a review of the literature and standards for ferritin concentrations,* Neonatology *92:77, 2007.)*

TABLE B–29 Reference Values For Nucleated Red Blood Cell (NRBC) Count from Umbilical Vein Sampling at Birth in 695 Newborns Divided into Four Groups According to Gestational Age

	No. of Patients	Birthweight (g) Mean ± SD 25th-75th Percentiles	Gestational Age (wk) Mean ± SD 25th-75th Percentiles	NRBC* Mean ± SD Median 25th-75th Percentiles
Group 1	120	954 ± 234 780-1105	26.7 ± 1 26-28	5643 ± 7228 2601 1147-7790
Group 2	128	1413 ± 398 1100-1720	30.4 ± 1 29-31	3328 ± 3577 1901 492-5970
Group 3	215	2189 ± 473 1940-2520	34.7 ± 1 34-36	1099 ± 1275 696 0-1672
Group 4	232	3201 ± 669 2905-3590	38.6 ± 1 38-40	442 ± 807 0 0-638

*Absolute count (NRBC/mm^3).

Adapted from Perrone S et al: Nucleated red blood cell count in term and preterm newborns: reference values at birth, *Arch Dis Child* 90:F174, 2005.

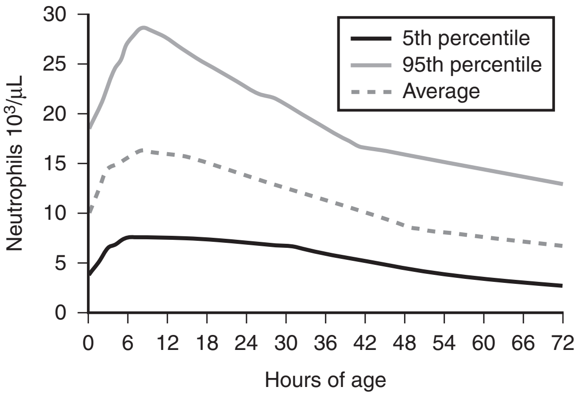

Figure B–9. Neutrophils per microliter of blood during the first 72 hours after the birth of term and near-term (>36 weeks' gestation) neonates. A total of 12,149 values were obtained for the analysis. The 5th percentile, the mean, and the 95th percentile values are shown. *(From Schmutz N et al: Expected ranges for blood neutrophil concentrations of neonates: the Manroe and Mouzinho charts revisited,* J Perinatol *28:275, 2008.)*

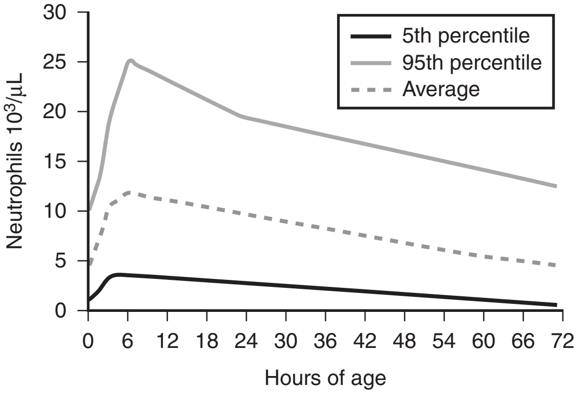

Figure B–10. Neutrophils per microliter of blood during the first 72 hours after the birth of 28- to 36-week gestation preterm neonates. A total of 8896 values were obtained for the analysis. The 5th percentile, the mean, and the 95th percentile values are shown. *(From Schmutz N et al: Expected ranges for blood neutrophil concentrations of neonates: the Manroe and Mouzinho charts revisited,* J Perinatol *28:275, 2008.)*

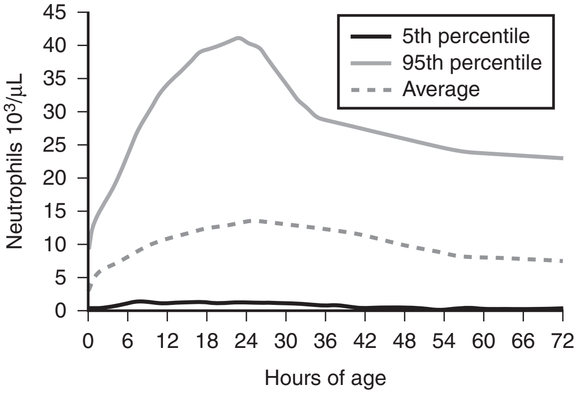

Figure B–11. Neutrophils per microliter of blood during the first 72 hours after the birth of <28-week gestation preterm neonates. A total of 852 values were obtained for the analysis. The 5th percentile, the mean, and the 95th percentile values are shown. *(From Schmutz N et al: Expected ranges for blood neutrophil concentrations of neonates: the Manroe and Mouzinho charts revisited,* J Perinatol *28:275, 2008.)*

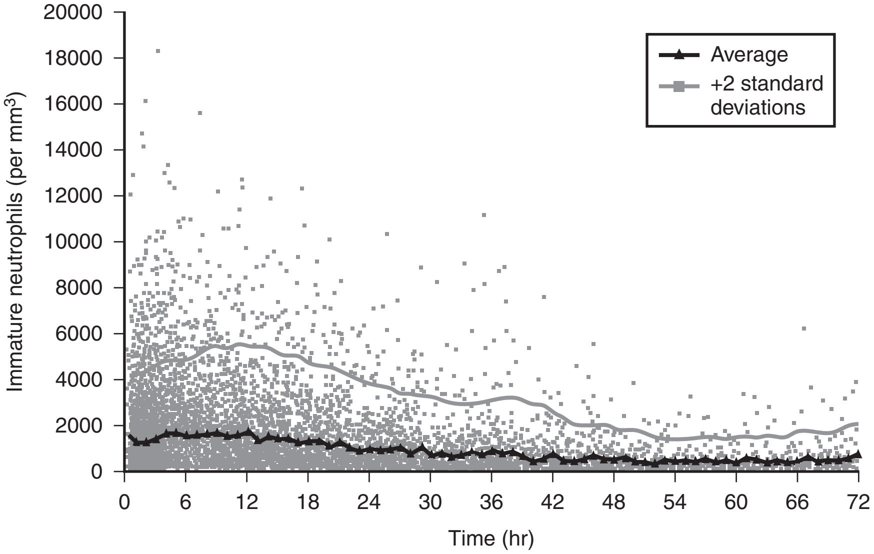

Figure B–12. Immature neutrophils (band neutrophils plus metamyelocytes) per microliter of blood during the first 72 hours after the birth of term and near-term (>36 weeks' gestation) neonates. A total of 12,857 values were obtained for the analysis. The average and 2 standard deviations above the mean value are shown. *(From Schmutz N et al: Expected ranges for blood neutrophil concentrations of neonates: the Manroe and Mouzinho charts revisited,* J Perinatol *28:275, 2008.)*

TABLE B–30 Neutrophil Values in Healthy Term Neonates at 4 Hours of Age

	Mean	±SD	Range, 10%-90%
I/T ratio	0.16	0.10	0.05-0.27
I/M ratio	0.21	0.25	0.06-0.35
ANC (/mm^3)	15,622	4685	9500-21,500
Immature	2484	1777	700-4300
Total leukocytes	24,060	6110	16,200-31,500

ANC, absolute neutrophil count; I/T, immature to total neutrophils; I/M, immature to mature neutrophils.

Modified from Schelonka RL et al: Peripheral leukocyte count and leukocyte indexes in healthy newborn term infants, *J Pediatr* 125:604, 1994.

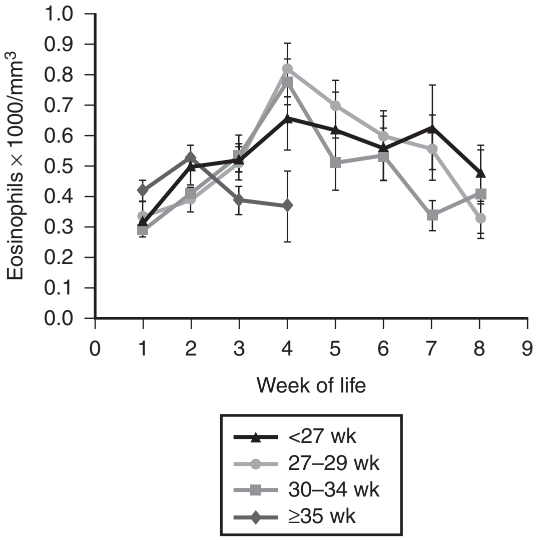

Figure B–13. Mean eosinophil counts (± standard error of the mean) plotted against postnatal age (weeks) for infants born at different gestational ages. *(From Juul SE et al: Evaluation of eosinophilia in hospitalized preterm infants,* J Perinatol *25:185, 2005.)*

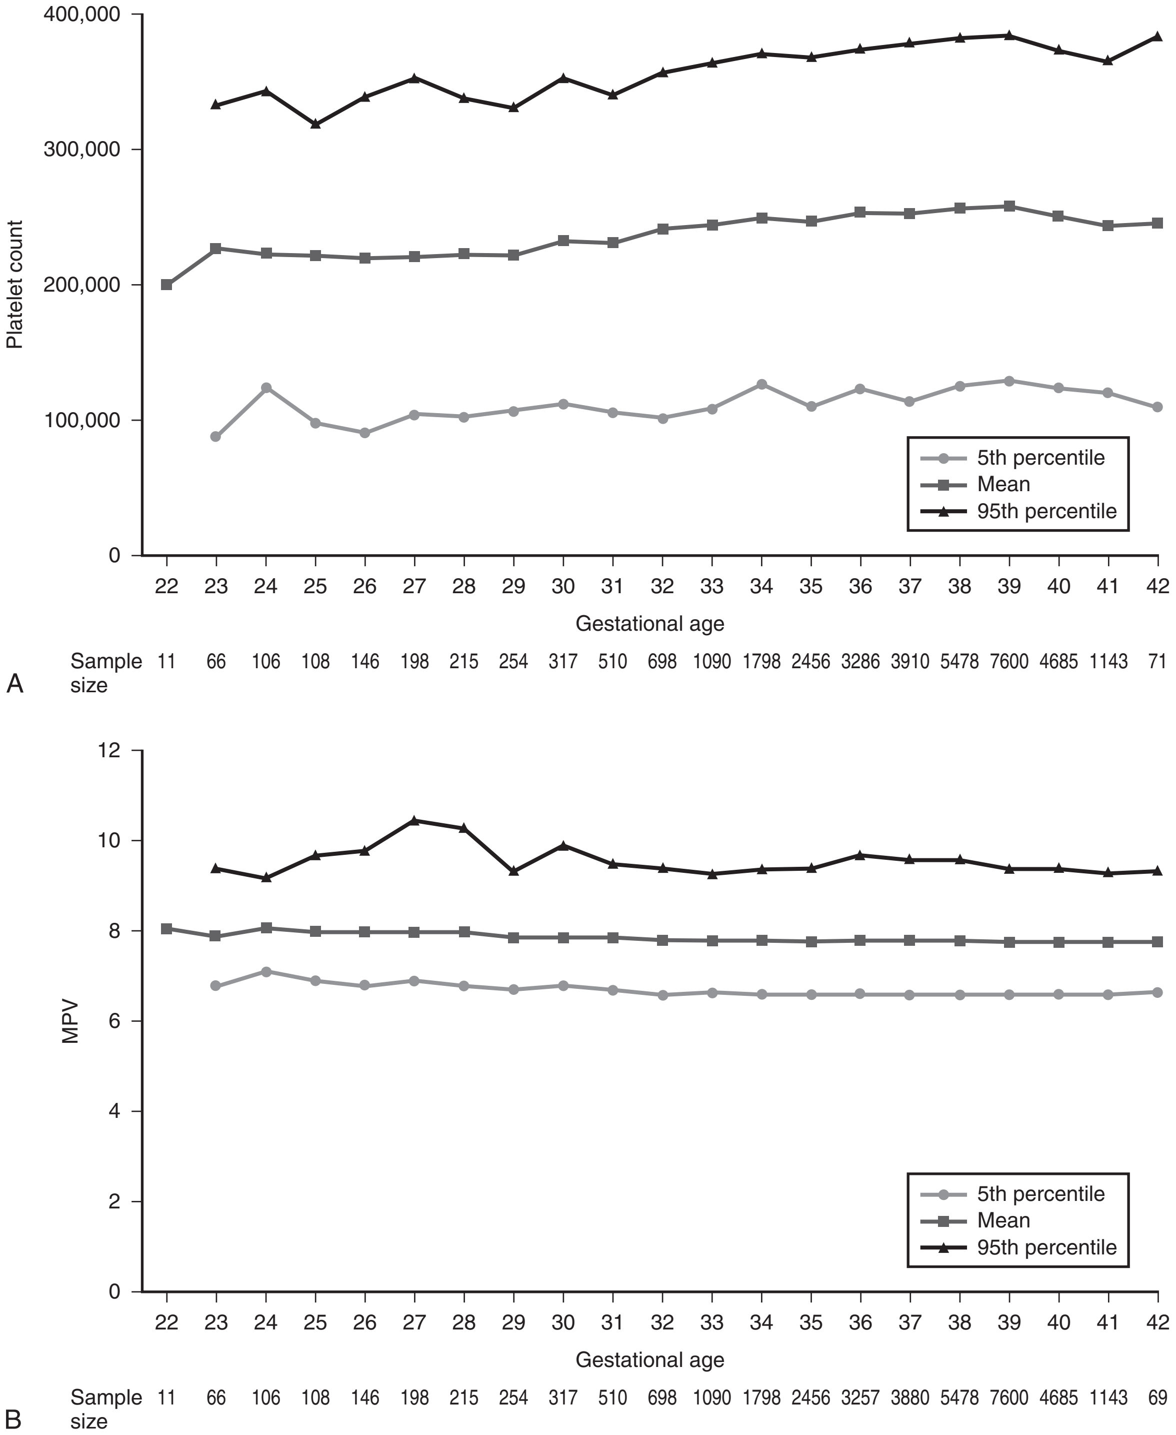

Figure B–14. First platelet counts (**A**) and concurrent mean platelet volume determinations (**B**) for neonates of 22 to 42 weeks' gestation. Samples obtained in the first 3 days after birth. *(From Wiedemeier SE et al: Platelet reference ranges for neonates, Platelet reference ranges for neonates, defined using data from over 47,000 patients in a multihospital healthcare system,* J Perinatol *29:132, 2009.)*

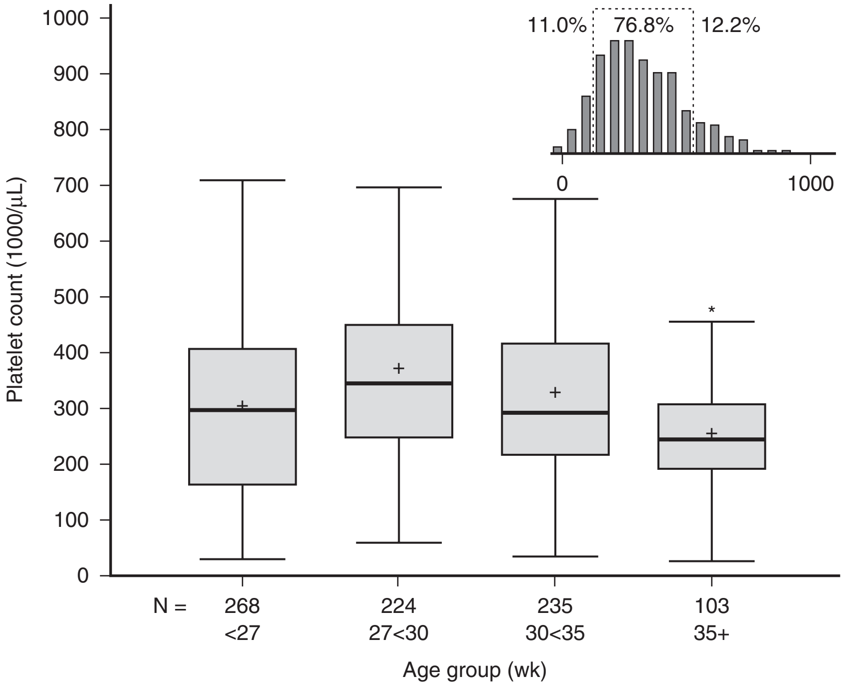

Figure B–15. Box and whisker plot showing distribution of platelet counts from 237 noninfected, non–pregnancy-induced hypertension-exposed infants in a neonatal intensive care unit separated by gestational age at birth. Box plots show mean (± standard error of the mean), median (center line), 25th and 75th percentile quartiles (box ends), and range of values (whiskers). *Inset* shows frequency distribution histogram of 830 platelet counts in increments of 50. *Dotted box* shows 76.8% were normal (>150,000 and <500,000). *(From McPherson RJ, Juul SE: Patterns of thrombocytosis and thrombocytopenia in hospitalized neonates,* J Perinatol *25:167, 2005.)*

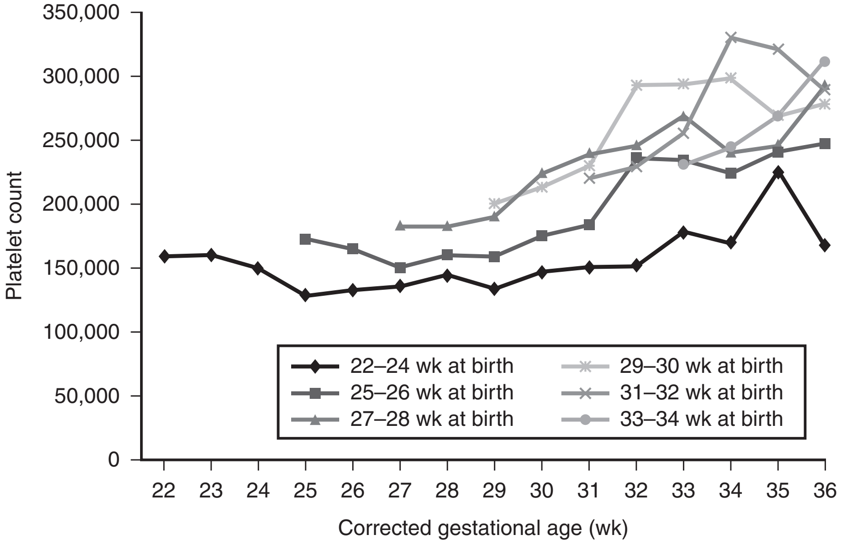

Figure B–16. Effect of postnatal age on mean platelet counts of premature infants. Mean platelet counts are plotted according to gestational age at birth. *(From Wiedmeier SE, Henry E, Sola-Visner MC, Christensen RD: Platelet reference ranges for neonates, defined using data from over 47,000 patients in a multihospital healthcare system,* J Perinatol *29(2):130, 2009). Epub 2008 Sep 25.*

Modified from Young DS: Implementation of SI units for clinical laboratory data: style specifications and conversion tables, *Ann Intern Med* 106:114, 1987 (erratum: published in *Ann Intern Med* 114:172, 1991).

Metric Units

TABLE B–32 Conversion Tables for Metric Units

A. Metric System Weights

1 kilogram (kg)	=	1000 grams (g)
1 milligram (mg)	=	0.001 gram (g)
1 microgram (μg)	=	10^{-6} g or μ
1 nanogram (ng)	=	10^{-9} g or mμ
1 picogram (pg)	=	10^{-12} g or μμ
1 femtogram (fg)	=	10^{-15} g or mμμ

B. Metric and Avoirdupois Systems of Volume (Fluid)

1 liter (L)	=	1000 milliliters (mL)
1 milliliter (mL)	=	1000 microliters (μL)
1 deciliter (dL)	=	100 mL

C. Standard Prefixes

Less than 1			More than 1		
atto	10^{-18}	a	deka	10^{1}	da
femto	10^{-15}	f	hector	10^{2}	h
pico	10^{-12}	p	kilo	10^{3}	k
nano	10^{-9}	n	mega	10^{6}	M
micro	10^{-6}	μ	giga	10^{9}	G
milli	10^{-3}	m			
centi	10^{-2}	c			
deci	10^{-1}	d			

D. Conversion Factors

1 kg	=	2.2046 pounds (usually rounded to 2.2)
1 pound	=	0.4536 kilogram
1 ounce	=	28.35 g (usually rounded to 30)
1 L	=	1.06 quarts
1 fluid ounce	=	29.57 mL (usually rounded to 30)
1 inch	=	2.54 cm
1 cm	=	0.394 inch
Degrees Celsius	=	(ºF − 32) × $^{5}/_{9}$
Degrees Fahrenheit	=	(ºC × $^{9}/_{5}$) + 32

Parts per million (ppm) to percent:

1 ppm	=	0.0001%
10 ppm	=	0.001%
100 ppm	=	0.01%
1000 ppm	=	0.1%

Atomic Weight and Valence

TABLE B–33 Atomic Weight and Valence for Common Elements

Element	Atomic Weight	Valence
Calcium	40	2
Sodium	23	1
Potassium	39	1
Chlorine	35.5	1
Magnesium	24.3	2
Phosphorus	31	*

Conversion of Common Elements from Milligrams (mg) to Milliequivalents (mEq)

To convert mg to mEq:

$$\frac{\text{mg} \times \text{valence}}{\text{atomic weight}} = \text{mEq}$$

To convert mEq to mg:

$$\frac{\text{mEq} \times \text{atomic weight}}{\text{valence}} = \text{mg}$$

*The valence of phosphorus varies. For nutritional purposes, it is convenient to express quantities in moles.

APPENDIX C

Schedule for Immunization of Preterm Infants

Jill E. Baley

ALL PRETERM INFANTS

- Vaccine doses should not be reduced for preterm infants.
- Use thimerosal-free vaccines.
- Intramuscular injections to preterm infants might require a shorter needle than the standard $^5/_8$- to 1-inch needle.
- Immunizations may be given during corticosteroid administration.
- Palivizumab (Synagis) should be given according to the respiratory syncytial virus (RSV) policy.
- Preterm infants should receive a full dose of diphtheria and tetanus toxoids and acellular pertussis (DTaP), *Haemophilus influenzae* type B (Hib) conjugate, inactivated poliovirus (IPV), and pneumococcal conjugate (PC7) at 60 days' chronologic age, regardless of birthweight and gestational age, as long as they are medically stable and consistently gaining weight.
- The 13-valent pneumococcal conjugate vaccine (PCV 13) should be substituted for PCV 7 when it becomes available.
- Immunizations for preterm infants may be given over 2 or 3 days to minimize the number of injections at a single time.
- Hospitalized infants with birthweight lower than 1000 g should be observed for apnea for 72 hours after the primary series of immunizations.
- Breast feeding by a mother who is positive for hepatitis B surface antigen (HBsAg) poses no additional risk for acquisition of hepatitis B virus (HBV) infection by the infant.
- Infants with chronic respiratory tract disease should receive the influenza immunization annually, before or during the influenza season, once they are 6 months postnatal age or older:
  - The infant should receive two doses of vaccine, 1 month apart.
  - Family and other caregivers should also receive influenza vaccine annually in the fall to protect the infant from exposure.
- The American Academy of Pediatrics recommends routine immunization of infants in the United States with rotavirus vaccine. There is no preference for either the live oral human-bovine reassortant vaccine (RV5) or the liver oral, human attenuated rotavirus vaccine (RVI).
  - Preterm infants who are clinically stable should be immunized on the same schedule and with the same precautions as term infants. The infant's postnatal age must be between 6 weeks and 14 weeks, 6 days postnatal age.
  - Preterm infants who are in the NICU or nursery may be immunized at the time of discharge if they are clinically stable and age-eligible for the vaccine. The AAP believes that the risk of shedding vaccine virus in the stool, and theoretically transmitting vaccine virus to another acutely ill or non–age-eligible infant outweighs the benefit of immunizing eligible infants who remain in the NICU or nursery.
  - Any rotavirus vaccine-immunized infant who requires readmission to the NICU or nursery within 2 weeks of vaccination should remain under contact precautions for 2 to 3 weeks after vaccine administration.

PRETERM INFANTS WITH BIRTHWEIGHT OF 2000 GRAMS OR MORE

- If mother is HBsAg positive:
  - Administer hepatitis B vaccine and hepatitis B immune globulin (HBIG) within 12 hours of birth.
  - Immunize with three doses at 0, 1, and 6 months' chronologic age.
  - Check antibody to hepatitis B surface antigen (anti-HBs) and HBsAg at 9 to 15 months of age.
  - If infant is anti-HBs and HBsAg negative, reimmunize with three doses at 2-month intervals and retest.
- If mother is HBsAg unknown:
  - Administer HBV by 12 hours of age.

  - If the mother tests positive, give HBIG within 7 days of birth and proceed as for HBsAg-positive mother.
- If mother is HBsAg negative:
  - Administering HBV vaccine at birth is preferable to waiting for the first pediatric visit.
  - Immunize with three doses at 0 to 2, 1 to 4, and 6 to 18 months of chronologic age.
  - Follow-up anti-HBs and HBsAg titers are not needed.

PRETERM INFANTS WITH BIRTHWEIGHTS LESS THAN 2000 GRAMS

- If mother is HBsAg positive:
  - Administer HBV and HBIG within 12 hours of age.
  - Immunize with four vaccine doses at 0, 1, 2 to 3, and 6 to 7 months' chronologic age.
  - Check anti-HBs and HBsAg at 9 to 15 months of age.
  - If anti-HBs and HBsAg are negative, reimmunize with three doses of vaccine at 2-month intervals and retest titers.
- If mother is HBsAg unknown:
  - Administer both HBV and HBIG by 12 hours of age because HBV is less reliable as a single agent under these conditions.
  - Test the mother immediately.
- If mother is HBsAg negative:
  - Administer the first dose of HBV at 30 days' chronologic age regardless of gestational age, or at discharge if the infant is discharged before 30 days of age. The infant must be medically stable and consistently gaining weight before receiving the vaccine.
  - Immunize with three doses at 1 to 2, 2 to 4, and 6 to 18 months' chronologic age.
  - HBV-containing combination vaccine may be given after 6 to 8 weeks' chronologic age.
  - Follow-up titers are not needed.

Organic acid analysis, urinary, in inborn errors of metabolism, 1657, 1657b

Organic acidemia/aciduria, 1657b, 1661-1663
  dysmorphic syndromes in, 1651-1653
  hypoglycemia and, 1672
  management of, 1662-1663
  metabolic acidosis and, 1661-1663
  summary of, 1627-1634t
  tests for, 1657
Organic anion transport protein (OATP), in bilirubin transport, 1449
Organoaxial volvulus, 1412
Orlistat, for unconjugated hyperbilirubinemia, 1477-1478
Ornithine transcarbamylase deficiency, 1674-1675
Orofacial malformations and oromandibular-limb hypogenesis, terminal transverse defects with, 1757
Oropharynx
  lesions of, 1171-1173
  suctioning of, for meconium aspiration syndrome, 1159-1160
Orthopedics, 1771-1802
  bone and joint infections in, 1778-1781
  congenital abnormalities in, 1782-1799
  musculoskeletal disorders in, 1771-1777
Ortho-tyrosine, as oxidative stress marker, 469-470
Ortolani test, for developmental dysplasia of hip, 488, 1789, 1789f
Oscillatory ventilation, high-frequency, 1129-1130, 1129t
Oscillometry, for blood pressure monitoring, 581-582, 582f
Oseltamivir, for novel H1N1 influenza A, 875
Osmolality
  of amniotic fluid, 377
  of breast milk and breast milk fortifiers, 659t
  of infant formula, 661-662t
Osmolar gap
  fecal, 1382
  in sucrase-isomaltase deficiency, 1387
Osmoregulation, astroglia in, 902
Ossification, 1772
Osteoblasts, 1535-1536
Osteochondritis, in congenital syphilis, 822, 823f
Osteoclasts, 1535-1536
Osteogenesis imperfecta, 170, 171f, 1796-1797, 1796f
  anesthetic implications of, 604-606t
Osteomyelitis, 814-816, 1778-1780
  in cephalhematoma, 504
  clinical manifestations of, 815
  diagnosis of, 815-816, 815f, 1778-1779
  diagnostic imaging in, 705, 1779-1780, 1779f
  etiology of, 814, 1778
  incidence of, 814
  pathogenesis of, 815
  pathology of, 815, 1778
  prognosis in, 816
  risk factors for, 1778-1779
  treatment of, 816, 1780
Osteopenia of prematurity, 1538, 1550-1553
  biochemical features of, 1552
  clinical manifestations of, 1552
  diagnosis of, 1552
  enteral nutrition for, 1553
  etiology of, 1551, 1551f
  hormonal features of, 1552
  mechanical stimulation program for, 1553
  mineral supplementation monitoring in, 1553
  outcome of, 1553
  parenteral nutrition for, 1552-1553
  prevention of, 1552-1553
  radiologic features of, 1552
  treatment of, 1552-1553
Osteopetrosis, hypocalcemia and, 1542-1543
Osteoporosis, physiologic, of infancy, 1538
Ostomy, for Hirschsprung disease, 1424
Otitis media, 810-811
  with effusion, in hearing loss patients, 1053
Otoacoustic emissions, 1049
  testing of, 1050, 1051t
    in high-risk children, 1043
Otolaryngologist, referral to, 1053
Outcomes of care, in neonatal databases, 71, 83
Ovalocytosis, hereditary, unconjugated hyperbilirubinemia in, 1458
Ovary(ies)
  cyst of, aspiration of, 190t, 191t, 193-194
  differentiation of, 1586, 1587f, 1588t
    disorders of, 1607
    genetic control of, 1585
  torsion of, 157
Ovotesticular disorder of sex development, 1600-1601, 1601f
Ovum, environmental exposures affecting, 216, 217f, 217t
Oxacillin
  for sepsis, 803t
Oxazolidinediones, fetal effects of, 719-721t
Oxidative stress
  biomarkers of, 469-470
  pathophysiology of, 468-470, 469f
  in persistent pulmonary hypertension of the newborn, 1219
  room air versus pure oxygen therapy and, 470, 470f
  in white matter injury etiology, 923-924, 924f
Oximetry
  cerebral, clinical applications of, 590-591
  pulse. *See* Pulse oximetry.
  visible light spectroscopy, 591-592
Oxybutynin chloride, for neurogenic bladder, 519
Oxycephaly, 1026t
Oxycodone
  abuse of, 745
  in breast milk, 732
Oxygen
  alveolar, partial pressure of, 1094
  noninvasive measurements of, 1095-1096. *See also* Pulse oximetry.
  toxicity of
    in bronchopulmonary dysplasia, 1183, 1183f
    in neonatal asphyxia, 468-469
  transcutaneous monitoring of, 584
Oxygen consumption
  fetal, 249-252, 249t, 250f
  insensible water loss and, 564, 564t
  measurement of, 1234
  in small for gestational age, 270-271
Oxygen content
  arterial, 1094
  calculation of, 1234
Oxygen saturation
  arterial, measurement of. *See* Pulse oximetry.
  measurement of, 1234
  monitoring of
    bedside, 122-123
    fetal, 186
Oxygen tension, 1094-1095, 1094f
  during labor, 450-451, 451t
  in respiratory distress syndrome, 1112
  transcutaneous, monitoring of, 584
Oxygen therapy
  blended oxygen levels in, 472-473, 601
  for bronchopulmonary dysplasia, 1186
  in congenital heart disease, 1290
  neonatal anesthesia and, 600-601
  in neonatal resuscitation, 468-474
    free-flow, 457
    optimal strategy for, 472-473
    oxidative stress and, 468-470, 469f, 470f
  in preterm infant, history of, 10
  retinopathy of prematurity after, 1765
  room air versus pure oxygen in
    differences between, 470, 470f
    for neonatal resuscitation, 470-472, 471f
Oxygenation
  derangement in, estimation of, 1095
  determinants of, 1119-1120, 1119b, 1120f
  extracorporeal membrane. *See* Extracorporeal membrane oxygenation.
  mucosal, measurement of, 591-592
  postnatal rise in, 1095, 1095f
  tissue, regional monitoring of, 589-591
Oxygenation index, 1095
  extracorporeal membrane oxygenation and, 1198
Oxygenation ratio, 1095
Oxyhemoglobin dissociation curve, 1094, 1094f, 1304-1306, 1306f
Oxytocin
  breast feeding and, 620
  during EXIT procedure, 207
  for labor induction, 355
  in maternal-infant attachment, 618, 620
  in preterm labor, 306
Oxytocin antagonists, for preterm labor, 324-325
Oxytocin challenge test, 176-177, 353t
  in intrauterine growth restriction, 265

P

P14 deficiency, neutropenia in, 1330
P-450 oxidoreductase (POR) deficiency, 1614-1615, 1615f
Pacing
  for fetal arrhythmias, 194
  for tachycardia, 1286-1287b
Pain
  labor. *See* Labor pain.
  management of. *See* Analgesics; Anesthesia.
Palate
  cleft
    examination of, 490, 540f, 543
    isolated, 543
    prevalence of, 489t
  examination of, 487
Palliative care, in neonatal intensive care unit, 42-43
Palmar crease, single, 545, 546f
Palmar grasp reflex, 498-499
Palmitate, 1525
Palpebral fissures, short, in congenital anomalies, 539
Pamidronate, for hypercalcemia, 1548
Pancreas
  agenesis of, intrauterine growth restriction and, 250
  annular, 1417-1418
  development and physiology of, 1378-1379
  lesions of, diabetes from, 1520
Pancreatectomy, for hypoglycemia, 1517
Pancreatic ducts, development of, 1378-1379
Pancreatic enzyme replacement
  for cystic fibrosis, 1385
  for Shwachman-Diamond syndrome, 1385
Pancreatic insufficiency disorder, 1383-1386
  cystic fibrosis as, 1383-1385, 1384f
  Johanson-Blizzard syndrome as, 1385-1386
  miscellaneous causes of, 1386
  Shwachman-Diamond syndrome as, 1385, 1385t
Pancreatitis
  familial, as pancreatic insufficiency disorder, 1386
  in inborn errors of metabolism, 1644
Pancuronium
  in neonatal anesthesia, 610
  umbilical vein-to-maternal vein ratio of, 436t
Pancytopenia, differential diagnosis of, 1653t
Panniculitis, cold, 1731
Pantothenic acid
  in breast milk and breast milk fortifiers, 659t
  in enteral nutrition, 658t
  in infant formula, 661-662t
Papilla, Bergmeister, 1753
Papilloma, of choroid plexus, 1018
Papillomatosis, juvenile-onset recurrent respiratory, 880-881
Papillomavirus infection, 880-881
PAPP-A (pregnancy-associated plasma protein A), in first-trimester screen, 138-139, 139t
Papule, 1709t
Para-aminosalicylate, in breast milk, 730-731
Paracervical block, for labor pain, 435
Parainfluenza virus, 853-854
Paramyxoviruses, 853-859
Parasagittal region, watershed injury to, 954
Parasympathetic innervation, of stomach, 1377
Parathormone-releasing protein, in calcium regulation, 1524
Parathyroid hormone, 1531-1532
  abnormalities of. *See* Hyperparathyroidism; Hypoparathyroidism.
  in calcium regulation, 1524, 1524f
  effects of, 1531
  fetal, 1532
  neonatal, 1532
  in phosphorus regulation, 1528-1530

Parathyroid hormone *(Continued)*
  reference values for, 1532, 1533t
  secretion of, regulation of, 1531-1532
Parechovirus infections, 865-866
Parenchymal hemorrhage, germinal matrix hemorrhage–intraventricular hemorrhage accompanied by, 937-938, 938f, 940, 941f, 942
Parent(s)
  autonomy/authority of, 34
  behavior of. *See also* Parent-infant attachment.
    major influences on, 617, 617f
    programmed nature of, 616
  blood donation by, 1366
  communication with, 36-37, 36b
Parenteral nutrition, 644-651
  administration guidelines for, 664-665
  amino acids in
    administration of, 664
    composition of mixtures used for, 646-647, 646t
    doses of, 645
    early, evidence supporting, 644-646
    requirements for, 644-645, 644f
    safety of, 645
  carbohydrate requirements in, 647-648
  catheter complications in, 651
  complications of, 650-651
  electrolytes in, 650
  energy requirements in, 649-650
  glucose in, 648, 664
  lipid emulsions in, 648-649, 649t, 664
  liver disease associated with, 650-651
  minerals in, 650
  for osteopenia of prematurity, 1552-1553
  protein requirements in, 644, 644f
  total, hepatic injury from, conjugated hyperbilirubinemia and, 1489
  trace elements in, 650
  vitamins in, 650
Parent-infant attachment, 615-628
  acceptance of pregnancy in, 616
  in first days of life, 620
  in first hours after birth, 618-620, 618f, 619f
  formation of, 615-616, 617f
  labor and, 617-618
  to malformed infants, 625-626, 625f
    interventions for, 625-626
  perception of fetus in, 616-617
  before pregnancy, 616
  during pregnancy, 616-617
  to premature or sick infants, 622-625
    family-centered care and, 624-625
    individualized developmental care approach for, 622-625
    interventions for, 622-625
    kangaroo care and, 623-624
  sensitive period for, 620-622
Parietal cells, 1377
Paris-Trousseau syndrome, 1355
Parotitis, 819
Paroxetine, in breast milk, 731
Partial thromboplastin time, normal values for, 1820t
Parturition, theories of, 305-306, 307f
Parvovirus B19, anemia from, 1323
Parvovirus infection, 411-412, 872-873
  clinical features of, 411-412, 872-873
  diagnosis of, 873
  epidemiology of, 411
  fetal, 412, 873
  isolation of patients with, 873
Patau syndrome. *See* Trisomy 13.
Patch, 1709t
Patent ductus arteriosus, 1261-1263
  anatomy and pathophysiology of, 1261
  in aortic stenosis, 1254
  associated defects in, 1261-1262
  in bronchopulmonary dysplasia, 1184
  clinical presentation in, 1262
  fluid and electrolyte therapy for, 676
  gestational age and, 305t
  laboratory evaluation of, 1262, 1262f
  management of, 1262-1263
  after mechanical ventilation, 1138
  neonatal anesthesia and, 599-600
  in respiratory distress syndrome, 1113-1114
Patent ductus arteriosus *(Continued)*
  stents to maintain, 1298

Figure 40–10. The cerebral wall displays five laminar compartments of varying MRI signal intensity (**B**), which partly correspond to laminar compartments delineated on Nissl-stained (**A**) and histochemical (**C**) sections. Starting from the ventricular surface, these laminar compartments are as follows. The ventricular zone (germinal matrix) of high MRI signal intensity, which corresponds to the highly cellular ventricular zone in Nissl-stained sections and, therefore, is marked with number 1 (1 in **D**). The periventricular zone of low MRI signal intensity, which largely corresponds to the periventricular fiber-rich zone (2 in **D**). The intermediate zone of moderate MRI signal intensity, which encompasses both the subventricular cellular zone and the fetal white matter (3 and 4 in **D**). The subplate zone of low MRI signal intensity, which closely corresponds to the compartment marked with 5 in Nissl-stained section (5 in **D**) and acetylcholinesterase-stained section (5 in **C**); therefore it is marked with 5 on MR images (5 in **B**). The cortical plate of high MRI signal intensity, which closely corresponds to the compartment marked with 6 on Nissl-stained sections (6 in **D**) but on MR images cannot be separated from the marginal zone (7 in **D**); therefore, it is always described on MR images as a band of high signal intensity situated above the subplate zone. *(From Kostovic I: Laminar organization of the human fetal cerebrum revealed by histochemical markers and magnetic resonance imaging,* Cereb Cortex *12:536, 2002, with permission.)*

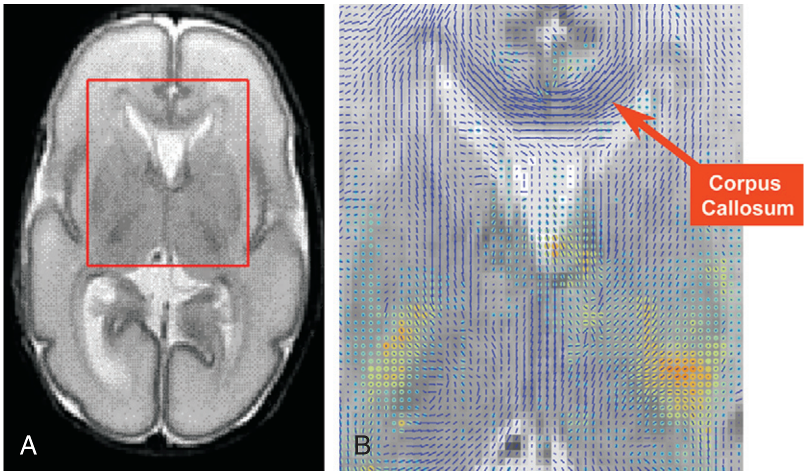

Figure 40–12. A, Anatomic axial T2-weighted MRI. B, Diffusion tensor vector maps for the regions indicated by the box in A, showing non-myelinated interhemispheric fiber connections in the corpus callosum at 28 weeks' gestational age. The blue lines represent the in-plane fibers, the out-of plane fibers are shown in colored dots ranging from green to red. *(Hüppi PS et al: Microstructural development of human newborn cerebral white matter assessed in vivo by diffusion tensor magnetic resonance imaging,* Pediatr Res *44:584, 1998, with permission.)*

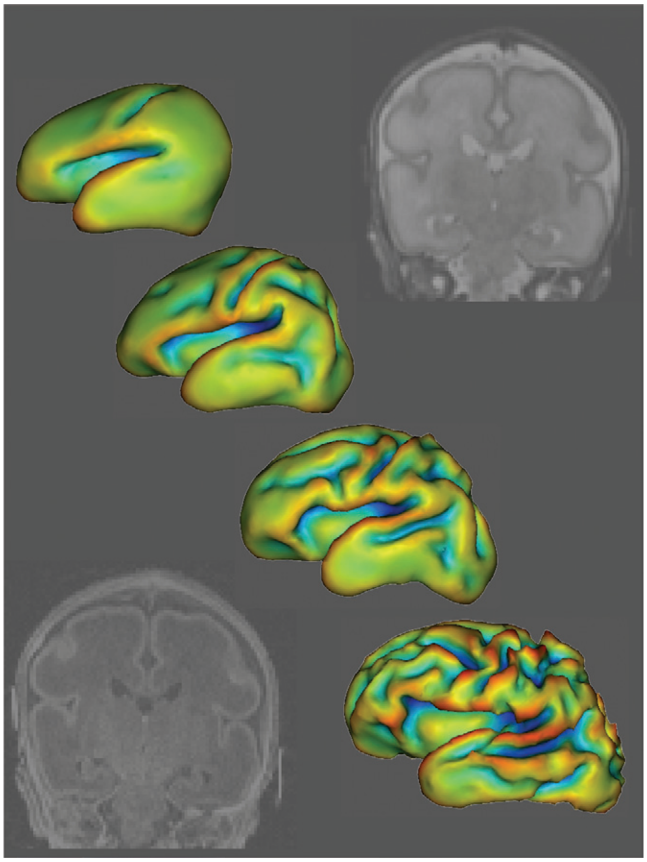

Figure 40–13. External and internal brain surface at from 26 to 36 weeks' gestation illustrated by three-dimensional models generated from magnetic resonance imaging, which illustrates timing of regional cortical folding and permits quantitative measures of surface and sulcation index. *(Images reconstructed by specialized image analysis software, courtesy of Dubois J, Benders M, Cachia A et al: Mapping the early cortical folding process in the preterm newborn brain,* Cereb Cortex *18:1444, 2008.)*

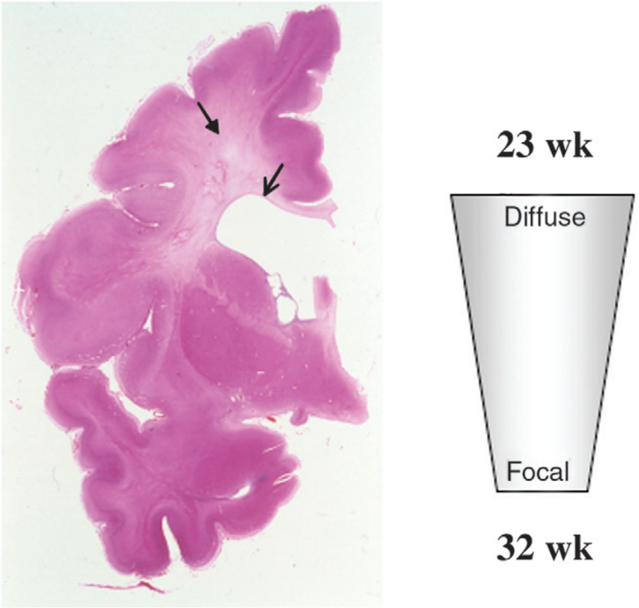

Figure 40–31. Neuropathology showing periventricular lesions primarily affecting the white matter and characterized by pale softened zones of degeneration (hematoxylin preparation) *(left arrow)* and thinning of the corpus callosum with ventriculomegaly *(right arrow)*. Lesions detected in infants with very low gestational age at birth tend to be diffuse with more focal cystic lesions than in infants with higher gestational age at birth.

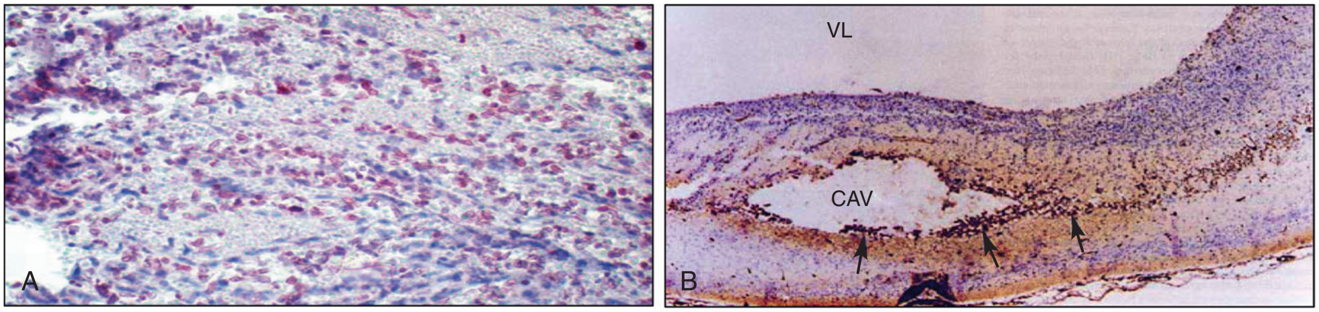
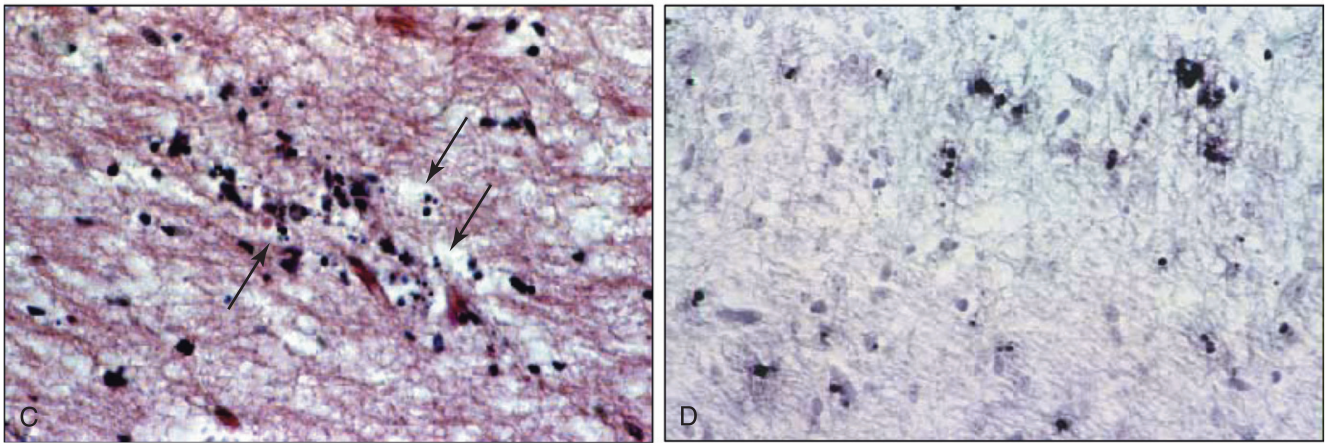


Macrophage marker – placenta

Macrophage marker – brain



H&E – brain

Tunel – brain

Figure 40–37. Intrauterine infection with *Escherichia coli* in pregnant rabbits induces a combination of placental and brain abnormalities. **A**, Macrophage activation is observed in all placentas. The numerous red cells correspond to activated macrophages labeled with a specific antigen. **B**, Focal cystic periventricular white matter lesions with macrophage activation are detected in some fetuses. Brown cells identified by *arrows* correspond to activated macrophages/microglia labeled with a specific antigen. CAV, cystic lesion; VL, lateral ventricle. **C** and **D**, Diffuse white matter cell death without detectable inflammatory response is observed in all fetuses on hematoxylin-eosin stained sections (**C**, *Arrows* point to examples of apoptotic nuclei in the periventricular white matter) and on Tunel (a marker of fragmented DNA and of accompanying cell death) stained sections (**D**, Purple-blue nuclei correspond to diffusely distributed dying white matter cells). *(From Debillon T et al: Intrauterine infection induces programmed cell death in periventricular white matter,* Pediatr Res *47:736, 2000, and Patterns of cerebral inflammatory response in a rabbit model of intrauterine infection-mediated brain lesion,* Brain Res Dev Brain Res *145:39, 2003, with permission.)*

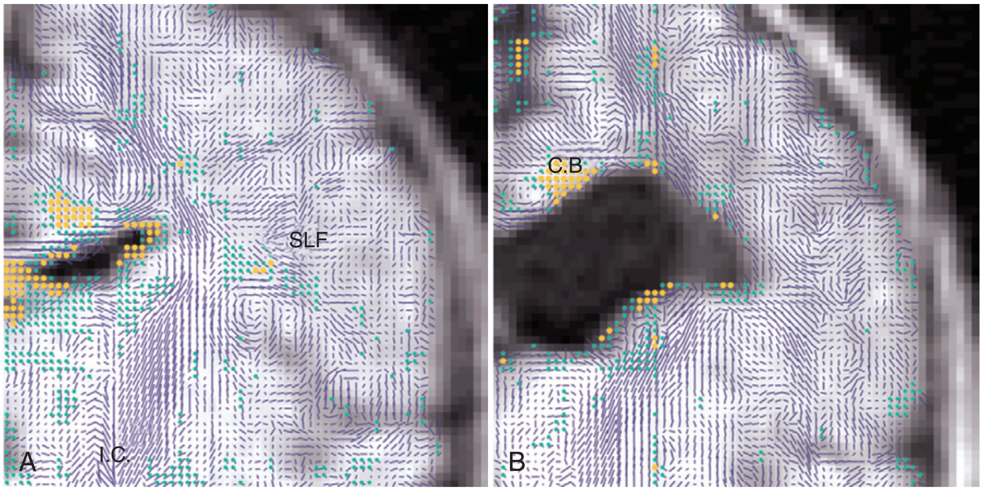


Figure 40–47. Diffusion vector maps overlaid on coronal diffusion-weighted images for a premature infant at term with no white matter injury (**A**) and a premature infant at term with perinatal white matter injury (**B**). The posterior limb of the internal capsule (I.C.) in **A** shows more homologous directed vectors that are longer and more densely packed than in the internal capsule of **B**. Anteroposterior-oriented white matter fibers in the area of the superior longitudinal fasciculus (SLF; yellow and green dots with yellow representing higher anisotropy than green) in **A** indicate the presence of fiber bundles that are missing or are less prominent in **B**. The only discrete anteroposterior fiber bundles that definitely are present in **B** are the cingulate bundle (C.B.). Fibers of the corona radiata appear less well organized in **B** than **A**. Loss of axons in the central white matter *(yellow area)* and the posterior limb *(red area)* will result in neuromotor disturbances illustrated schematically in **C**. (**A**, **B**, *Reproduced by permission from Hüppi P, Murphy S, Maier S, et al: Microstructural brain development after perinatal cerebral white matter injury assessed by diffusion tensor magnetic resonance imaging,* Pediatrics *107:455, 2001.* **C**, *Schema reproduced from Volpe JJ:* Neurology of the newborn, *4th ed, Philadelphia, 2001, Saunders, p 362.)*

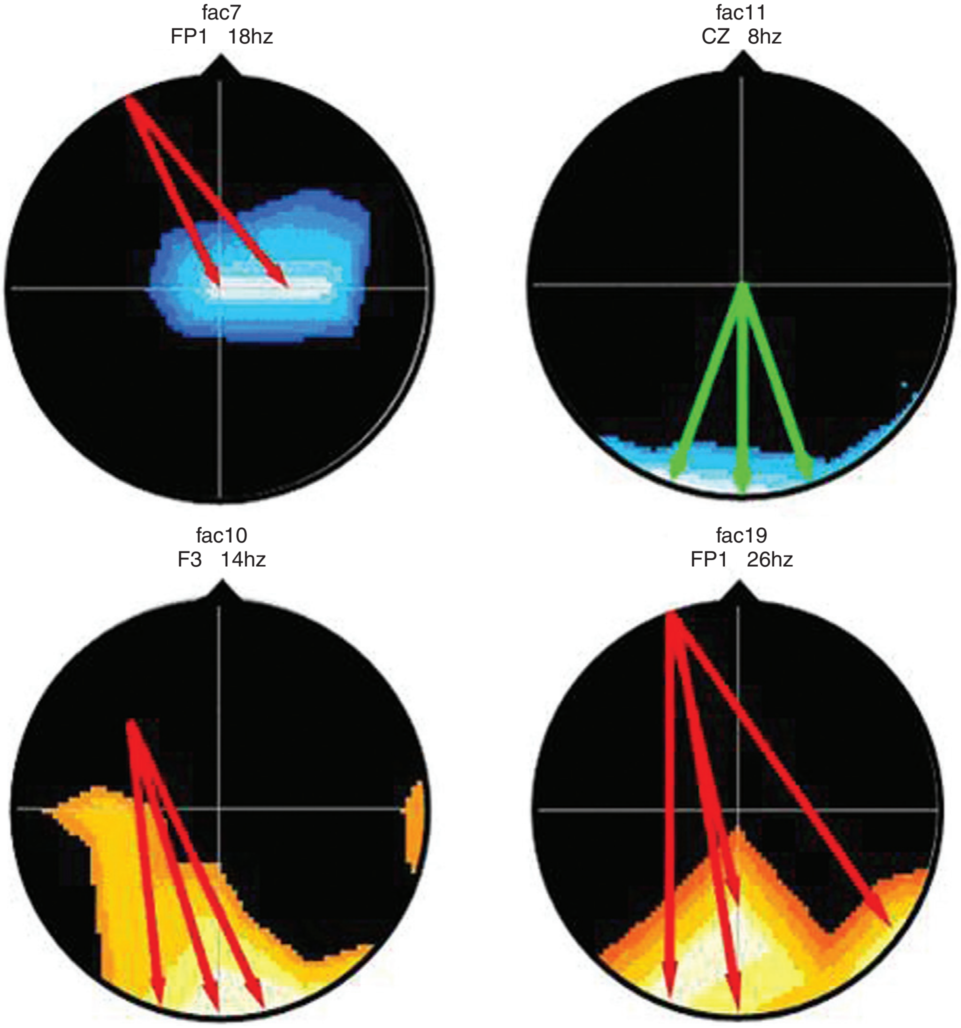

Figure 43–5. Electroencephalographic coherence measures at 2 weeks' corrected age, control versus experimental group infants. Four heads, each corresponding to a utilized coherence factor, *top view, scalp left to image left*. Each shows the maximal loadings (correlations) of original coherence variables on the indicated factor. An index electrode and frequency are printed above each head. *Colored regions* indicate location, magnitude, and sign (*red,* positive; *blue,* negative) of maximally loading coherences on the factor. *Arrows* also illustrate coherence variables; however, *arrow color* compensates for signs of factor loadings on subsequent statistically derived canonical variates, thus illustrating how original coherence variables differ between experimental (*red,* increased; *green,* decreased) and control infants. *(From Als H et al: Early experience alters brain function and structure,* Pediatrics *113:847-857, 2004. Copyright © 2004 by the AAP.)*

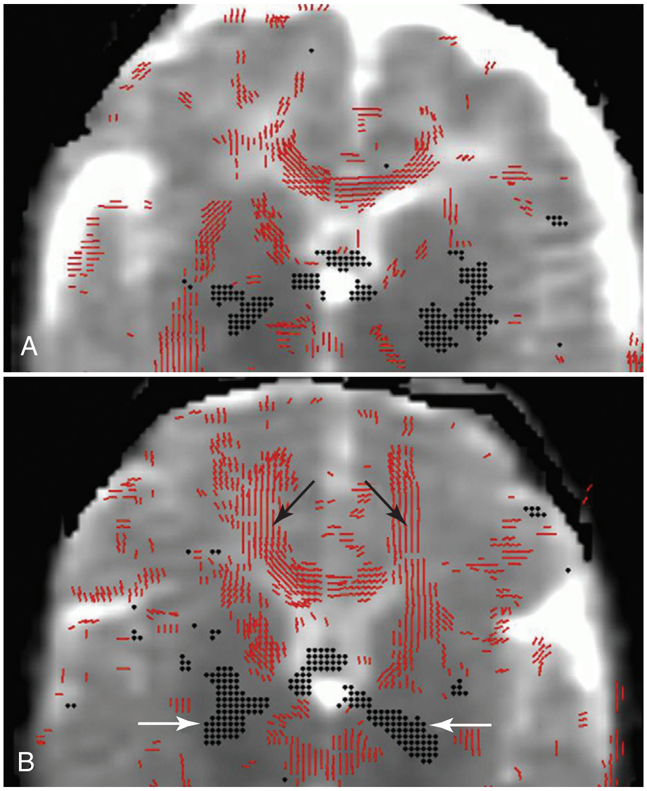

Figure 43–6. Comparison of control and experimental group infants, at 2 weeks' corrected age, with magnetic resonance imaging and diffusion tensor imaging. Examples of diffusion tensor maps from identical axial slices through the frontal lobes of a representative control (**A**) and an experimental group (**B**) infant obtained at 2 weeks' corrected age. In each example, the principal eigenvectors (shown in *red* and *black*) overlie the apparent diffusion coefficient (ADC) map to show anisotropy in white matter. The *red lines* denote eigenvectors located within the plane of the image, and the *black dots* indicate eigenvectors oriented mostly perpendicular to the image plane. The ratio E1/E3 has been used as a threshold to show only eigenvectors at those voxels where E1/E3 exceeds a threshold value of 1.3 in both images. Note the greater anisotropy of white matter found in the experimental infant (**B**) compared with the control infant (**A**), at the posterior limbs of the internal capsule (*white arrows* in **A** and **B**) and the frontal white matter adjacent to the corpus callosum (*black arrows* in **A** and **B**). The greater anisotropy found in the experimental infant (**B**) suggests more advanced white matter development in these regions than is found in the control infant (**A**). (*Reproduced with permission from Als H et al: Early experience alters brain function and structure,* Pediatrics *113:847-857, 2004. Copyright © 2004 by the AAP.*)

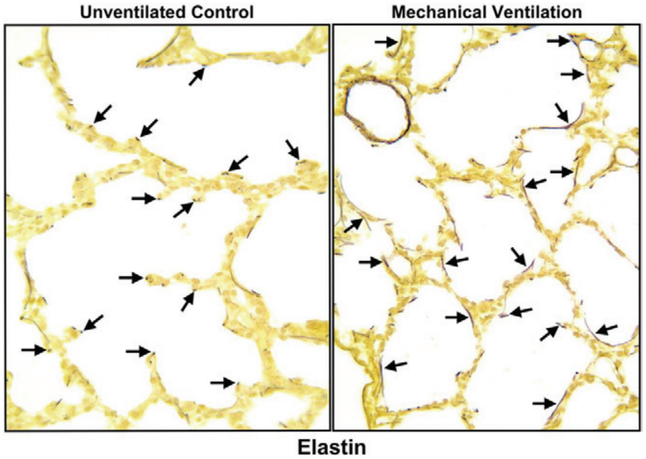

Figure 44–7. Changes in elastin distribution in lungs of 5-day-old mice ventilated for 24 hours with 40% oxygen. Lung sections from controls *(left)* demonstrate elastin with Hart's stain at the tips of developing septa. In contrast, the ventilated lungs *(right)* have more elastin without the focal distribution in the distal airspaces. *(Reprinted with permission from Bland RD et al: Mechanical ventilation uncouples synthesis and assembly of elastin and increases apoptosis in lungs of newborn mice. Prelude to defective alveolar septation during lung development?* Am J Physiol Lung Cell Mol Physiol *294:L3, 2008.)*

with additional light source below infant

Figure 48–20. Important factors in the efficacy of phototherapy. The absorbance spectrum of bilirubin bound to human serum albumin (*white line*) is shown superimposed on the spectrum of visible light. Clearly, blue light is most effective for phototherapy, but because the transmittance of skin increases with increasing wavelength, the best wavelengths to use are probably in the range of 460 to 490 nm. Term and near-term infants should be treated in a bassinet, not an incubator, to allow the light source to be brought to within 10 to 15 cm of the infant (except when halogen or tungsten lights are used), increasing irradiance and efficacy. For intensive phototherapy, an auxiliary light source (fiberoptic pad, light-emitting diode [LED] mattress, or special blue fluorescent tubes) can be placed below the infant or bassinet. If the infant is in an incubator, the light rays should be perpendicular to the surface of the incubator in order to minimize loss of efficacy due to reflectance. PT, phototherapy. *(From Maisels MJ, McDonagh AF: Phototherapy for neonatal jaundice,* N Engl J Med *358:920, 2008.)*
